where f_n represents the normal contact force and μ is the static coefficient of friction. For an idealized two-finger parallel gripper, Nguyen established that a grasp resists arbitrary in-plane disturbance forces if and only if the line connecting the two contact points lies strictly within the interior of both friction cones (Nguyen 1988).

The general formulation operates in wrench space. For each contact point i, a grasp map $\mathbf{G}_i$ transforms the local contact force $\mathbf{f}_i$ into an object wrench composed of the force and its moment $\mathbf{d}_i \times \mathbf{f}_i$ about the object reference frame. Here $\mathbf{d}_i$ denotes the displacement from the reference origin to the contact point. Mapping the extremal rays of every friction cone into wrench space yields a set of primitive contact wrenches. The grasp achieves **force closure** when the origin of wrench

↩ The machine's multi-rate cadences, from motor current loops through safety screening to deliberative planners, are established in section 4.3.1.

[1] **Affordance** (from the verb *to afford*): Gibson (1979) coined the noun for what an environment offers an animal able to act on it, and the sense is relative to the agent. A handle affords a grasp only to a gripper whose aperture and wrench ceiling fit it, so the affordance record carries the gripper's limits as well as the mug's geometry.

[2] **Special Euclidean Group**: "Euclidean" because its elements preserve distances, "special" because the rotation part has determinant $+1$, which excludes mirror reflections. A learned regressor carries no such constraint. An unnormalized quaternion or a matrix with determinant -1 is a valid tensor and an impossible pose, so admission rechecks quaternion normalization (section 10.8) instead of trusting the output head.

space lies strictly within the interior of the convex hull of these primitive wrenches, guaranteeing that admissible contact forces can equilibrate any external disturbance wrench. Because fingers can only push into the surface, the net wrench they apply is a nonnegative scaling of a point inside that convex hull, and enclosing the origin strictly inside the hull ensures that a ray pointing opposite to any external disturbance wrench intersects the hull interior so the fingers can scale up their normal forces to cancel disturbances from every direction. Ferrari and Canny formalized this condition into a scalar quality metric. The metric is the radius of the largest origin-centered ball inscribed within that convex hull, and it represents the minimum disturbance wrench the grasp resists per unit of applied normal force (Ferrari and Canny 1992).

Force closure, however, remains an idealized geometric property that specifies stability without bounding magnitude. A physical grasp requires finite capacity. The normal squeeze force must counter the mug's gravitational load and dynamic accelerations during transit while remaining strictly below structural limits that would fracture ceramic or spill contents. Section B.7.5 derives the lower bound on squeeze force from Newton's second law and develops friction cones and force closure from first principles. These dynamic bounds constitute the effort envelope that the Brain proposes and the permission path enforces.

Turning a spoken request into a checkable physical target is the robotic form of the **symbol grounding problem** (Harnad 1990), which asks how arbitrary symbols connect to measurable sensorimotor states.[3] For the mug, that connection runs through the calibrated transform chain from the camera frame to the manipulator base, the handle's affordance frame, and the contact wrench bounds. An uncalibrated detection box or an autoregressively sampled coordinate carries none of those bounds. The permission path must therefore catch and reject an unsupported model proposal (a hallucination, in machine learning terms[4]) deterministically, regardless of the model's reported confidence. When a spatial feature instead bundles a calibrated base-frame pose, certified wrench limits, and an evidence timestamp, it forms a grounded affordance.

[3] **Symbol Grounding Problem**: Harnad (1990) compared the problem to learning Chinese from a Chinese-to-Chinese dictionary alone, in which every definition points only to more undefined symbols. A model's text embedding is that dictionary. Only a calibrated camera-to-base chain breaks the circle for the mug, so the proposal must carry its evidence record and not only its label.

[4] **Hallucination**: In text generation the word names fluent output that the source does not support (Maynez et al. 2020). For a robot the unsupported output is a coordinate, and nothing in its format marks it as unsupported. Containment therefore has to be a check on evidence that the model does not produce.

Definition 10.1: Grounded affordance

Grounded affordance is an affordance expressed in the robot's own frame and units: a feature pose in the base frame, an approach direction, an aperture, and a contact wrench ceiling, each tied to dated sensor evidence through a calibrated measurement chain.

1. **Significance**: It turns a label into quantities the permission path can check. The mug handle's grounded affordance is a pose that must land inside a 15 mm task tolerance from evidence with a 3 mm initial error, and on the moving belt that evidence stays valid for only 60 ms (section 10.5).
2. **Distinction**: Unlike a detector box or a language label, which designates where an object appears in image space or what it is called, a grounded affordance defines where and how an end effector may establish contact. Unlike Gibson's perceptual affordance, it is bound to one gripper's limits and to one capture time.
3. **Common pitfall**: Treating a learned grasp score or a confident detection as grounding. Neither carries a metric error bound, a wrench limit, or an evidence epoch, so neither can be admitted or expired.

A high-level task action like `Grasp(Mug, Handle)` specifies an operational objective, but its preconditions require rigorous physical verification. Perceptual noise and latency prevent open-loop execution from guaranteeing that the handle remains unobstructed or that the jaws are properly aligned. **Motion predicates** formalize these physical prerequisites by mapping abstract conditions to measurable geometric tolerances and wrench readings:

1. *Pre-contact approach predicate:* $P_{\text{approach}}(\mathbf{T}_{\text{TCP}}) \iff \|\mathbf{p}_{\text{TCP}} - \mathbf{p}_{\text{pre}}\| \le r_{\text{tol}} \wedge \arccos(\hat{\mathbf{z}}_{\text{TCP}} \cdot \hat{\mathbf{a}}_{\text{approach}}) \le \theta_{\text{tol}}$, requiring the tool center point (TCP) frame $\mathcal{F}_{\text{TCP}}$, whose origin sits between the gripper fingertips, to align with the affordance approach axis $\hat{\mathbf{a}}_{\text{approach}}$ within spatial tolerance r_{tol} and angular orientation tolerance θ_{tol}.
2. *Guarded contact predicate:* $P_{\text{contact}}(\mathbf{w}) \iff f_{\min} \le f_n \le f_{\max}$, checking a normal squeeze band under the illustrated parallel-jaw model. Here the contact-force magnitude denotes the relevant

normal squeeze at each finger, measured or conservatively inferred under qualified contact geometry; a generic force-vector norm or net wrench does not establish that quantity. The task profile sets the band from friction, payload load and acceleration, and crush limits. Passing it supports retention under those premises but does not establish object identity or task completion.

3. *Spatial clearance predicate:* $P_{\text{clear}}(\mathbf{p}, \mathcal{M}) \iff \min_{\mathbf{o}\in\mathcal{M}} \|\mathbf{p}-\mathbf{o}\| \geq d_{\text{margin}}$, evaluating candidate point $\mathbf{p}$ against obstacle geometry stored in the spatial memory map $\mathcal{M}$. This point clearance test serves as a fast preliminary check. Certifying the physical gripper, manipulator links, and their swept transit volumes requires a continuous path collision query during trajectory synthesis.

Together, the spatial and angular tolerances delineate an admissible **geometric goal set** $\mathcal{G}_{\text{goal}} \subset SE(3)$:

$$\mathcal{G}_{\text{goal}} = \left\{ \mathbf{T} = (\mathbf{R}, \mathbf{p}) \in SE(3) \;\middle|\; \|\mathbf{p}-\mathbf{p}_{\text{target}}\|_{\mathbf{E}} \leq 1,\ \angle(\mathbf{R}, \mathbf{R}_{\text{target}}) \leq \theta_{\text{tol}} \right\} \tag{10.1}$$

Contact and obstacle clearance predicates operate as distinct, phase-specific execution constraints outside this static pose volume. Within equation 10.1, the weighted ellipsoidal norm $\|\mathbf{p}-\mathbf{p}_{\text{target}}\|_{\mathbf{E}} = \sqrt{\sum_{i\in\{x,y,z\}} \left(\frac{p_i - p_{\text{target},i}}{r_i}\right)^2}$ bounds spatial deviation within an ellipsoid whose principal semi-axes are $\mathbf{r} = (r_x, r_y, r_z)$. Here r_{tol} denotes the corresponding semi-axis r_i along any individual coordinate direction. The rotation error metric $\angle(\mathbf{R}, \mathbf{R}_{\text{target}}) = \arccos\left(\frac{\text{tr}(\mathbf{R}^\top \mathbf{R}_{\text{target}})-1}{2}\right)$ bounds geodesic orientation divergence on $SO(3)$, equivalent to $2\arccos(|\mathbf{q}_{\text{quat}} \cdot \mathbf{q}_{\text{quat,target}}|)$ when unit quaternions represent orientations. Terminal grasp poses falling outside $\mathcal{G}_{\text{goal}}$ lead directly to task aborts or damage. Translational errors exceeding r_i cause gripper fingers to impact the ceramic rim or close on empty space, while angular misalignments exceeding θ_{tol} jam the fingers against the handle opening, tripping joint torque protection or shattering the object.

For the warehouse mug, the nominal task profile assigns all three ellipsoidal semi-axes to the 15 mm grasp tolerance. A terminal TCP offset of 10 mm along the x-axis yields a normalized ellipsoidal distance of 0.67, remaining well within the admissible goal set. Conversely, an offset of 20 mm yields a normalized distance of 1.33, falling outside the set and triggering immediate rejection. Checking angular alignment requires the angular tolerance θ_{tol} specified in the verified task profile, which the mug model registers during commissioning.

This goal set is an operational task specification rather than an estimate of target pose. The **task tolerance region** defines the maximum terminal error that the physical grasp can absorb; state estimator covariance captures uncertainty in the target's actual pose. For the mug pick, the approved task profile permits at most 15 mm of translational discrepancy. The proposed affordance must therefore supply a conservative target error bound that fits inside this envelope, leaving sufficient headroom for the motion controller's dynamic tracking error. Artificially expanding the task tolerance to accept an uncertain perception estimate corrupts the safety invariants of the physical task.

Generating candidate affordances prior to intent proposal packaging typically relies on a **learned 6-DoF grasp generator** applied to an incoming point cloud. Architectures such as Contact-GraspNet predict grasp poses anchored directly to surface points in cluttered point clouds (Sundermeyer et al. 2021). Frameworks like AnyGrasp predict dense $SE(3)$ grasp distributions with learned quality scores and track them across temporal observation sequences (Fang et al. 2023). The generator outputs a set of candidate grasp configurations paired with scalar confidence scores. However, a learned score merely reflects the network's predictive confidence relative to its training distribution. It provides neither an analytic stability metric like the Ferrari-Canny radius nor a measured empirical grasp success rate for this specific gripper and workpiece geometry.

Candidate poses surviving initial filtering must satisfy rigorous downstream physical constraints that learned generators omit:

1. *Kinematic feasibility*: The manipulator must possess a valid inverse kinematics (IK) solution that avoids joint position and velocity limits. A well-conditioned kinematic Jacobian does not guarantee clearance from mechanical joint stops, making explicit joint travel verification mandatory.

2. *Geometric compatibility*: Gripper jaw stroke must exceed workpiece thickness at the grasp site with sufficient clearance margin.
3. *Corridor clearance*: The approach trajectory must provide an unobstructed approach vector clear of surrounding bin walls and adjacent cargo.

When no candidate grasp satisfies these constraints, or when target identification remains unresolved across ambiguous visual candidates, the control pipeline must not execute an argmax guess. Instead, the proposal's producer on the application processor issues an explicit **intent grounding refusal** (`ERR_GROUNDING_AMBIGUITY`), signaling a typed rejection of the goal itself. A planning failure means that the planner has not produced a collision-free path to a valid, well-formed goal. An intent grounding refusal halts execution earlier. It rejects an ungrounded or ambiguous goal before invoking the motion planner, which prevents unverified guesses from generating physical trajectories. When a symbolic task planner sits above the grasp generator, its discrete task operators must discharge these same geometric and contact predicates before any step of the plan is admitted.

10.2 Task Operators and Geometric Samplers

A symbolic task planner can emit the discrete action `Grasp(Mug, Handle)` and mark the mug as held in its internal state even when no collision-free inverse kinematics solution reaches the handle, a bin wall blocks the approach, or the mug has not been separated from adjacent items on the belt. The high-level action `Grasp(Mug, Handle)` inherits from classical planning traditions, where actions are formalized as **operators** defined by preconditions, an add list, and a delete list. The formalism traces back to the STRIPS[5] framework (Fikes and Nilsson 1971) and was standardized by the Planning Domain Definition Language (PDDL) (McDermott et al. 1998). A discrete world state s consists of a set of grounded predicates. An operator o is applicable in state s if its preconditions hold, $\text{pre}(o) \subseteq s$, producing the successor state

$$s' = (s \setminus \text{del}(o)) \cup \text{add}(o) \tag{10.2}$$

A symbolic planner searches sequences of operators, advancing states by the delete-then-add update of equation 10.2 until reaching a state satisfying the target goal predicates. For the warehouse pick, an operator `pick(mug, handle, conveyor)` requires preconditions `Reachable(handle)`, `Clear(approach)`, `Singulated(window)`, and `HandEmpty`, where a singulated window holds exactly one separated candidate object. Upon execution, it adds `Holding(mug)` and deletes `HandEmpty`.

Abstract symbols disguise the primary computational challenge: verifying whether a predicate like `Reachable(handle)` holds requires finding a continuous end-effector pose, a valid inverse kinematics solution, and a collision-free joint trajectory. A symbolic planner cannot evaluate these continuous constraints natively. **Integrated task and motion planning** (TAMP) resolves this disconnect by coupling discrete symbolic search with **geometric samplers**, computational routines that sample continuous configuration spaces (proposing candidate grasps, inverse kinematics configurations, and transit paths) to certify symbolic preconditions (Kaelbling and Lozano-Pérez 2011; Garrett et al. 2021). For instance, PDDLStream treats each geometric sampler as a generator stream whose continuous outputs certify symbolic facts. The task planner can then make optimistic symbolic progress, backtracking or branching when a sampler fails to find a valid configuration (Garrett et al. 2020). A sampler failure means that the search has not found a collision-free grasp for the given base pose; unless the sampler certifies infeasibility, it does not prove that none exists. The symbolic planner can spend more search effort, reposition the mobile base, or select an alternate interaction sequence.

Large language models (LLMs) increasingly generate the symbolic layer. Systems such as LLM+P prompt an LLM to translate natural-language task specifications into formal PDDL domain and problem instances, subsequently delegating resolution to a classical symbolic planner (B. Liu et al. 2023). While this decouples linguistic parsing from plan generation, neither the language model nor the symbolic planner verifies geometric feasibility or sensorimotor validity against real-world scene observations. Bridging this gap requires mapping each symbolic precondition to a verifiable motion predicate or geometric certificate evaluated against live physical measurements, as summarized in table 10.1.

[5] **STRIPS (Stanford Research Institute Problem Solver)**: The formalism was built to plan for Shakey, a physical mobile robot at SRI (Nilsson 1984), so symbolic planning began on a machine that moved. Its operators treat an action's listed effects as certain, an assumption that slipping wheels and a misreading camera cannot grant. The gap that geometric samplers and motion predicates close is therefore as old as the formalism itself.

DRAFT

Table 10.1: From task operator to motion predicate: Each fact the symbolic `pick` operator requires or predicts for the mug maps directly to a predicate over measured physical quantities and to an explicit verification check in the execution pipeline.

Operator fact	Motion predicate or certificate	Check that discharges it	Where it is checked
`Reachable(handle)`	$\mathbf{T}_{\text{grasp}} \in \mathcal{W}$ with an IK solution inside joint limits	Static workspace check and transit lower bound	Admission (section 10.6)
`Clear(approach)`	P_{clear} along the approach corridor	Occupancy and forward occupancy screen, then swept-volume check	Admission, then planner
`Singulated(window)`	One candidate cluster in the pick window	Independent count from fresh depth evidence	Station rule (section 10.7)
`At(gripper, pregrasp)`	P_{approach} within r_{tol} and θ_{tol}	Goal-set membership (equation 10.1)	Planner, then permission path
`Holding(mug)` (effect)	P_{contact}: $f_{\min} \le f_n \le f_{\max}$	Per-contact normal squeeze after closure; required for retention	Runtime check

In this execution architecture, the predicted effect `Holding(mug)` remains a conditional hypothesis until the declared terminal pose, contact, and retention checks pass following finger closure. The guarded contact predicate P_{contact} supplies the normal squeeze check under the task profile; it cannot alone confirm that the intended mug is held. A symbolic task plan operates as an intent proposal in the same manner as a neural VLA target. It asserts the preconditions and effects it intends to achieve, while the deterministic permission path verifies whether calibrated physical evidence supports execution.

Grounding an open-ended directive therefore yields a structured, time-stamped **intent proposal**. The immediate systems design challenge is converting an identified image region into a calibrated metric target without corrupting its semantic identity, understating its measurement uncertainty, or obscuring its evidence epoch. Once packaged with these invariants, the proposal enters the independent permission path to verify physical admissibility, effort bounds, and expiration limits before execution begins.

10.3 Semantic Request Translation to Geometric Proposals

When an operator asks for the red mug and the vision backbone instead binds the word "mug" to an adjacent table fixture, the coordinate that crosses the proposal boundary arrives in the trajectory pipeline indistinguishable from a valid handle target. Low-level motor drives monitor encoder counts, winding temperatures, and phase currents, so they have no way to tell whether the setpoint they track belongs to a mug or a bolted bracket. Any unmodeled arm compliance or thermal expansion also adds metric bias that a high semantic confidence score never reveals. Before any motion planner accepts a target, the grounding pipeline must therefore turn the model's selection into a geometric proposal that carries bounded spatial uncertainty, dated selection evidence, and an explicit expiration time.

10.3.1 The four-stage open-vocabulary grounding pipeline

Passing a detector's 2D bounding box or an uncalibrated pixel coordinate straight to a motion planner hides two failures at once. Two identical mugs can both score high without triggering an ambiguity warning, and a small depth error along the camera ray can stretch into centimeters of pose error in the robot base frame. To expose each failure where it can be checked, the **four-stage open-vocabulary grounding pipeline** separates semantic referent selection from metric localization and physical actuation:

1. **Stage 1: Visual encoding**: RGB-D frames from static or eye-in-hand cameras enter a vision backbone running at batch size one on the machine's accelerator, transforming raw image patches into dense feature embeddings.
2. **Stage 2: Referent selection**: Given a prompt such as "pick the red ceramic mug," an open-vocabulary detector such as Grounding DINO or OWL-ViT proposes candidate bounding boxes and scores each against the text prompt (S. Liu et al. 2023; Minderer et al. 2022). The model evaluates each candidate independently without global normalization across boxes

DRAFT

(OWL-ViT trains with a sigmoid focal loss (Minderer et al. 2022), while Grounding DINO filters tokens against an absolute threshold). Two identical mugs can therefore both yield high confidence, or a lone glass jar can score above threshold even when no mug is present. A promptable segmentation model such as SAM 2 can refine the chosen box into an object mask and track it across video frames (Ravi et al. 2024). However, a 2D bounding box or segmentation mask provides only image-space localization without metric depth, surface normals, or wrench limits. It indicates where the object projects onto the camera sensor, leaving contact dynamics and grasp mechanics completely unspecified.

3. **Stage 3: Metric lifting**: Calibrated camera intrinsics, depth measurements, and the hand-eye extrinsic transformation lift the selected pixels into 3D points in the robot base frame, while propagating sensor noise into a base-frame covariance matrix. For stereo and structured-light systems, depth error grows quadratically with range, $\sigma_z \approx Z_c^2 \sigma_d/(bf)$ for baseline b (the stereo term of equation 8.6), focal length f, and disparity error σ_d, whereas lateral error grows only linearly, $\sigma_u Z_c/f$. Their ratio, approximately $(Z_c/b)(\sigma_d/\sigma_u)$, scales with range and baseline rather than remaining constant, while time-of-flight sensors have their own range-dependent error profiles. The resulting uncertainty ellipsoid elongates dramatically along the optical line of sight. Any unmodeled extrinsic error from wrist compliance or mounting deflection tilts this elongated ellipsoid directly into the robot's clearance margin.
4. **Stage 4: Affordance parameterization**: The lifted 3D geometry transforms into candidate actions. Depending on the architecture, these candidates may take the form of scored 6-DoF grasp sets from a learned grasp generator, 3D attraction and repulsion cost fields (Huang et al. 2023), parameterized motion primitives (Liang et al. 2023), or decoded action tokens (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023). Stage 4 filters these candidates against the kinematic reachability, gripper aperture, and collision clearance criteria detailed in section 10.1. It then constructs a goal tolerance set $\mathcal{G}_{\text{goal}}$ around each surviving affordance frame and assigns the required motion predicates. Finally, it serializes these hypotheses into a fixed-size, statically verified proposal structure (table 10.2) and carries them across the physical silicon boundary between the non-real-time Linux Application Processor (AP) and the hard real-time Safety MCU.

↪ The pinhole camera model and the propagation of pixel and depth noise into a base-frame covariance are developed in section C.12.

↪ **Byte layout:** The intent payload's fields, types, and offsets are given in section C.15.2.

DRAFT

Field	Representation	Physical semantics	Invariant and admission check

Table 10.2: Untrusted intent proposal fields: Layout and validation invariants of the candidate proposal transmitted from the Application Processor across the proposal boundary.

Field	Representation	Physical semantics	Invariant and admission check
`evidence_epoch_ns`	`uint64_t` (ns)	Sensor capture timestamp t_0 from parent belief record	Must match retained belief epoch; reject if stale or unrecorded
`affordance_frame_id`	`uint32_t` (enum)	Target coordinate frame $\mathcal{F}_{\text{affordance}}$ (for example, $\mathcal{F}_{\text{handle}}$)	Must resolve to an approved kinematic frame on the target object
`predicate_mask`	`uint32_t` (bitmask)	Requested motion predicates ($P_{\text{approach}}, P_{\text{contact}}, P_{\text{clear}}$)	Verified against task requirements before planner invocation
`target_pose_se3`	`double[7]`	Proposed pose $[x, p_y, z, q_x, q_y, q_z, q_w]$ in robot base frame	Finite values; unit quaternion ($\|\mathbf{q}_{\text{quat}}\| = 1$); within $\mathcal{W}$
`pos_error_envelope_m`	`double[3]` (m)	Bounded spatial uncertainty semi-axes (e_x, e_y, e_z)	Conservative perception bounds; $0 \leq e_i \leq r_i$ is a preliminary screen; full error plus tracking reserve must fit $\mathcal{G}_{\text{goal}}$
`task_tolerance_m`	`double[3]` (m)	Allowable goal region semi-axes (r_x, r_y, r_z)	Must meet task profile tolerances; defines $\mathcal{G}_{\text{goal}}$
`max_linear_vel_mps`	`double` (m/s)	Requested tool center point speed ceiling $v_{\max}$	Clamped to plant ceiling; verified against dynamic transit time
`max_wrench`	`double[6]` (N, N·m)	Maximum effort ceiling $[F_x, F_y, F_z, \tau_x, \tau_y, \tau_z]$	Must not exceed structural yield or sensor saturation limits
`lease_duration_ms`	`uint32_t` (ms)	Requested administrative lease T_{admin}	Clamped to evidence horizon τ_{ev} and stopping deadline
`fallback_policy_id`	`uint32_t` (enum)	Advisory terminal mode (`HOLD`, `STOP`, `TORQUE_OFF`)	Advisory only; Safety MCU overrides based on load and contact state

To prevent a learned output from masquerading as a deterministic setpoint, the producer must link the proposed referent to the dated sensor evidence that justified its selection. The upstream observation contract often carries bounding boxes, attention weights, class probabilities, and a full oriented covariance matrix, which are too bulky and variable to send across a real-time link. Instead, the intent proposal references its parent belief record by a SHA-256 digest (which traces data lineage rather than authenticating the sender) and an evidence epoch. Because the digest, a monotonically increasing sequence number, and a trailing CRC-32 checksum belong to the common wire header (section C.15.1), table 10.2 lists only the intent payload. The payload holds the candidate pose, conservative base-frame error bounds, task tolerances, and a requested administrative lease T_{admin} that caps how long the host may hold the target before the MCU presumes a stall. That duration is only a request, because the MCU clamps it to the evidence horizon and the stopping deadline derived in section 10.5 and section 10.8. Since an object on the belt can shift, roll, or become occluded moments after camera exposure, the permission path immediately rejects any target coordinate that arrives without an active evidence link and a bounded deadline.

When a vision-language model evaluates multiple candidate objects, retaining only the highest-scoring bounding box conceals an unresolved selection. In purely digital applications, a misranked recommendation misleads a user but moves no mass. In robotics, an admitted spatial proposal immediately commands physical momentum. For instance, if a red glass jar sits beside the requested red mug on a conveyor, an uncalibrated tie-break may inadvertently target the jar. This case, the jar beside the mug, returns later in the chapter. The architecture must preserve candidate identity and calibrated uncertainty, rejecting proposals whenever ambiguity exceeds task-specific safety thresholds. The host system can then solicit operator clarification or acquire additional sensor viewpoints, while any previously admitted motion executes under strict lease and fallback guarantees.

Formally, **open-vocabulary grounding ambiguity** occurs when perceptual evidence supports multiple candidate referents, making the selection of any single target an arbitrary tie-break. Because open-vocabulary detectors score candidate bounding boxes independently rather than generating a normalized categorical distribution across objects, they do not natively report this condition. The host application must therefore construct a distribution explicitly. By collecting all candidate boxes exceeding an initial detection threshold and normalizing their raw scores into a vector $\mathbf{c} = (c_1, \ldots, c_n)$ where $\sum_i c_i = 1$, the system can evaluate candidate spread. Although the Shannon entropy $H(\mathbf{c}) = -\sum_i c_i \log c_i$ quantifies distributional dispersion, an arbitrary entropy threshold provides no rigorous statistical error bound.

Conformal prediction removes this limitation by replacing the single best answer with a set of candidate answers whose coverage holds in finite samples (Vovk et al. 2005; Angelopoulos and Bates 2023). A threshold calibrated on held-out labeled cases keeps every candidate it cannot exclude, so the set contains the true answer at a chosen rate across cases without assuming any model of how the scores are distributed. For example, the KnowNo framework applies conformal prediction to identify when a robot should halt and request human clarification (Ren et al. 2023). On a calibration dataset of n_{cal} labeled scenes, the nonconformity score for scene j is $s_j = 1 - c_{y_j}$, representing one minus the normalized score assigned to the ground-truth referent y_j. This construction assumes that the true label belongs to the defined candidate option space in calibration and deployment. An absent or filtered-out true object violates that premise unless the option space explicitly includes a no-valid-referent option calibrated in the same way. The critical threshold $\hat{q}_{1-\epsilon}$ corresponds to the $\lceil (n_{\text{cal}}+1)(1-\epsilon) \rceil / n_{\text{cal}}$ empirical quantile of these nonconformity scores. At runtime, the prediction set $\mathcal{C}$ retains every candidate whose normalized score cannot be excluded at significance level ϵ:

$$\mathcal{C} = \{\, i : c_i \geq 1 - \hat{q}_{1-\epsilon} \,\} \tag{10.3}$$

Provided that calibration and deployment scenes satisfy exchangeability,[6] the set $\mathcal{C}$ is mathematically guaranteed to cover the true referent with probability at least $1-\epsilon$. Under exchangeability, the nonconformity score of a new test scene is equally likely to occupy any of the $n_{\text{cal}}+1$ ranks relative to the calibration samples. It therefore exceeds the $\lceil (n_{\text{cal}}+1)(1-\epsilon) \rceil$-th smallest calibration score with probability at most ϵ. This is marginal true-label coverage across scenes, not the same error bound conditional on singleton acceptance or a guarantee of task success. If the resulting prediction set is a singleton ($|\mathcal{C}| = 1$), the pipeline passes its candidate to downstream metric lifting and the remaining admission checks. If $|\mathcal{C}| > 1$, the producer refuses with `ERR_GROUNDING_AMBIGUITY`, prompting the system to request clarification from an operator or maneuver for an unoccluded viewpoint before transmitting any motion proposal across the boundary. An empty set ($|\mathcal{C}| = 0$) means that no retained option meets the threshold, and the producer refuses it as well. It does not reliably detect an absent mug, because a lone retained wrong jar normalizes to one and survives this score test.

When both the mug and the glass jar appear simultaneously within the pick window, an open-vocabulary detector assigns raw box scores of 0.62 and 0.48 respectively. Normalizing these values yields normalized candidate scores of 0.56 and 0.44, producing a Shannon entropy of 0.685 nats relative to the two-candidate maximum of 0.693 nats. The entropy shows high dispersion across the two candidates. It does not measure the probability that either is the correct object. Conformal calibration instead supplies marginal true-label coverage under the declared option-space and exchangeability premises.

Across a calibration set of 200 labeled scenes with an allowable error rate $\epsilon = 0.10$, the rank formula selects which calibration score becomes the threshold $\hat{q}_{1-\epsilon}$, the nonconformity score at rank 181 in ascending order. Its value depends on the measured scenes. Assuming that score is $\hat{q}_{1-\epsilon} = 0.60$, any candidate must achieve a normalized score of at least 0.40 to remain in the prediction set. Because both objects exceed this threshold, the resulting prediction set retains two elements ($|\mathcal{C}| = 2$). The producer correctly flags an ambiguity error and refuses to emit a trajectory. Conversely, if the jar scores only 0.10, its normalized value drops to 0.14, falling below the admission threshold. In that contrast case, the prediction set collapses to a singleton ($|\mathcal{C}| = 1$), permitting the mug proposal to proceed.

Because conformal coverage guarantees hold marginally across scenes and degrade under distribution shift, production workcells enforce defense-in-depth through deterministic physical invariants. The station therefore adds its own singulation check, a candidate count on fresh depth evidence that

[6] **Exchangeability**: A sequence of random variables is exchangeable when its joint probability distribution remains invariant under arbitrary permutations of sample order. Exchangeability is strictly weaker than assuming independent and identically distributed (i.i.d.) observations, yet it suffices for the $1-\epsilon$ marginal coverage guarantee. Modifying station lighting or altering the conveyor layout introduces distribution shift that invalidates exchangeability, causing coverage guarantees to lapse silently. Calibration records must therefore be maintained on a per-station basis with mandatory expiration horizons, matching the lifecycle of target sensor evidence.

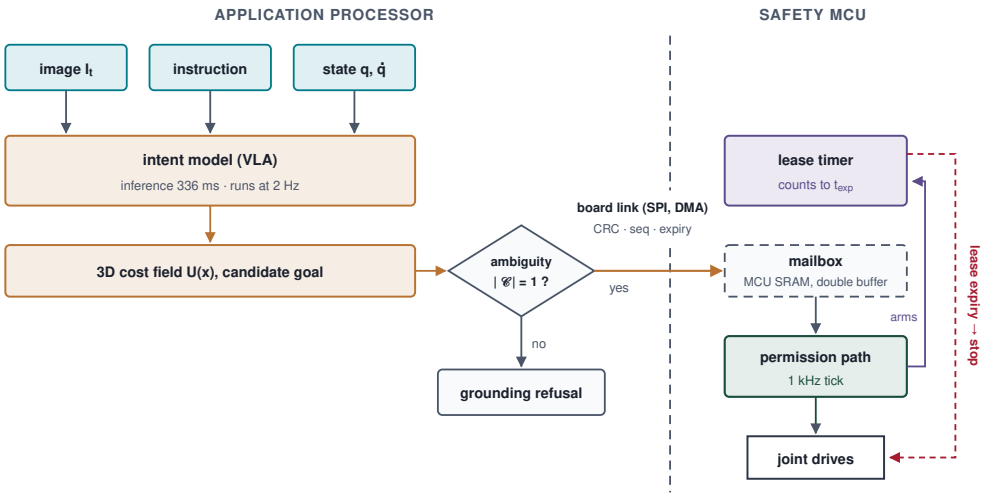

Figure 10.1: Grounded intent pipeline architecture across the silicon boundary: Physical AI system architecture partitioning high-capacity deliberative reasoning on the Application Processor (AP) from deterministic safety enforcement on the real-time Safety Microcontroller Unit (MCU). The AP processes multimodal streams (RGB-D vision, natural language prompts, proprioception) through the intent model, whose computed 336 ms inference sets its 2 Hz rate. The 3D cost field box stands for an optional producer family of the VoxPoser kind; the running machine's intent model emits a target pose directly. A producer-side ambiguity filter, which passes only a singleton calibrated prediction set ($|\mathcal{C}| = 1$), rejects ambiguous hypotheses before sending a structured intent proposal over the board-level link into the MCU's own memory; the two processors share no memory. The MCU independently verifies evidence epochs, physical actuator ceilings, and braking stopping reserve before arming the lease timer, whose expiry stops the drives without any message from the application processor; the permission path runs at 1 kHz, and trajectory admission remains a separate check (synthesized from Huang et al. (2023), Ahn et al. (2022), and Gray (1989)).

runs apart from the grounding model and must find a unique candidate within the pick envelope (section 10.7). This operational gate prevents arbitrary tie-breaking at the station. When multiple objects populate the workspace, downstream motion planners proceed only when perceptual evidence unambiguously discriminates the requested target.

The pipeline therefore spans two processors that share no memory (figure 10.1). Everything that can be wrong about meaning runs on the application processor, and everything that must hold regardless of meaning runs on the Safety MCU. Its 1 kHz permission loop arms a lease timer that drops authority without any message from the host. That separation buys independence only when memory access, bus timing, and fault containment are qualified in each of three domains:

- *Application Processor (AP Domain):* A general-purpose, non-real-time operating system executing on host CPUs and hardware accelerators runs the vision-language backbones and, in architectures that use them, 3D cost fields. If the conformal prediction set over candidate referents contains multiple entries (equation 10.3), an upstream filter halts execution with an ambiguity alert. When the prediction set yields a unique referent ($|\mathcal{C}| = 1$), the AP serializes the candidate goal pose, requested wrench limits, and parent belief digest into a fixed-size, statically structured intent proposal.
- *Board-Level Transport Boundary:* The proposal packet crosses from the AP to the discrete safety MCU over an isolated board-level interconnect, such as a Serial Peripheral Interface (SPI) bus backed by Direct Memory Access (DMA). The MCU receiver copies the transmission into a dedicated staging mailbox within local SRAM. The communication channel is treated as untrusted. Embedded CRC-32 checksums, monotonically increasing sequence numbers, and strict hardware timeout limits detect frame corruption, packet loss, and transmission stalls. The protocol design must also account for worst-case bus latency, as the bus interface alone guarantees no real-time delivery bounds.
- *Safety Microcontroller Unit (MCU Domain):* Operating on a dedicated real-time core, a deterministic control loop evaluates the incoming proposal as an unverified request. The MCU checks

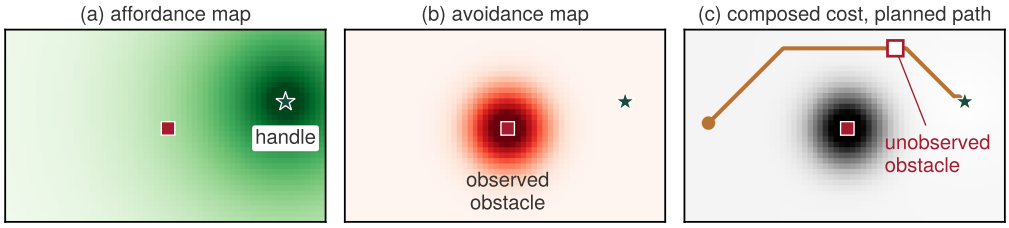

Figure 10.2: Composing value maps for a grasp request: An original schematic of the value-map interface introduced by VoxPoser (Huang et al. 2023), drawn on one horizontal slice of a voxel grid. (a) An affordance map rewards voxels near the handle the instruction names. (b) An avoidance map penalizes voxels near an observed obstacle. (c) The planner searches the composed cost for a path. The path is good only with respect to the maps: an obstacle the observations missed adds nothing to the avoidance map, so the path can run through it.

the evidence timestamp against its internal monotonic clock, verifies workspace envelopes and joint reachability limits, and clamps requested forces and velocities to certified plant limits. Furthermore, the MCU verifies that a deceleration trajectory can execute safely within existing clearance margins. The MCU arms a hardware countdown timer to the lease expiry $t_{\text{intent_exp}}$ only after the proposal passes all admission gates. The expiry is the earliest of evidence decay, host silence, and the stopping deadline (section 10.8 formalizes it). The MCU then grants bounded tracking authority to the joint drives.

10.3.2 What each proposal family leaves to admission

This three-domain boundary stays fixed even when the upstream grounding model is swapped for a different proposal family. What changes from one model family to the next is which physical checks remain for admission to supply. An upstream model may emit a 2D bounding box, a 3D cost field, a scored 6-DoF grasp, or a chunk of normalized action tokens. In every case, treating that output directly as a motion command skips the physical checks that prevent an unseen obstacle collision, a joint-limit hit, or an unbraked contact impact. The pipeline's stages draw on multimodal feature extraction, cross-attention alignment, and open-vocabulary phrase grounding from computer vision and natural language processing (Kamath et al. 2021; Gu et al. 2022; Radford et al. 2021; S. Liu et al. 2023), yet an embodied machine cannot rely on a model's internal activations for physical safety. For example, a semantic skill ranker like SayCan outputs a discrete skill identifier scored by language affordance and value functions (Ahn et al. 2022). A programmatic generator like Code as Policies produces a control script that calls perception and motion APIs (Liang et al. 2023). VoxPoser synthesizes 3D spatial value maps (figure 10.2). OK-Robot emits a distribution of sampled grasp poses (figure 10.3). Because none of these outputs natively carries a bounded wrench envelope, a certified clearance margin, or a hardware lease expiration, choosing one model family over another only shifts where conversion happens and leaves the admission checks in table 10.3 unchanged.

Predicting a syntactically valid coordinate or control script never guarantees physical feasibility. Vision-language and action models are trained to maximize sequence likelihood over offline demonstration datasets. Their loss functions encode neither metric distances, rigid-body collision avoidance, manipulator Jacobian conditioning, nor frictional contact dynamics. Validating a candidate action requires deterministic physical checks evaluated within explicit coordinate frames. These checks include signed-distance queries over robot and environment meshes to verify clearance, numerical inverse-kinematics solvers with joint-limit and singularity screening, and Coulomb friction models to confirm that the planned grasp wrench resists expected gravitational and inertial loads. For contact-rich tasks such as sliding an object, turning a latch, or executing a handover, the system can simulate candidate trajectories in a rigid-body physics engine before committing actuator current. However, simulation fidelity remains bounded by the accuracy of estimated surface friction and inertial parameters. Downstream controllers must still enforce real-time admission checks regardless of simulation outcomes.

In VoxPoser's value-map interface (figure 10.2), an affordance map rewards voxels near the handle the instruction names, an avoidance map penalizes voxels near observed obstacles, and the planner

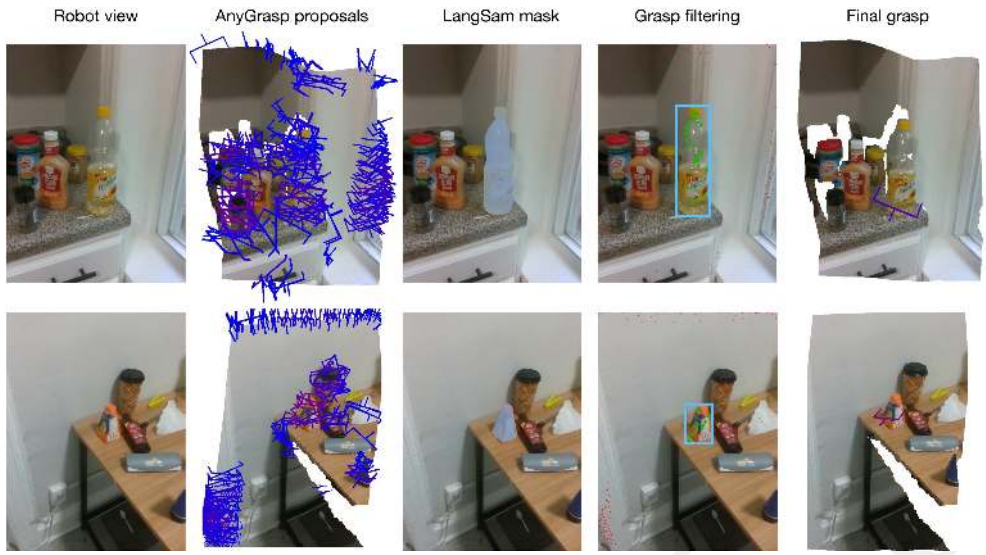

Figure 10.3: Open-vocabulary grasp grounding pipeline: OK-Robot combines candidate grasp generation with language-conditioned object selection and geometric filtering (P. Liu et al. 2024). An open-vocabulary detector isolates the target object mask, candidate grasps are sampled across the 3D point cloud, and geometric heuristics prune inadmissible approaches. The resulting grasp pose represents a candidate proposal; bounding tolerances, evidence deadlines, and independent permission checks are an architectural wrapper developed in this chapter. (Source: P. Liu et al. (2024), CC BY 4.0).

follows the composed cost around the obstacle it can see. Because the planned path is optimal only with respect to what the maps contain, an obstacle that the observations missed adds no cost and the path runs straight through it, leaving clearance against unobserved space to the permission path.

OK-Robot shows the same division in a modular pipeline (figure 10.3) (P. Liu et al. 2024). Open-vocabulary detectors (OWL-ViT and SAM) isolate the queried object, a class-agnostic generator (AnyGrasp) samples dense 6-DoF candidates over the point cloud, and geometric heuristics prune them to a single pose. That pose is still an uncertified Stage 4 proposal. Before it can command joint motion, it must be bound to dated sensor evidence, given a wrench envelope, and admitted under an expiring lease on the Safety MCU. Every proposal family in table 10.3 leaves a comparable residue, which the table's last column itemizes as the evidence admission must still supply.

Table 10.3: Grounding representations and admission questions: Outputs from different model families require different conversions before a physical permission check.

Proposal source	Representation sent downstream	Early check	Remaining evidence needed
2D box or mask	Image region plus measured depth and camera calibration	Reject absent depth or a target outside a validated region	3D pose error, occlusion, object identity, and swept-path clearance
3D feature or value field	Candidate target or cost field in a stated frame	Reject out-of-workspace targets and stale map cells	Conservative occupancy, unknown-space policy, actuator and timing bounds
Action VLA	Decoded action or action chunk in its trained range	Reject out-of-range or inadmissible proposals	State-dependent physical limit and independent permission; the action head provides no clearance proof
Learned grasp generator	Set of 6-DoF grasp poses with learned scores	Reject grasps outside the workspace or jaw aperture	Measured success on this gripper, IK and joint limits, approach clearance, and wrench capacity
Language-selected skill	Skill identifier with estimated success	Rank or decline low-confidence candidates	Current preconditions, path feasibility, and separate physical enforcement

Regardless of the specific output architecture, raw actions generated by VLA models carry no certified metric bounds. These heads normalize action spaces relative to empirical training dis-

tributions rather than physical workspace obstacles. For example, RT-1 and OpenVLA discretize each continuous action dimension into 256 uniform bins across bounded ranges (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Kim et al. 2024). FAST tokenizes the discrete cosine transform coefficients of a multi-step trajectory chunk (Pertsch et al. 2025). In contrast, π_0 generates continuous action chunks through a flow-matching diffusion expert, predicting 50 steps per inference and streaming them at up to 50 Hz (Black et al. 2024). Although each approach outputs kinematically coherent trajectories within its training distribution, none verifies dynamic feasibility or collision clearance against surrounding obstacles. Similarly, spatial location tokens in vision-language models like PaliGemma quantize normalized pixel coordinates on the camera sensor. These image tokens transform into metric poses only after incorporating measured depth maps, camera intrinsics, and hand-eye calibration matrices. The geometric uncertainty propagated through this calibration chain, particularly along the camera's optical axis, often dwarfs the discretization error of the underlying token grid.

Table 10.3 sorts proposals by the representation they send downstream, a classification that outlasts any one model. The systems that fill each role change within a few years, so table 10.4 dates them separately, pairing what each current system emits with what the permission path must still establish on its own.

Table 10.4: State of practice for grounded intent, as of 2026: Representative published systems for each pipeline role (Minderer et al. 2022; S. Liu et al. 2023; Ravi et al. 2024; Sundermeyer et al. 2021; Fang et al. 2023; B. Liu et al. 2023; Ren et al. 2023; Kim et al. 2024; Black et al. 2024; Pertsch et al. 2025). The required validation checks in the rightmost column remain architectural invariants even as specific model architectures are refreshed.

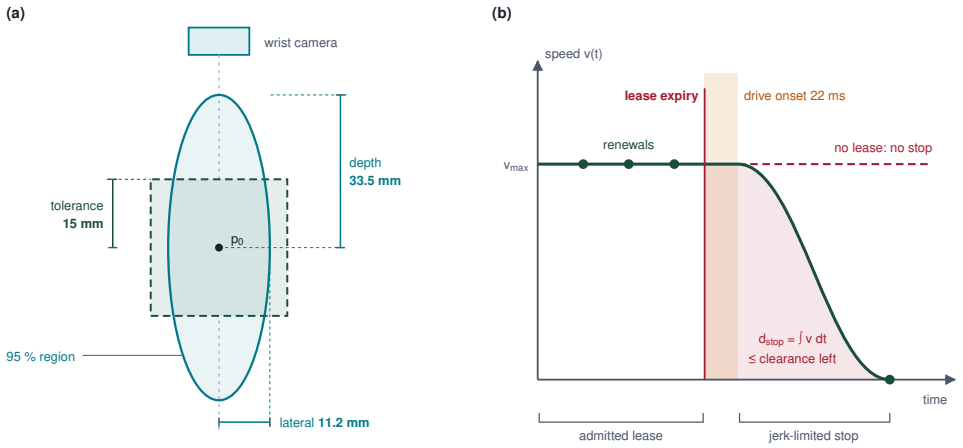
Role in the pipeline	Representative systems (year)	What the system emits	What the permission path must still establish
Open-vocabulary detection	OWL-ViT (2022), Grounding DINO (2023)	Boxes with independent per-box text scores	Uniqueness, depth, and object identity
Promptable segmentation and tracking	SAM 2 (2024)	Object masks propagated through video	The tracker's own error and latency bounds
Learned grasp generation	Contact-GraspNet (2021), AnyGrasp (2023)	Scored 6-DoF grasp sets	IK, aperture, clearance, and wrench capacity
Language to symbolic plan	LLM+P (2023)	A PDDL problem solved by a classical planner	Every geometric precondition
Calibrated request for help	KnowNo (2023)	A conformal prediction set over options	Coverage under distribution shift; physical singulation
VLA action heads	OpenVLA (2024), π_0 (2024), FAST (2025)	Binned tokens, flow-matched chunks, or compressed tokens	Clearance, timing, and effort bounds

Every row leaves admission the same two questions, whether the metric estimate is tight enough for the task and whether it belongs to the right object. The mug's handle shows how each can fail while the other holds.

10.3.3 Imprecise estimates and wrong objects

When the wrist camera views the red mug from across the workstation before the arm begins its reach, depth uncertainty along the optical ray stretches the 95 percent error region to more than twice the handle's grasp tolerance. Closing the gripper on that single-frame estimate can therefore drive the fingers into the ceramic rim. Under an illustrative calibrated Gaussian sensor model for that pre-approach wrist-camera frame, the principal standard deviations in the camera frame are 4 mm and 5 mm laterally, and 12 mm along the optical depth axis. Because the optical axis aligns with the gripper's approach vector, range uncertainty directly challenges position control. A **95 percent statistical region** surrounding the estimated handle coordinate $\mathbf{p}_0$ is defined by the Mahalanobis squared distance $(\mathbf{p}-\mathbf{p}_0)^\top \Sigma_{\text{depth}}^{-1}(\mathbf{p}-\mathbf{p}_0) \le \chi^2_{3,0.95}$. With the three-degree-of-freedom chi-square quantile $\chi^2_{3,0.95} = 7.815$, the distribution expands into principal semi-axes of 11.2 mm, 14.0 mm, and 33.5 mm.

Against the mug's 15 mm physical grasp tolerance (figure 10.4, panel a), the ellipsoid fails on one axis only. While both lateral semi-axes fall comfortably within the mechanical tolerance window,



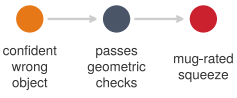


Figure 10.4: Localization uncertainty and authority expiry: Panel (a) draws the handle estimate's 95 percent region to scale against the 15 mm grasp tolerance: the lateral semi-axis of 11.2 mm fits, while the 33.5 mm depth semi-axis along the camera ray does not. Panel (b) sketches speed against time: renewals keep the lease alive, and when they stop the lease expires, the drive takes 22 ms to begin braking, and a jerk-limited stop follows. The shaded area is the stopping distance, which must fit the clearance that remains; the dashed trace is motion with no lease, which never stops.

the depth semi-axis of 33.5 mm substantially exceeds the allowed threshold. Consequently, the admission gate rejects the proposal, because the controller cannot guarantee that closing the gripper fingers at that estimated setpoint will capture the handle rather than collide with the rim.

The remedy, worked through in section 10.6, decomposes the reach into distinct phases. The system first admits an intermediate, collision-checked inspection waypoint, allowing the arm to travel closer to the workspace. Once positioned nearby, a second wrist-camera observation constructs a refined belief record, reducing the initial position uncertainty to 3 mm. Because a Gaussian probability region retains an unbounded asymptotic tail, statistical distributions alone cannot certify absolute spatial clearance. The downstream intent proposal therefore needs independently justified conservative error envelopes in the robot base frame before requesting trajectory tracking. Covariance alone supplies only a statistical region.

While a configured statistical gate cleanly rejects detections with large variance envelopes, it cannot catch an entirely incorrect object identified with high semantic confidence. This is a different case from the jar beside the mug, where both candidates entered the prediction set and the producer refused. Consider instead the jar in place of the mug, where a fragile, thin-walled glass jar sits on the workstation where the ceramic mug was expected and no mug is present. When prompted to pick the mug, the vision-language model misidentifies the jar with strong semantic certainty, generating a sharp, low-variance geometric proposal centered on the glass container. The downstream trajectory planner accepts the coordinate, solves inverse kinematics in $SE(3)$, verifies joint position and velocity limits, and confirms that the approach path clears all static obstacles in the occupancy map. Because the requested motion satisfies all kinematic and wrench envelopes, the real-time permission path authorizes execution. However, if the gripper applies the clamping force required to hold a heavy ceramic mug, the jaws crush the thin glass container upon contact despite clearing every geometric check.

This scenario marks the boundary between physical verification and semantic premises. The deterministic permission path enforces coordinate envelopes, kinematic limits, actuator torque thresholds, and obstacle clearance against known geometric occupancy grids. These physical invariants cannot confirm whether a given coordinate actually corresponds to the requested object. The premise that the targeted item is indeed the requested ceramic mug remains an unverified upstream assumption outside the hardware controller's reach. Establishing that premise requires distinct task-level perceptual evidence, which must be tracked through the handover release case (section 16.6) and recorded in the residual-claims register (section 18.3.3). A learned task filter upstream cannot close this gap either. The AutoRT deployment showed that a language-model

A confident wrong object passes every geometric check until the gripper closes.

task filter improved the fraction of sensible task proposals while unsafe commands still passed it. Human teleoperators therefore had to intervene and halt execution (war story 10.1) (Ahn et al. 2024).

War Story 10.1: AutoRT task filtering and supervision (2024)

Context: AutoRT deployed foundation models to propose and filter physical manipulation tasks for fleets of mobile manipulators operating in unstructured human office environments (Ahn et al. 2024).

Mechanism: In a sample of 259 proposed tasks, human annotators judged 228 (88 percent) acceptable. A second LLM pass then filtered the tasks against a robot "constitution" of safety and embodiment rules. Of the 214 tasks it kept, 200 (93 percent) were acceptable. The filter rejected 17 of the 31 unsuitable tasks, a recall of 55 percent, and passed the other 14.

Impact: All 14 misses arose during teleoperated collection. Although the filter raised overall proposal quality, human supervisors had to intervene to intercept every unsafe proposal before robot execution.

Response: The system architecture placed physical safety outside the model's domain. Deployments supplemented learned proposals with hardware joint-force limits, physical emergency stop buttons, and direct human line-of-sight supervision or physical perimeter barricades.

Systems lesson: A learned task filter can improve proposal quality, but it cannot serve as a safety referee. An independent, deterministic permission and fallback path must validate every physical action against real-time plant limits before execution.

The distant view and the glass jar mark two distinct verification boundaries. The distant view fails on metric uncertainty along the depth axis, whereas the jar in place of the mug fails on an unverified semantic premise, because metric precision does not establish object identity. A safe geometric proposal must therefore carry both dated physical evidence and task-specific selection evidence across the silicon boundary. By this point the mug proposal holds most of what the lease will carry. The grounded affordance has fixed the target pose and its goal region, and the squeeze bounds of the grasp analysis have set the wrench ceiling. The operator table has named the predicates the grasp must discharge, and the handle's error envelope has been compared with the task tolerance. Carrying these values is not yet holding authority, however. The proposal still lacks a grant, a deadline, and a stop that works without the proposer, and turning it into bounded authority over the arm is the work of the handoff.

10.4 The Intent Handoff and Bounded Authority

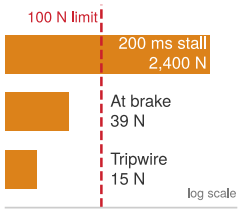
If a deliberative host could stream raw joint trajectories or actuator currents directly to the drives, a two-millimeter depth error into a rigid latch plate or a stalled inference thread mid-reach would drive motor currents to saturation before any host process could intervene. When the arm reaches for the red mug, the deliberative host instead submits a candidate intent specifying a bounded target region, an expiration deadline, and explicit physical effort ceilings. The region and the ceilings are the grounding results packaged for transit, the affordance pose with its goal set and the grasp's wrench and speed limits, and the requested deadline is computed from the parent belief record's evidence epoch. An independent real-time supervisor intercepts this proposal, vetting each requested parameter against retained sensor evidence and configured plant dynamics. Granting a target lease merely authorizes downstream trajectory planning within certified safety bounds. The deliberative model remains isolated from low-level actuator registers.

This permission path validates every requested target constraint before any motion planner can generate trajectory setpoints. Rather than forcing memory-constrained microcontrollers to maintain full scene representations, host-side spatial engines export compact geometric evidence across a strictly typed interface. The supervisor verifies four mandatory invariants against this evidence:

1. *Spatial containment invariant:* The proposed geometric goal set $\mathcal{G}_{\text{goal}} \subset SE(3)$ must lie strictly within the robot's reachable workspace manifold $\mathcal{W}$. The bounded spatial uncertainty envelope (e_x, e_y, e_z) must fit inside the task tolerance (r_x, r_y, r_z) without intersecting persistent obstacle geometry in spatial memory $\mathcal{M}$.

2. *Temporal freshness invariant:* The sensor evidence epoch t_0 must match a retained parent belief record. The unobserved elapsed time on the Safety MCU's monotonic hardware clock must not exceed the evidence horizon τ_{ev} that section 10.5 takes from the parent belief record.
3. *Dynamic effort invariant:* Requested tool-center-point velocity $v_{\max}$, acceleration $a_{\max}$, and contact wrench $\mathbf{w}_{\max} = [F_{\max}, \tau_{\max}]^\top$ must remain strictly within actuator thermal ratings, link inertia limits, and workpiece structural yield thresholds.
4. *Certified deterministic fallback invariant:* The robot must possess an independently verified, pre-computed stopping or hold trajectory that brings all moving links to rest within current physical obstacle clearance ($d_{\text{stop}} \leq D_{\text{clear}}$) if authority is abruptly revoked.

The first three invariants turn the requirements that opened the chapter into checks: metric physicality and bounded error become spatial containment and the effort ceiling, while temporal expiration becomes freshness. The fourth adds the obligation those requirements left implicit, a stop that works without the proposer. Each invariant guards against a distinct failure mode in physical interaction. Loose target bounds can exceed kinematic grasp tolerances, and stale sensor evidence risks collision with a displaced object. Excessive commanded effort can shatter a workpiece, and an unvetted handoff leaves moving mass without a safe recovery trajectory. The resulting intent lease records the validated envelope that survives these four checks and constrains the downstream trajectory planner, which must synthesize path timing and deceleration profiles that satisfy supervisory admission criteria (section 10.8). Pairing the evidence epoch with a finite lease expiration keeps the temporal bound deterministic even if the host crashes, because the safety controller compares its own clock against the admitted deadline rather than waiting for a cancellation packet (section 10.5).



Spatial and temporal bounds alone cannot guarantee safety if the downstream controller commands unbounded effort. Every intent proposal must therefore declare explicit effort ceilings covering tool-center-point velocity, acceleration, and contact wrench. Consider a depth perception error of two millimeters that places a target goal slightly inside a rigid workpiece. An unrestricted position controller will drive actuator currents to saturation trying to eliminate tracking error, imposing severe mechanical stress on the gear train. During a guarded approach to a spring-latched cage door, for example, the host proposes a 15 N tripwire ceiling, well below the 100 N structural latch threshold, paired with an approach velocity capped at 0.03 m/s. The permission path evaluates these values against hardware torque-speed curves and environmental thresholds, admitting only parameters that guarantee structural integrity.

Downstream of the permission path, an impedance controller shapes interaction dynamics, answering a position error with the restoring force of the virtual spring-damper established in section 2.4.4. Under quasi-static contact, scaling the virtual stiffness along the approach vector directly limits steady-state contact force for a given positional error. Transient impacts, however, demand more than static stiffness modulation; containing peak collision forces requires coordinating approach velocity, passive mechanical compliance, sensor latency, and actuator closed-loop bandwidth.

Omitting spatial, temporal, or dynamic boundaries leaves physical hardware vulnerable during communication dropouts or perception stalls. Stopping distance scales linearly with the reaction delay preceding brake engagement and quadratically with operating velocity (equation 2.2). For a mobile base navigating within physical obstacle clearances, a silent or stalled proposer inflates this reaction window by the entire lifespan of the active command lease. As established in section 4.4, this chunk lease duration directly extends the unbraked latency parameter τ_{delay}. The verified safety envelope must therefore maintain obstacle clearance greater than the total stopping distance, factoring in sensor pipeline latency, transport jitter, and state estimation uncertainty. Furthermore, powered deceleration requires electrical bus energy and closed-loop control authority to survive an upstream fault. Logic-level power alone cannot generate mechanical braking torque.

The intent lease defines the temporal horizon over which a deliberative goal remains valid. It operates alongside the chunk lease of section 4.4 rather than replacing it, because the two hold different kinds of authority even though the Safety MCU's permission path checks both. The chunk lease authorizes motion. It allows an admitted chunk to drive the actuators only for its short lease unless the chunk policy renews it at its own rate. By contrast, the intent lease authorizes a goal, fixing which target that motion may pursue, how hard it may press, and until when, and only newer evidence can renew it. Consequently, each lease ends authority from its own side. When

the chunk lease lapses, motion stops even though the goal remains valid. When the intent lease lapses, nominal tracking toward the goal ends at once, even if the current chunk still has lease time left, and the MCU engages the validated fallback (section 11.2.2). A rejected proposal is the gentler case, because it revokes nothing and leaves already admitted motion running until its own leases lapse. The physical stopping budget must accommodate the cumulative delay across perception, communication, actuator response, and mechanical braking in every case.

A 200 ms unbraked stall drives the latch to 2,400 N, far past its limit.

Napkin Math 10.1: What the latch ceilings buy

Problem: The intent lease for the cage door requests a 15 N tripwire and a 0.03 m/s approach speed against a 100 N latch limit. With the local contact loop in place, what force does the latch see when the brake command issues, and what would it see in a counterfactual design with no local contact trip, where pressing stops only when the proposer or the intent lease acts?

Variables:

- Tripwire 15 N and approach speed $v_{\text{latch}} = 0.03$ m/s, the requested ceilings; latch limit 100 N (Illustrative)
- Plate stiffness $k_{\text{latch}} = 400$ N/mm (Illustrative) and contact-loop response 2 ms
- Unbraked stall $\Delta t = 200$ ms (Illustrative), shorter than one 500 ms intent period

Math:

1. **Force at brake command**: The tripwire fires at 15 N, and the plate keeps compressing while the 2 ms contact loop responds, so the force when the brake command issues is $F_{\text{cmd}} = F_{\text{trip}} + k_{\text{latch}}\, v_{\text{latch}}\, T_c = 15\,\text{N} + 400\,\text{N/mm} \times 0.03\,\text{m/s} \times 2\,\text{ms} = 39\,\text{N}$. The arm stop that follows has only a fraction of a millimeter of compression left to spend; section 12.7.2 derives that stop (equation 12.11).
2. **Stall travel** (counterfactual, no local trip): $\Delta x = v_{\text{latch}}\, \Delta t = 0.03\,\text{m/s} \times 200\,\text{ms} = 6\,\text{mm}$ past first contact.
3. **Stall force**: $F = k_{\text{latch}}\, \Delta x = 400\,\text{N/mm} \times 6\,\text{mm} = 2{,}400\,\text{N}$.

Result: The contact loop brakes at 39 N. Without the local trip, a stop that waited on the proposer would let the arm press on, and the spring model predicts 2,400 N.

Systems insight: The predicted force lies far past the 100 N limit, beyond the point where the spring model applies at all; the latch has failed. Sizing and arresting transient contact within milliseconds is the duty of the high-rate, low-latency contact loop. The intent lease supplies the operational boundaries (velocity caps and force tripwires) that keep dynamic loads within the contact loop's braking envelope, ensuring physical safety even when upstream deliberative proposers stall across multiple intent cycles.

Both the mug grasp and the latch engagement depend on a **privilege separation boundary**.[7] While deliberative models propose goal targets and operational bounds, an independent supervisor enforces safety invariants and executes certified fallback maneuvers whenever evidence expires or contact states change unexpectedly. This design decouples deliberative reasoning from real-time physical protection, inverting the classical priority hierarchy found in early reactive control systems (Brooks 1986).

Structured intent handoffs explicitly disentangle task tolerance, sensor uncertainty, actuator effort limits, and fallback trajectories. External dynamic processes, however, dictate how long these static bounds remain valid. On a moving conveyor, for instance, a correctly localized workpiece drifts continuously after perception capture. The mathematical model governing this uncertainty growth establishes the strict temporal deadline that the independent safety controller must enforce.

10.5 Expiring Goals and Temporal Validity Leases

Suppose the host application processor hangs while the robotic arm reaches for the red mug on the moving belt. The fault that makes canceling the reach necessary is the very fault that prevents a cancellation command from being sent. An explicit abort requires a working sender, scheduler, and

[7] **Subsumption Architecture**: In the classic subsumption architecture of Brooks (1986), a higher layer subsumes a lower one by suppressing its inputs or inhibiting its outputs. Physical AI systems invert that priority. The lower, real-time layer retains absolute veto authority over deliberative proposals because its timing, stability, and failure behavior can be strictly bounded.

network link, while the belt carries the mug beyond the grasp tolerance regardless of when the model last published a coordinate. An intent lease must therefore expire autonomously from the physics of environmental drift. Autonomous expiry applies the third law, proposal is not permission (principle 3), to physical goals, so that the permission side and not the proposer decides when authority ends. In distributed systems, Gray and Cheriton (1989) introduced leases to maintain cache consistency: a coordinator grants time-bounded authority that lapses unless explicitly renewed, preventing a crashed client from blocking others indefinitely. That correctness proof assumes bounded clock drift between client and coordinator. In an embodied system, the Safety MCU enforces this assumption by transforming every incoming timestamped epoch into its own local monotonic timebase with a strictly bounded synchronization error. The physical domain raises the stakes, because an expired cache lease merely delays a read, whereas an unexpired motion lease lets moving mass keep consuming physical clearance unchecked. The privileged Safety MCU acts as coordinator, issuing a transient tracking lease to the unprivileged deliberative host. If the host stalls during inference, pauses for garbage collection, or experiences an operating system kernel panic, the Safety MCU's local hardware countdown expires and automatically engages a validated fallback response. This requires no network packet or cancellation command from the failed host.[8]

Lease duration is measured exclusively against the Safety MCU's monotonic hardware clock.[9] Network time-synchronization daemons or operator adjustments can step wall-clock time abruptly backward or forward, while host-level software watchdogs can freeze alongside the user-space process they are designated to monitor. Furthermore, no inference pipeline, regardless of its mean throughput, completely eliminates long-tail p99 scheduling stalls. Placing the lease countdown on an isolated, hardware-timed MCU counter ensures that target authority is revoked locally the instant the lease expires. This hardware isolation decouples expiry detection from host operating system jitter, although total physical stopping distance must still account for fieldbus transmission, drive response, and kinematic deceleration.

The deadline the lease enforces is the evidence horizon τ_{ev} of section 3.5.2 put to a new use. There it bounded how long the evidence behind a chunk keeps the tracked mug within tolerance (equation 3.5). Here the intent lease starts from the same quantity, and memory supplies its value. The mug-handle belief record carries an invalidation horizon T_{inv} (equation 9.14), the elapsed time before its error growth law (equation 9.12) reaches the task tolerance. The lease reads that horizon with the grasp tolerance r_{tol} as the error ceiling and the initial sensor error e_0 as the starting bound.

For a conveyor pick, the growth law charges two bounded effects against that ceiling:

$$E(\Delta t) = e_0 + v_{\text{drift}}\,\Delta t + \tfrac{1}{2}\,a_{\text{slip}}\,\Delta t^2 \tag{10.4}$$

Here v_{drift} bounds the relative velocity between the gripper frame and the target, including both conveyor motion and unmodeled mobile-base odometry drift, and a_{slip} bounds the residual slip acceleration of the mug on the belt. The evidence-only horizon is the elapsed time at which $E(\Delta t)$ reaches r_{tol}. The numerical examples in this chapter evaluate this upper ceiling with zero additional controller tracking reserve. An admission gate, however, must first subtract a separately qualified nonnegative scalar tracking reserve from r_{tol}. It then solves equation 10.4 against the reduced budget. It refuses immediately if the initial target error plus that reserve already reaches the tolerance (alongside the full 3D error-set containment check of section 10.8). The two limiting regimes are horizons derived earlier in the volume. With no tracker, the horizon is the linear horizon of equation 9.15, with belt speed as its growth rate. With a tracker that cancels belt velocity, the horizon is the slip-only root of equation 3.5. In this chapter's symbols they read

$$\tau_{\text{ev,untracked}} = \frac{r_{\text{tol}} - e_0}{v_{\text{drift}}} \quad (a_{\text{slip}} = 0), \qquad \tau_{\text{ev,tracked}} = \sqrt{\frac{2(r_{\text{tol}} - e_0)}{a_{\text{slip}}}} \quad (v_{\text{drift}} = 0) \tag{10.5}$$

These evidence-only roots are upper ceilings on target lifetime. When drift velocity and slip acceleration act together, τ_{ev} is the positive root of $E(\Delta t) = r_{\text{tol}}$ in equation 10.4, which is strictly shorter than either single-effect root.

If $r_{\text{tol}} \le e_0$, the target is inadmissible at the moment of perception. Initial measurement uncertainty alone consumes the entire task tolerance, which obligates the safety controller to reject dependent motion commands immediately. Even when the evidence horizon is strictly positive, granting motion

[8] **Watchdog Timer**: An independently clocked down-counter that forces a hardware reset or a safe fallback output unless software reloads it before reaching zero. Because a crashed host cannot reload it, the lease countdown runs on the isolated Safety MCU rather than in the host process it supervises.

[9] **Monotonic Clock**: A counter that only advances forward at a fixed nominal rate, such as POSIX `CLOCK_MONOTONIC` or a free-running microcontroller timer. A lease evaluated against wall time could gain or lose its entire remaining window in a single clock adjustment. Every measurement in this chapter is therefore evaluated on the Safety MCU's monotonic counter and converted from external clocks with a bounded synchronization error.

permission requires a separate geometric verification. The system must verify that current physical clearance accommodates total sensing latency, permission evaluation time, fieldbus transmission delay, mechanical brake engagement, and physical braking distance.

For a red mug carried on a takeaway conveyor, the untracked linear root dictates the evidence deadline. Sizing the control pipeline requires determining whether deliberative intent models can refresh targets rapidly enough to renew authority before this window elapses. While the evidence-horizon calculation in section 3.5.2 sized the low-level chunk execution policy against this horizon, deliberative intent models evaluate on a substantially slower cycle.

Napkin Math 10.2: The cadence gap

Problem: The conveyor carries the mug at 0.20 m/s. Can the 2 Hz intent model keep the target inside its tolerance by re-proposing it, and how slowly would the belt have to run for a model-only renewal to suffice?

Variables:

- Grasp tolerance $r_{\text{tol}} = 15$ mm and initial handle error $e_0 = 3$ mm (Illustrative)
- Belt speed $v_{\text{drift}} = 200$ mm/s (Illustrative)
- Intent period $T_{\text{period}} = 500$ ms (Chosen, 2 Hz) and inference $t_{\text{infer}} = 336$ ms (Derived, section 3.4.1)

Math:

1. **Horizon** (equation 10.5): with no tracker, $\tau_{\text{ev}} = \tau_{\text{ev,untracked}} = (15\text{ mm} - 3\text{ mm}) \,/\, 200\text{ mm/s} = 60$ ms.
2. **Error at one period**: $3\text{ mm} + 200\text{ mm/s} \times 500\text{ ms} = 103$ mm, 88 mm past the tolerance. Inference alone overruns the horizon by $336\text{ ms} - 60\text{ ms} = 276$ ms.
3. **Renewal ceiling**: Each model-only renewal installs a target computed from a frame captured one inference earlier, and that target stays in force until the next renewal replaces it one period later. Just before the replacement, the evidence behind it is $T_{\text{period}} + t_{\text{infer}} = 836$ ms old (the reaction latency of section 3.5.1, here for the intent model), so the drift it can keep up with is $(15\text{ mm} - 3\text{ mm}) \,/\, 836\text{ ms} = 14.4$ mm/s.

Result: The model alone could renew the target only on a belt running at 7.2 percent of its speed. Even a slow settling drift of 20 mm/s, such as a mug still sliding to rest after the belt stops, whose 600 ms horizon is charted against inference latency in figure 10.6, is too fast for it.

Systems insight: Physical drift and allowable tolerance dictate τ_{ev}, independent of computing performance. An intent renewal can extend operational authority only if the sum of its dispatch period and inference latency fits entirely within this window. Artificially inflating the lease duration to cover inference delay leaves the pose estimate outside its declared tolerance envelope for 276 ms. Without a qualified, high-frequency local tracker, the system must either slow or stop the conveyor, or refuse the pick task entirely.

The 60 ms limit is a physical evidence deadline that only fresh sensor observations, validated against current motion, can extend. Faster deliberative inference does not lengthen this physical evidence horizon, although a sufficiently fast capture-to-admission pipeline and renewal cadence can fit inside it.

Deploying a qualified local tracker changes these dynamics. By re-measuring the mug in every camera frame and matching conveyor velocity, the local tracking loop prevents conveyor speed from driving error growth. While the initial perception uncertainty of 3 mm still counts against the grasp tolerance, it leaves a target-only error margin of 12 mm for unmodeled physical perturbations before reserving controller tracking error. Sizing against an illustrative worst-case residual slip acceleration of 0.50 m/s², this remaining margin yields the same 219 ms tracked horizon that section 3.5.2 computed for the chunk policy. Because the local tracking pipeline runs at high frame rates, only the tracker's brief period plus sensing latency must fit within this expanded horizon. The tracker also changes who renews the lease. Each tracked frame yields a newer belief record of the same handle,

and the producer re-proposes the same referent against it. The Safety MCU therefore receives renewals with a newer capture epoch on the tracker's cadence rather than the model's. Relieved of geometric tracking, the deliberative intent model only re-confirms semantic identity (which mug to grasp) at its own rate, and no renewal waits for a fresh inference. The lease attaches its target to the handle's affordance frame, whose base-frame pose under a qualified tracker follows the belt. The goal set therefore moves with the mug. The tolerance bounds only how far the handle departs from the tracked estimate under residual slip, rather than how far it departs from a fixed point in the base frame. Whichever horizon governs the active operating mode caps the duration of the intent lease granted for that target (section 10.8).

Examining a host processor stall illustrates the protection each horizon provides. Suppose the robotic arm reaches toward the red mug under a target admitted without local tracking, and the application processor stalls during neural network inference. If the system held that unvalidated target across a 200 ms stall, the actual mug position would drift 43 mm away from the commanded setpoint, causing the gripper to close on empty air or strike the rim. The Safety MCU does not rely on host health to catch this fault. In the ideal zero-additional-reserve case, at 60 ms the lease expires automatically, commanding braking to begin within 22 ms (accounting for one permission evaluation tick, one fieldbus cycle, and actuator brake onset), even if the current chunk's own lease has time left. In contrast, under a qualified local tracker, an identical 200 ms stall leaves the target estimate displaced by only 13 mm, inside the target-only tolerance budget, because the ideal tracked horizon extends to 219 ms. Delegating fast geometric updates to local tracking is what allows a 2 Hz deliberative intent model to operate safely in a dynamic physical environment.

On one clock, the proposer's timing loses to both horizons (figure 10.5). Both idealized zero-additional-reserve countdowns end before the 336 ms inference returns and well before the next proposal at 500 ms, so the model can renew neither lease. Absent other renewals, each expiry is followed by the 22 ms stop onset. Under a qualified tracker the tracked countdown restarts with every tracked frame, long before it reaches 219 ms, so the tracked bar in the figure shows what happens only when those renewals stop, as they do when the host stalls. What follows that expiry is still motion, as panel (b) of figure 10.4 sketches in speed against time. The drive begins braking 22 ms after expiry, and the stopping distance under the falling curve must already fit the clearance that remains. This is why the lease carries the stopping deadline as a term of its own (section 10.8).

Panel (a) of figure 10.6 generalizes the cadence gap across drift speeds. The 336 ms inference alone fits under the 600 ms horizon of slow settling drift but far exceeds the 60 ms conveyor horizon, and adding the proposal period, as the cadence-gap notebook showed, breaks even the settling case. Panel (b) previews the cheap early filters (sequence and evidence, workspace, transit lower bound, and ambiguity) that reject impossible proposals before the planner spends compute on them. Sustaining continuous tracking safely requires *fresh physical evidence*, not merely retransmitting a new packet computed from stale sensor observations. Every renewal must derive from an independent physical capture and reach the Safety MCU before the active lease expires. The end-to-end timing budget must account for image capture, inference processing, fieldbus transmission, clock synchronization uncertainty, and permission verification. The timing condition $T_{\text{period}} + L_{\text{lat}} < \tau_{\text{ev}}$ serves only as a necessary scheduling check. When a renewed proposal arrives, the trajectory planner computes a jerk-limited splice originating from the measured physical state. The safety controller admits this spliced trajectory only if the new swept volume, refreshed evidence validity, and emergency stopping reserves remain fully verified. An abrupt target displacement that violates kinematic or clearance bounds triggers immediate refusal or a controlled stop.

Safely executing a bounded lease presupposes that the commanded geometric target is physically achievable by the robot. If a proposed coordinate falls outside kinematic reach or demands joint velocities that exceed actuator limits across the lease window, granting the lease squanders control authority. It also risks tripping drive overcurrent protection as motor controllers saturate attempting to reach unattainable velocities. Determining whether an incoming goal is kinematically and dynamically admissible must precede trajectory generation, establishing a physical admissibility filter between high-level deliberative intent and real-time execution.

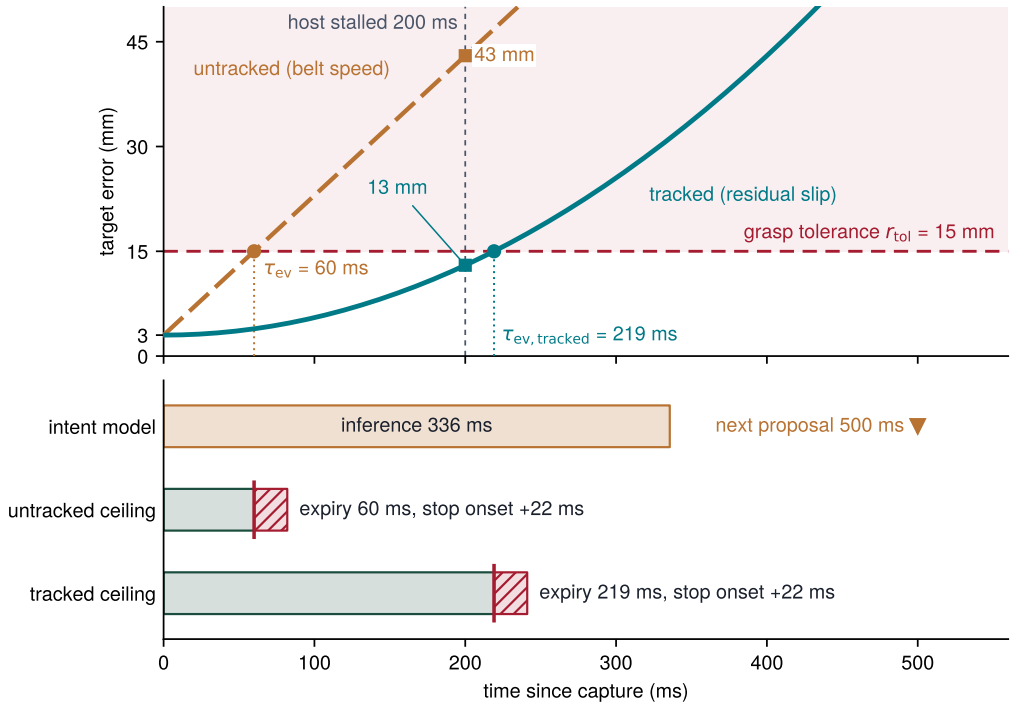


Figure 10.5: Mug lease against the intent model's timing: The top lane charges the conveyor mug's modeled target error against the 15 mm grasp tolerance. Without tracking, belt speed exhausts it at 60 ms; with a tracker that cancels belt velocity, residual slip exhausts it at 219 ms. The bottom lane puts idealized countdowns with zero additional controller reserve on the Safety MCU's clock beside the 336 ms inference and the 500 ms proposal period; each expiry is followed by the 22 ms stop onset (hatched). Neither lease can wait for the next proposal. After a 200 ms host stall the untracked target sits 43 mm off and the tracked one 13 mm.

10.6 Admissible Goal Sets

If the red mug rides past on the far side of the belt, beyond the arm's physical reach from where the base is parked, no sequence of joint torques can bring the gripper to its handle. In an embodied ML system, this physical impossibility must be intercepted at the proposal boundary, before the target enters the trajectory optimization queue. When an upstream vision-language model or diffusion policy emits a candidate Cartesian coordinate, treating that output as an unverified proposal protects the real-time motion pipeline from executing physically impossible trajectories and from wasting compute cycles attempting to solve them.

A reachability screen also protects the planner's computational budget. When a target cannot be reached at all, the trajectory optimizer faces an empty feasible set. Local nonlinear solvers cannot certify infeasibility quickly. They typically exhaust their entire iteration budget before timing out, transforming an upstream geometric hallucination into compute starvation on the planning core. Similarly, a requested terminal move that cannot complete before its supporting sensory evidence expires must fail before entering detailed planning. Long-horizon tasks should instead request guarded progress under renewable evidence leases rather than attempting an ungrounded terminal grasp on a single sensor capture.

To avoid spending the planning budget on an already impossible request, the admission layer evaluates proposals against two low-cost preliminary checks:

1. **Static Workspace Manifold Check ($\mathbf{T}_{\text{target}} \in \mathcal{W}$):** Geometric workspace analysis defines the closed spatial manifold $\mathcal{W} \subset SE(3)$ of reachable end-effector configurations given link dimensions, joint travel limits, and mounting geometry (Craig 2005; Lynch and Park 2017).[10] An analytical reachability check evaluates whether the target $SE(3)$ pose $\mathbf{T}_{\text{target}}$ resides inside

[10] **Workspace vs. Singularity**: Membership in $\mathcal{W}$ says that some joint configuration reaches the pose, not that the arm can move freely there; inside the workspace the Jacobian can still lose rank at a singular configuration, where some Cartesian velocities become unattainable. A workspace screen therefore rejects unreachable targets early, leaving singularities to the configuration and path checks; section B.6.1 develops the Jacobian rank loss behind them.

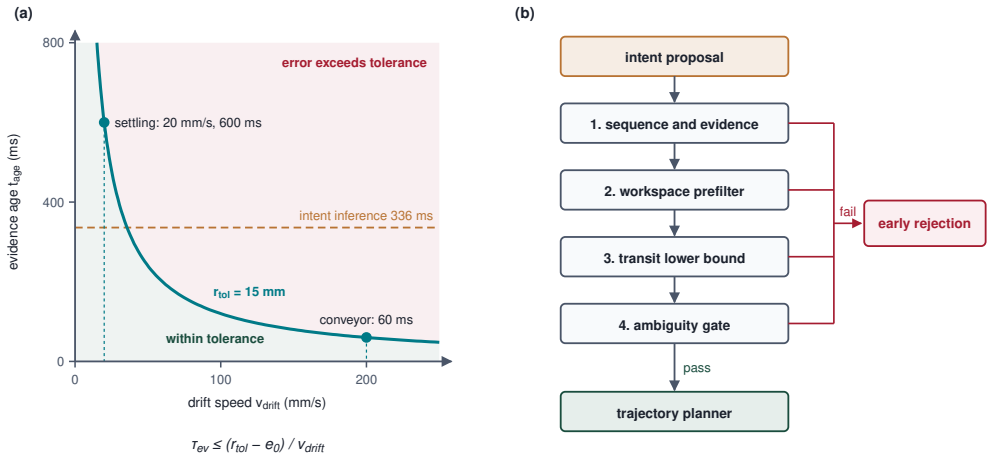

Figure 10.6: Target-evidence horizon and early filters: Panel (a) plots the bound $\tau_{ev} \le (r_{tol} - e_0)/v_{drift}$ for the 15 mm tolerance and 3 mm initial error; the shaded region below the curve means only that the target remains within the task tolerance. The machine's computed 336 ms intent inference sits far above the 60 ms conveyor horizon and below the 600 ms settling horizon. Panel (b) shows early rejection stages that precede the full path and stopping checks.

this workspace manifold $\mathcal{W}$, while an occupancy lookup in spatial memory confirms that the target volume does not intersect persistent static obstacles.

2. **Dynamic Reachability Transit Check:** Even when a target lies inside the static workspace manifold $\mathcal{W}$, it may be physically unreachable within the finite window during which its sensor evidence remains valid. This check evaluates whether the end effector can transition from its measured state $(\mathbf{p}_0, \mathbf{v}_0)$ to the target pose within the remaining window $t_{\text{intent_exp}} - t_{\text{now,mono}}$ while respecting its velocity, acceleration, jerk, and thermal torque limits.

Whatever continuous trajectory profile the actuators follow, no physical move covers distance $d = \|\mathbf{p}_{\text{target}} - \mathbf{p}_0\|$ faster than its maximum speed ceiling allows. Here both $\mathbf{p}$ terms are translation vectors in the same Cartesian frame, not full $SE(3)$ poses; orientation feasibility requires a separate check. For terminal completion before the current expiry, a necessary condition is:

$$\frac{d}{v_{\max}} \le t_{\text{intent_exp}} - t_{\text{now,mono}}. \tag{10.6}$$

Actuator acceleration limits, jerk ceilings, and motor torque-speed curves only lengthen the required transit time beyond this kinematic floor. A proposal that violates this inequality cannot promise terminal completion in that window. A request for an intermediate guarded segment may remain feasible if its executed motion and stopping fallback fit the current authority, deferring continuation to newly admitted evidence. Section B.6 gives triangular and trapezoidal transit bounds and explains how jerk limits change the complete-move check.

The scalar lower bound is an early rejection test, not a trajectory generator. It avoids optimizing a terminal request that is already too late, leaving detailed acceleration profiles, obstacle avoidance, and stopping reserves to the fuller motion check. Equation 10.6 couples spatial distance to evidence lifetime, so dynamic reachability evaluates the target and its supporting evidence together rather than the spatial coordinate alone.

↪ Resolving the admitted goal region into a timed trajectory is developed in section 11.3.

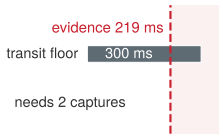
Definition 10.2: Dynamic reachability

Dynamic reachability is the property that the end effector can move from its measured state to a target pose, within its velocity, acceleration, jerk, and thermal limits, before the evidence supporting that target expires.

DRAFT

1. **Significance**: It prices a target in time as well as space. At the arm's 1 m/s TCP limit, equation 10.6 allows at most 219 mm of travel inside the mug's 219 ms tracked evidence window, so a handle 300 mm away is dynamically unreachable on one capture even though it lies well inside the workspace.
2. **Distinction**: Static reachability evaluates geometric feasibility alone (whether any joint configuration can achieve the pose). Dynamic reachability introduces the clock and actuator dynamics. Unlike the dynamic obstacle forecasting of section 10.6.1, which bounds where external actors might move, dynamic reachability bounds where the robot's end effector can safely travel within a bounded lease.
3. **Common pitfall**: Attempting to resolve an unreachable target by stretching its evidence deadline in software. Only fresh sensor measurements can renew an expiring window; the remedy is a staged approach whose segments each fit their own evidence and fallback.

On the arm, the mug's evidence under the qualified tracker stays valid for 219 ms after its capture. At the 1 m/s TCP speed limit, the gripper could cover at most 219 mm even if the entire window remained. A terminal proposal issued with the gripper 300 mm from the handle needs at least 300 ms of transit. It therefore receives `ERR_DYNAMIC_TIME_INSUFFICIENT` if it promises completion on that record. Without the tracker, the full window is only 60 ms and the corresponding speed-only reach is 60 mm. Processing and transport consume part of either window. Acceleration further reduces the reachable distance.



This bound and the fuller checks behind it assume that actuators stay within their nominal thermal ratings, that encoders report the initial state $(\mathbf{p}_0, \mathbf{v}_0)$ correctly, and that the payload matches the inertial model. When winding temperatures cross the thresholds of section 2.5.1, or a force measurement reveals a payload mismatch, the permission path lowers $a_{\max}$ and $v_{\max}$ (**thermal derating**). It then evaluates new proposals against the reduced limits and rechecks any admitted path that the derating may have made infeasible.

A rejection must not simply discard the packet, which would leave the reasoning model waiting for a task timeout. The intent filter returns a structured diagnostic across the proposal boundary: the classification (`ERR_WORKSPACE_OUT_OF_BOUNDS`, `ERR_DYNAMIC_TIME_INSUFFICIENT`, or `ERR_OCCUPANCY_BLOCKED`) and the numerical margin of failure. A dynamic failure reports the shortfall between the transit bound and the remaining window; a workspace failure reports the nearest reachable point on the boundary of $\mathcal{W}$. The reasoning layer can then seek fresher evidence, choose another approach, slow the process, or propose moving the base. It cannot extend the evidence horizon without new sensor data.

The diagnostic makes a staged approach possible. Consider a setup where the pre-contact corridor and its stopping reserve are qualified, a closer wrist observation supports the 3 mm error bound, and the tracker holds the declared slip bound. The rejected terminal promise becomes a pre-contact observation goal. A separately checked corridor carries the gripper toward a better view while keeping a stop outside contact, and the closer capture supplies the mug-handle belief record whose error fits the 15 mm tolerance.

Better sensing does not shorten the physical transit floor. The 300 mm approach still takes at least 300 ms, longer than the 219 ms horizon of any one capture, so it needs at least 2 fresh captures. The planner executes guarded segments under chunk leases, and each continuation is checked against the current intent, target evidence, corridor, and fallback. The predicted route beyond the admitted segment carries no authority. Once the last segment and the closure pass the full trajectory check, the gripper completes the grasp inside the tolerance and moves to the admitted hold for handover. If the closer observation fails, identity becomes unresolved, or a renewal arrives late, the next segment is refused, and existing motion continues only while its own evidence, authority, and fallback remain valid.

↪ The staged approach, with each trajectory segment re-anchored to a fresh wrist-camera capture, is developed in section 11.3.2.

The 300 ms reach outlasts one 219 ms evidence window; it needs 2 captures.

10.6.1 Dynamic obstacle forecasting and forward occupancy

Even when the mug handle lies within kinematic and dynamic reach, a coworker may be about to cross the approach corridor, a conflict that the static workspace and transit tests alone cannot reject.

Dynamic obstacle forecasting carries the perception and memory estimates forward into regions that moving obstacles could occupy so the intent stage can reject blocked corridors early, before the planner and permission path check the complete timed trajectory. Because this forecast predicts only where people might move and says nothing about whether those people can tell where the machine will move, it covers only one half of how coworkers and robots stay clear of one another.

The intent filter consumes the dynamic track manifest $[(\mathrm{ID}_k, \hat{\mathbf{p}}_k, \hat{\mathbf{v}}_k, \mathbf{P}_k, t_{\text{last}}, \text{state})]$ published by the multi-object tracker, alongside tentative detections, raw occupied regions, and unknown-space evidence, because failure to confirm an identity does not make its occupied region clear. For each confirmed or coasting track k, the admission engine constructs a **forward occupancy set** $\mathcal{R}_k(\Delta t)$, the region the actor could occupy Δt after its last measurement:

$$\mathcal{R}_k(\Delta t) = \{\mathbf{p} \in \mathbb{R}^3 \mid \|\mathbf{p} - \hat{\mathbf{p}}_k\| \le r_k + v_h \Delta t + k_\sigma \sigma_{\text{track}}(\Delta t)\} \tag{10.7}$$

Here r_k is a declared body envelope that covers torso, limbs, and carried objects. The term v_h is a validated bound on the actor's speed. The term k_σ is a selected multiplier whose joint spatial coverage must be calibrated rather than read off a scalar Gaussian rule. The term $\sigma_{\text{track}}(\Delta t)$ is the root-mean-square position deviation of the propagated track covariance. That deviation need not grow monotonically during coasting, so the check needs a conservative bound over the whole interval. $\mathcal{R}_k(\Delta t)$ is called an occupancy set rather than a reachability set because dynamic reachability bounds where the robot can get in time, whereas forward occupancy bounds where a person might be. A tracker with a validated acceleration bound can instead center the set on the predicted position $\hat{\mathbf{p}}_k + \hat{\mathbf{v}}_k \Delta t$ and grow it with $\frac{1}{2} a_{k,\max} \Delta t^2$, which is tighter over short intervals. The speed-bound form is the conservative one that safety standards use.

↪ Motion and signals that let the people around a machine infer its goal early enough to yield are developed in section 17.6.1.

Equation 10.7 is the human half of speed and separation monitoring (SSM), a certified safety function that runs beneath the permission path and keeps a protective separation distance between the moving robot and a person. Section 12.9.3 sizes that distance under ISO 10218-2:2025, which incorporates the collaborative-application requirements formerly published as ISO/TS 15066 (the technical specification itself remains published and is under revision) (International Organization for Standardization 2025b, 2016; Marvel and Norcross 2017). The separation calculation assumes the ISO 13855 walking approach speed[11] of 1.6 m/s for an approaching person (International Organization for Standardization 2024a). The intent stage uses the same speed bound for an earlier and coarser purpose, rejecting a corridor before the planner spends time on it.

↩ The dynamic track manifest and the tentative, confirmed, and coasting track lifecycle are established in section 9.2.2.

Screening a corridor means sweeping the robot's candidate transit volume $\mathcal{T}_{\text{robot}}(\Delta t)$ forward in time beside every person's set. On the aisle of figure 10.7, the coworker's set grows at the ISO 13855 walking speed from 96 mm over the untracked horizon to 351 mm over the tracked one, and the corridor enters the larger disc, so the screen refuses it. Under declared motion bounds, the early screen requires the candidate transit volume to remain disjoint from every active occupancy set across the execution window. Here t_{age_k} is the upper age of actor k's last measurement at the current admission epoch, including bounded clock-conversion error, and Δt is additional future time:

$$\mathcal{T}_{\text{robot}}(\Delta t) \cap \mathcal{R}_k(t_{\text{age}_k} + \Delta t) = \emptyset \quad \forall \Delta t \in [0, t_{\text{intent_exp}} - t_{\text{now,mono}}], \ \forall k \tag{10.8}$$

Full trajectory admission must extend the exclusion check through the response delay and the complete stopping fallback. If a candidate corridor violates equation 10.8 by intersecting an expanding set, the early screen can return `ERR_DYNAMIC_OCCUPANCY_CONFLICT` and request a different corridor or a yield. The refusal diagnostic returns the earliest predicted conflict time $\Delta t_{\text{conflict}}$ and the conflicting actor identifier ID_k. Passing this screen does not establish a collision-free trajectory. The planner must supply the timed motion, and the permission path must check its swept volume and stopping reserve against evidence that remains valid. The arithmetic of this linear growth is simple; what decides the outcome is the horizon over which it runs.

[11] **Approach-Speed Constant**: The standard's speed describes a design person walking toward a safeguard, not a measured coworker, and the standard applies a higher constant to hand and arm reach at short separations (International Organization for Standardization 2024a). A forecast built on the walking value is valid only for the motion it describes. A coworker who runs or reaches across the corridor lies outside that bound, and the growth term must therefore be validated for the site rather than copied from the standard.

↩ The mapping of the robot's protective-separation terms onto its stopping-distance budget is established in section 2.3.1.

Napkin Math 10.3: The freezing radius

Problem: A coworker walks in the 1.30 m aisle while the arm screens its corridor. How far can the growth term of equation 10.7 carry that person's set over the mug's evidence horizons and

over a 2 s planning horizon, and beyond what horizon does one person's set alone span the aisle?

Variables:

- Approach speed $v_h = 1.6$ m/s (Datasheet, ISO 13855 design value)
- Evidence horizons 60 ms untracked and 219 ms tracked (Derived, equation 10.5); planning horizon 2 s (Illustrative)
- Aisle width $w = 1.30$ m (Illustrative)

Math:

1. **Evidence horizons**: 1.6 m/s $\times$ 60 ms $=$ 96 mm, and 1.6 m/s $\times$ 219 ms $=$ 351 mm.
2. **Planning horizon**: 1.6 m/s $\times$ 2 s $=$ 3.2 m.
3. **Crossover**: The growth term reaches the aisle width when $v_h\,\Delta t = w$, at $\Delta t = 1.30$ m / 1.6 m/s $= 0.81$ s.

Result: Over the evidence horizons the set grows by centimeters to decimeters; past 0.81 s a single person's set covers the full aisle before the body envelope and tracking terms are even added.

Systems insight: The duration of the screening horizon dictates whether the robot can plan feasible motion. Extending a dynamic forecast beyond the admitted motion and its complete stopping fallback can reject a corridor for possible human movements outside the current commitment. In narrow operating aisles, unnecessarily long forecast horizons can block otherwise admissible progress. The shorter screen must still cover response delay and deceleration; evidence expiry does not end physical motion.

A set that outgrows the aisle is the root of the **freezing robot problem**. Trautman and Krause showed that when a planner predicts each person independently and lets that uncertainty grow, the predicted occupancy of a crowd covers every path, and the robot stops even though people would make room for it (Trautman and Krause 2010). Three choices reduce unnecessary conservatism, and none permits shrinking a physically justified bound merely to obtain motion:

1. *Short receding horizons:* Screening over the evidence horizon rather than seconds ahead keeps the growth term near 351 mm instead of meters. The forecast must still cover the entire executed prefix and the physical fallback, including response delay and deceleration; shortening the lease does not shorten an actor's possible motion while the robot stops.
2. *Re-centering on fresh evidence:* A qualified tracker re-centers each set on new measurements ($t_0 \leftarrow t_{\text{fresh}}$), resetting the growth term and the propagated covariance, provided its accuracy and latency support the required bound.
3. *Interaction-aware prediction:* Trautman and Krause's own remedy predicts the people and the robot jointly, so that each accounts for how the others will respond. Such predictions are learned or modeled proposals, and they may narrow a set only after their error has been bounded by the same kind of evidence the permission path demands of any other input.

The discs are centered on the coworker's last measured position, so the tracker's lifecycle sets their age. A confirmed track receives fresh measurements, while a coasting track accumulates propagated uncertainty and widens the exclusion region as its evidence ages. A goal proposal cannot refresh a stale track without incoming sensor data, and a detour proposed after a refusal needs its own timed check. When a person walks out of view, terminating the software track does not make the occluded space free. Memory already erodes certified free space behind an occlusion at the same walking-speed bound (section 9.7), and that unknown-space policy remains in force until new observations justify a different claim.

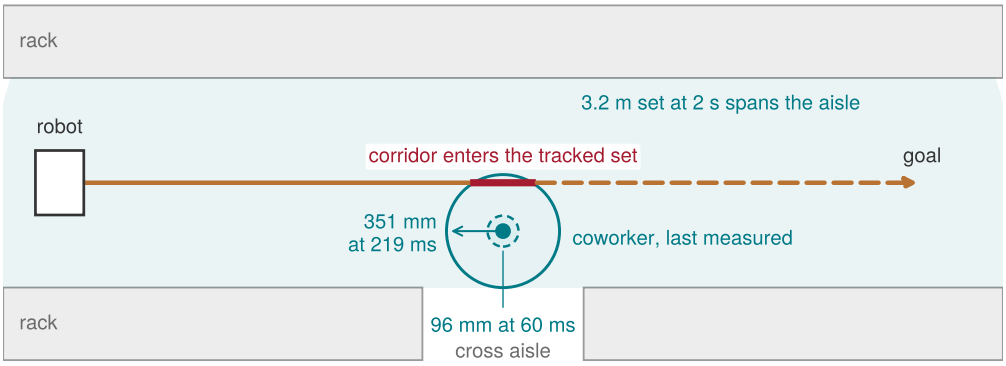


Figure 10.7: Forward occupancy sets on the aisle: A top-down view of a candidate corridor screened against a coworker's forward occupancy sets, centered on the last measured position. The discs show only the growth term $v_h \Delta t$ at the ISO 13855 speed of 1.6 m/s: 96 mm over the untracked 60 ms horizon and 351 mm over the tracked 219 ms horizon; the body envelope r_k and the tracking term $k_\sigma \sigma_{\text{track}}$ add to every radius. The corridor enters the tracked set (red segment), so the screen refuses it and asks for a detour or yield. Over a 2 s horizon the set grows to 3.2 m and spans the aisle.

Checkpoint 10.1: Evidence windows and reach

A target is admissible only while its evidence lasts, and every early screen in this section is sized by that window.

- ☐ **Evidence-horizon estimate**: Suppose the mug drifts at 50 mm/s instead of riding the belt, with the same 15 mm tolerance and 3 mm initial error. Can you compute the untracked evidence horizon and decide whether the 2 Hz intent model could renew it without a tracker?
- ☐ **Transit bound**: Can you explain why a terminal move inside the static workspace can still fail admission, and what a staged approach changes about it and what it cannot change?
- ☐ **Occupancy vs. reachability**: Which question does a forward occupancy set answer that dynamic reachability does not, and why does screening over the evidence horizon rather than seconds ahead keep the robot from freezing?
- ☐ **Stretched deadlines**: Why can neither faster processing of the same old frame nor a longer requested lease extend a target whose evidence has expired?

Reachability and corridor filters reject provably impossible requests before planning begins. The survivors remain candidates, carrying the target bounds and obstacle evidence needed for the full motion check. The remaining challenge is distinguishing between failures these physical checks can expose and errors in task meaning that geometry and kinematics alone cannot resolve.

10.7 Intent Grounding Failure Modes and Their Checks

Whether an error arises from physical drift or from task misunderstanding, a vision-language model or multimodal transformer emits the same $SE(3)$ target pose for a physical manipulator. A specular reflection in empty air, a stale coordinate from a moving belt, or a bolted fixture mistaken for a handle all arrive across the proposal boundary as the same clean seven-number pose:

1. **Phantom target (hallucination):** Attention concentrates on a specular glare, a shadow, or a transparent surface, and the pipeline predicts an object where none exists. Missing or corrupted depth returns then place the target in empty space or inside a transparent barrier, and an admitted proposal sends the arm into air or into glass.

2. **Stale target (pipeline latency or temporal drift):** The physical workpiece shifts on a conveyor, vibrates on a feeder tray, or is displaced by a human coworker while the multi-stage perception pipeline buffers, batches, and decodes frames. The machine's intent model takes 336 ms per inference, longer than the 60 ms untracked horizon before any tail latency is added. A chunked action stream can keep the arm moving throughout, but on the target the model last saw. The resulting proposal arrives downstream with mathematically valid coordinates that describe where the object *used to be* rather than where it *is*, consuming physical clearance before motion begins.
3. **Semantic ambiguity (bimodal posterior or argmax failure):** Two visually identical candidate objects (e.g., two red mugs) reside within the pick zone, and both score high because the detector scores each box independently. The calibrated prediction set holds both ($|\mathcal{C}| = 2$). Keeping only the top box or averaging the candidates' centroids commands an arbitrary choice or drives the end effector toward the empty midpoint between the objects, risking a dual-object collision.
4. **Misclassified affordance:** A bolted fixture is taken for a movable handle, or a thin-walled container for a robust one, and the requested grip force destroys it. The approach can be collision-free while the contact wrench is wrong.
5. **Dynamic unreachability (kinematic transit shortfall):** A requested terminal move is geometrically within the static workspace manifold $\mathcal{W}$, but the transit time demanded by actuator velocity and acceleration limits exceeds the remaining sensor evidence window ($t_{\text{transit}} > t_{\text{intent_exp}} - t_{\text{now,mono}}$). The terminal request must be rejected or replaced with guarded stages supported by fresh observations; extending its old evidence deadline cannot make it feasible.

All five failures arrive across the proposal boundary in the same format: a candidate position $\mathbf{p} \in \mathbb{R}^3$ and orientation $\mathbf{R} \in SO(3)$. While a pose in empty air leads to a futile reach and a pose inside a fixture leads to contact unless path and permission checks intervene, the wrong-object case can satisfy every geometric and kinematic check while targeting the wrong item. Because the independent permission path checks only what it can measure (freshness, coverage, geometry, current state, and actuator limits), it makes no claim to verify the task's meaning. **The Safety MCU enforces physical feasibility, not semantic truth. A goal can be collision-free, kinematically smooth, and torque-limited, yet wrong for the task.** Semantic verification therefore belongs to upstream task monitoring and operator oversight, and the same boundary holds under adversarial attack, where an injected instruction or a printed patch in the camera view still yields a well-formed pose.

↪ What the permission path can and cannot catch when the proposer itself is attacked is developed in section 15.6.3.

A fresh depth observation can reject a proposed grasp when required object evidence is absent inside a covered, visible region, whereas missing returns in an occluded or unobserved region leave that space unknown. On this station, the singulation rule goes further by requiring independently qualified depth evidence of a single candidate in the pick window, even when the grounding model reports high confidence. Because the Safety MCU holds no scene representation with which to count objects, this check runs in a separate station component before any proposal is forwarded. The component routes any window with multiple candidates to a coworker for manual selection (a scoped station policy; another qualified operating mode could select a uniquely identified mug among several objects). Counting itself depends on validated sensor coverage and segmentation, so it shares a failure mode with phantom targets. Touching items can merge into a single cluster, and transparent objects such as the glass jar return little or no depth (Sajjan et al. 2020). The counter's qualified domain must therefore exclude those cases or route them to a manual pick. Even when the count finds a single cluster, it still cannot verify that the lone object is a mug, and while the producer's calibrated ambiguity filter may refuse earlier, it cannot replace the station's independent check.

Table 10.5 groups these failures by the check that can expose them. Dynamic transit insufficiency can be rejected before motion, whereas a misclassified affordance may first become observable through contact residuals. The table separates admission checks from responses after motion or contact has begun. At the cage-door latch of notebook 10.1, the 2 ms contact-loop response already leaves 39 N at brake-command onset, and the peak comes later. Precontact speed and force limits,

actuator response, compliance, and available clearance therefore determine whether the full contact trace stays within the validated contact limits.

Table 10.5: Grounding failure modes and their evidence limits: Each check addresses a different failure class. The table separates proposal rejection from a response to an already moving plant.

Failure mode	Evidence or check	Admission or response	Physical limit to verify
Phantom target: image artifact in empty space	Fresh depth evidence and target-region occupancy, with coverage and occlusion checked	Reject the proposal when the required object evidence is absent; request another view if the region is unknown	Rejection precedes motion only if the proposal has not already been admitted. Missing returns alone do not prove empty space.
Stale target: workpiece moved after capture	Converted capture time, bounded clock error, local tracking, and target-error envelope	Revoke dependent tracking when the evidence limit fails; select the validated fallback	Total detection, communication, actuation, and braking delay must fit the measured clearance.
Station singulation failure: multiple candidates in the pick window	Independent count of candidates in the pick window from fresh depth evidence; calibrated prediction-set size as an earlier producer-side signal	Refuse admission and route the item to the coworker for a manual pick	A single wrong object passes the count, and a confident model can return a singleton set; independent physical checks remain necessary.
Misclassified affordance: bolted fixture selected as graspable	Contact-force and motion residuals after contact; precontact task/geometry checks where possible	Limit precontact speed and force, then invoke the validated contact response on a threshold crossing	A reactive trip does not cap the first impact peak; test the full force trace, response delay, and stopping energy.
Dynamic unreachability: target cannot be reached in its valid window	Speed-ceiling transit lower bound followed by a complete path and stopping check	Reject terminal completion on that record; consider separately admitted guarded segments	Passing the lower bound proves neither collision-free motion nor a feasible stop.

Every row of the table therefore requires the proposal to carry its spatial bounds, the provenance of its evidence, and its expiry in a form the permission path can check without the model. A rejected proposal returns a diagnostic reason to the learned layer without revoking an earlier active record, which remains usable while its own state, evidence, lease, and fallback hold. An admitted proposal stays subject to independent permission checks as the plant moves, and the record the permission path grants from it is the intent lease.

10.8 The Intent Lease Specification and Contract

If a target region, an actuator effort ceiling, and an expiration deadline travel as separate messages across the inter-core bus, a dropped or delayed packet can leave the trajectory planner tracking a new pose under an old force limit or an expired evidence timestamp. For the red mug, upstream perception and belief filtering distill raw sensor telemetry into those three quantities: a target region bounded by empirical evidence, an effort ceiling on actuator output, and an explicit deadline after which tracking must cease. The intent lease binds them into a single, immutable record for downstream control. Its lineage anchors to the belief record through a SHA-256 digest, while its evidence timestamp maps that record's sensor transduction epoch directly into the Safety MCU's monotonic clock domain. This admitted target establishes a verified envelope for downstream planning, leaving trajectory generation and execution permission to subsequent safety stages.

This stage emits the **intent lease**, the eighth record in the book's sixteen-record chain. Authority divides cleanly between the two processors. The high-performance Application Processor generates an untrusted intent proposal (table 10.2), while the independent, real-time Safety MCU validates and latches the admitted lease. By binding the admitted target to a verified goal set, an affordance frame, and a collection of active safety predicates, this latched lease strictly constrains the downstream trajectory planner before the hardware admits any joint motion.

To guarantee deterministic processing on the safety controller, the proposal payload uses a statically bounded schema. Fixed-size fields eliminate dynamic heap allocation and pointer dereferencing, enabling the validation pipeline to reject malformed records in bounded execution cycles. However, static memory layout alone does not guarantee real-time deadlines. Inter-core memory copies,

cache maintenance, lock contention, and bus arbitration must all remain within measured worst-case execution time bounds. The inbound proposal remains an advisory request from untrusted software; the Safety MCU retains exclusive authority over parameter bounds, expiration deadlines, and fallback activation.

↪ Mailboxes, memory barriers, and copy costs on the inter-core seam are developed in section C.8.

The covariance ellipsoid derived for the mug handle in section 10.3.3 represents an upstream producer estimate. Rather than serializing a dense, oriented 3×3 covariance matrix across the real-time wire, the protocol projects these bounds into three axis-aligned **position-error envelopes** (e_x, e_y, e_z) alongside three requested **task tolerances** (r_x, r_y, r_z) expressed in the robot base frame $\mathcal{F}_{\text{base}}$. The componentwise test $0 \leq e_i \leq r_i$ is a necessary preliminary screen. Admission must also establish that the full conservative error set, together with reserved controller tracking error, fits inside the ellipsoidal task region defined in section 10.1. Passing each axis independently does not establish that containment. Three axis-aligned bounds define a rectangular box rather than an ellipsoid, so a corner where errors peak along all three axes simultaneously can protrude outside the curved task boundary even when each individual axis stays within its limit, requiring the Safety MCU to evaluate the ellipsoidal norm at the worst-case corner of that error box plus the reserved tracking margin. The upstream producer must mathematically justify its projection from raw state covariance to these conservative error envelopes, accounting for camera calibration drift, latency jitter, and declared tail-risk percentiles. Angular tolerances and contact-mode transition rules derive from an independently certified task profile, allowing the wire proposal to transmit only the nominal target orientation quaternion.

Temporal validation hinges on the **belief record's evidence epoch** (the physical instant of sensor exposure, not the time processing completed), mapped into the Safety MCU's local clock domain. The Safety MCU verifies the parent digest and evidence epoch against retained belief records in local memory, adding the bounded synchronization error to the calculated evidence age. Requested expiration times reference this same monotonic hardware clock. Here, the parent digest establishes **data lineage rather than cryptographic authentication**, enabling forensic analysis to trace an actuator command directly back to the originating camera frame. Because the safety controller gates proposals exclusively on physical invariant checks and kinematic feasibility, the wire format omits cryptographic signatures, prioritizing physical truth over sender identity.

↩ Converting a producer's evidence epoch into the Safety MCU's monotonic clock, with a bounded synchronization error, is established in section 4.4.1.

An intent lease progresses through five discrete lifecycle states on the Safety MCU: `Pending`, `Active`, `Renewed`, `Expired`, and `Aborted`. The controller transitions a proposal from `Pending` to `Active` only after verifying all geometric and dynamic ceilings and confirming that a collision-free stopping path remains executable from the current state. Transitioning to `Renewed` requires a strictly monotonic sequence counter, a newer parent belief record with an updated sensor capture epoch, and a fully passed admission re-check. A complex approach trajectory can span multiple consecutive lease renewals as long as fresh perception evidence continues to justify the motion. Dropping an isolated camera frame does not immediately abort tracking if the current coasting window remains valid. However, absent renewal, the hardware timer continues counting toward expiration. When an anomaly, force limit breach, or evidence timeout revokes tracking authority, the controller immediately engages a pre-calculated deceleration or hold trajectory to manage the kinetic energy of the moving manipulator safely.

Figure 10.8 draws the same machine. Its one subtle transition is the self-loop on a stale renewal. A packet with an old sequence number or an old capture is discarded without resetting the timer, so a host that keeps talking without new evidence still runs out of authority. Expiry and abort end in the same place, the validated fallback that the MCU selects for the measured state.

Definition 10.3: Expiring intent lease

Expiring intent lease ($\mathcal{J}_{\text{intent}}$) is a time-bounded target authorization issued by the independent permission path that binds an admitted target pose and effort ceilings to a monotonic hardware deadline $t_{\text{intent_exp}}$:

$$t_{\text{intent_exp}} = \min(t_0 + \tau_{\text{ev}},\ t_{\text{adm}} + T_{\text{admin}},\ t_{\text{deadline,stop}}) \tag{10.9}$$

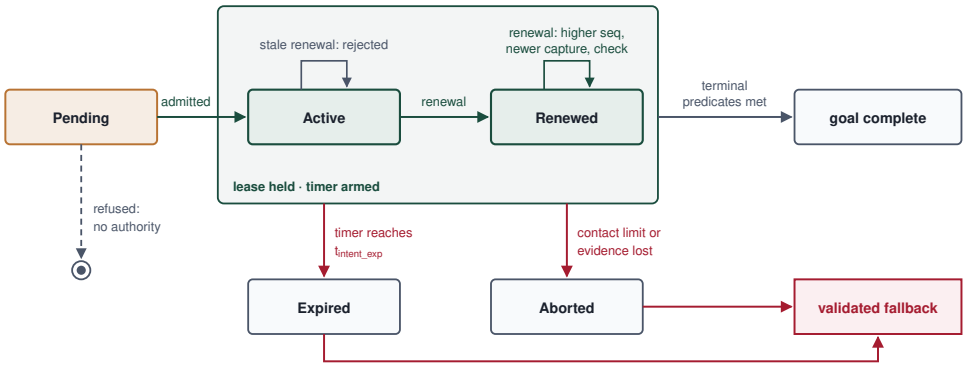

Figure 10.8: Intent lease lifecycle: A proposal waits in `Pending` until admission either refuses it, granting no authority, or arms the lease. While the lease is held, only a renewal with a higher sequence number, a newer capture, and a passing permission check moves it to `Renewed` or keeps it there; a stale renewal is rejected without resetting the timer. The held lease ends in one of three ways: the terminal predicates complete the goal, the timer reaches $t_{\text{intent_exp}}$, or a contact limit or evidence loss aborts it. Expiry and abort both start the validated fallback, which the MCU selects for the measured state.

upon whose expiration dependent target-tracking authority is automatically revoked without requiring an explicit cancellation packet. The lease establishes geometric targets and effort bounds for downstream trajectory generation, reserving path execution authority for independent trajectory-level validation.

1. **Significance**: Revokes tracking authority autonomously on a hardware deadline whenever upstream deliberation stalls, engaging a validated fallback response without depending on cooperative shutdown signals from the host processor.
2. **Distinction**: Unlike a standard network keepalive or software heartbeat ping, an intent lease physically couples the temporal validity of sensor evidence (τ_{ev}) with real-time braking feasibility, capping lease duration so that a validated stopping maneuver always fits within the verified spatial clearance.
3. **Common pitfall**: Artificially inflating lease durations to mask tail latency (p99) in vision models or neural planners. Generous timeouts create dangerous open-loop blind spots where the robot sweeps through physical space after environmental conditions have already evolved.

The three terms in the minimization enforce distinct safety bounds that prevent different classes of failure across the cyber-physical stack:

- The **physical target validity horizon** ($t_0 + \tau_{\text{ev}}$) marks the instant on the monotonic clock when unobserved environmental motion or state drift can exhaust the target-error budget remaining within task tolerance r_{tol}. This term dates strictly from physical sensor capture rather than packet arrival, where τ_{ev} is the admitted target horizon after reserving controller tracking error, bounded above by the upstream belief record's evidence-only horizon (equation 10.5). Once this horizon elapses without fresh perception updates, the robot would be tracking an ungrounded hallucination, regardless of whether host software runs without error.
- The **software administrative lease** ($t_{\text{adm}} + T_{\text{admin}}$) establishes an upper bound, measured from the admission tick t_{adm}, on how long the Application Processor may retain active tracking authority before the Safety MCU presumes host failure. Even in static environments where objects do not move ($\tau_{\text{ev}} \to \infty$), operating system scheduling jitter, garbage-collection stalls, memory bus starvation, or kernel panics can freeze the host pipeline. The administrative lease T_{admin} forces the system to decelerate smoothly rather than fly blind. This administrative horizon differs from the trajectory chunk lease T_{lease} of section 4.4: while a chunk lease governs

the execution duration of an individual trajectory polynomial, T_{admin} bounds the persistence of the macro-level target goal itself.

- The **physical stopping boundary** ($t_{\text{deadline,stop}}$) dictates the absolute latest revocation instant from which a worst-case braking profile can still arrest motion within remaining swept clearance. Given a verified swept-volume clearance D_{clear} and a dynamic stopping distance $d_{\text{stop}} = v\tau_{\text{rev}} + v^2/(2a_{\text{brake}})$, the deadline evaluates to $t_{\text{deadline,stop}} = t_{\text{adm}} + (D_{\text{clear}} - d_{\text{stop}})/v$. Here τ_{rev} is the post-revocation delay, the tick, bus, and brake-onset terms that make up the 22 ms stop onset. It is the tail of the full pre-brake delay τ_{delay} of section 1.4.3, not a replacement for it. The other terms of τ_{delay}, observation age and the lease, are exactly what the deadline itself measures, so charging them again here would count them twice. This kinematic bound assumes positive velocity ($v > 0$) and nominal braking deceleration. When the manipulator is stationary ($v = 0$), a static hold assessment replaces the distance formulation. Any dynamic change in tool speed, detected clearance, or actuator thermal limits requires immediate recomputation.

By taking the minimum across all three terms on the Safety MCU's local hardware timer, motion authority terminates at whichever safety margin exhausts first: sensor evidence staleness, host processor silence, or kinematic clearance depletion. Upon expiration, whatever the state of the host processor, a hardware timer interrupt revokes tracking authority and triggers the fallback response the MCU selected for the current payload, kinematics, and contact mode. The choice depends on physical context. A powered position hold requires continuous motor torque but stabilizes a suspended payload. A controlled path deceleration bleeds kinetic energy within the clearance boundaries. Safe torque disable may protect the windings of compliant backdrivable joints but can drop a suspended load or leave momentum uncontrolled. Any terminal mode requested in the original proposal remains purely advisory. For instance, an upstream policy requesting torque disable while suspending a heavy payload cannot override the powered hold mandated by the safety controller. If no fallback can guarantee safety from the current state, admission rejects the lease before motion begins. Neither a 1 kHz discrete tick nor a hardware interrupt can arrest physical mass instantaneously. Mechanical deceleration is governed by inertia and actuator torque limits, so the clearance it needs must be reserved before any motion is admitted.

The admission pipeline enforces the four handoff invariants of section 10.4 as a staged series of validation gates, ordered from lowest computational cost to highest so that execution time stays bounded:

1. **Evidence and sequence validation:** Ingest the proposal record from the IPC ring buffer. Instantly drop packets with obsolete sequence numbers or mismatched schema versions. Compare the `parent_belief_digest` and sensor epoch against locally retained spatial memory records. Transform the evidence timestamp into the MCU monotonic clock domain, incorporate the worst-case clock synchronization uncertainty, and reject the request if the resulting evidence age already exceeds the evidence horizon τ_{ev}.
2. **Kinematic and tolerance bounds:** Verify that all pose coordinates are finite numbers and that the orientation quaternion is strictly normalized ($\|\mathbf{q}_{\text{quat}}\| = 1.0 \pm 10^{-4}$). Confirm that error envelopes and requested task tolerances satisfy $0 \leq e_i \leq r_i$ along all coordinate axes in $\mathcal{F}_{\text{base}}$. Then verify that the full conservative error set, together with reserved controller tracking error, fits inside the ellipsoidal task region. Validate requested wrench thresholds against static actuator ratings and workplace occupancy constraints.
3. **Dynamic feasibility and fallback clearance:** Evaluate current joint velocities, payload inertia, and sensor-verified spatial clearance to confirm that a valid stopping trajectory exists. Reject any proposal where the sum of reaction delay travel and braking distance exceeds available swept clearance ($d_{\text{stop}} > D_{\text{clear}}$). The MCU does not count candidates in the pick window, because it holds no scene representation. The station's singulation check runs before a proposal is forwarded (section 10.7), and a window it has not cleared never reaches this stage. This stage admits target geometry and effort bounds rather than a path. The trajectory planner proposes the full continuous trajectory, which the permission path must separately admit.
4. **Authority latch:** Commit the verified target pose, admitted wrench ceilings, validated expiration deadline ($t_{\text{intent_exp}}$), and pre-selected fallback policy into protected MCU memory. Arm

the hardware countdown timer for the admitted interval. Advisory values from the untrusted proposal cannot write to drive registers.

5. **Runtime watchdog monitoring:** On every high-frequency control cycle and hardware interrupt, compare measured joint states, motor currents, and contact forces against the admitted lease bounds. If the hardware timer expires or force limits are breached, immediately revoke tracking authority and engage the latched fallback routine. A missed renewal does not revoke authority by itself. It leaves the timer running toward expiry.

Stage 1 checks temporal freshness, stage 2 checks spatial containment and the effort ceilings, stage 3 checks the certified fallback, and stages 4 and 5 latch what passed and keep checking it while the plant moves. Together, these five gates emit the admitted target record consumed by the trajectory planner (table 10.6), establishing the formal contract boundary between spatial perception and trajectory planning.

Table 10.6: Intent lease schema: Data types, physical semantics, and invariant checks for the admitted target emitted by the Safety MCU and consumed by trajectory planning.

Field	Representation	Physical semantics	Invariant and consumer check
`magic` & `version`	`uint32_t[2]`	Magic bytes (`0x494E5453`, 'INTS') and contract revision	Statically reject mismatched schema revisions across inter-core boundary
`parent_belief_digest`	`uint8_t[32]` (SHA-256)	Digest of the upstream belief record	Establishes custody chain; matches retained belief record in memory
`intent_digest`	`uint8_t[32]` (SHA-256)	Digest over all admitted fields in this record	Emitted to the trajectory record to bind downstream planning
`evidence_epoch_ns`	`uint64_t` (ns)	Physical measurement epoch t_0 from sensor transduction	Evaluated on MCU clock; upper age must not exceed τ_{ev}
`admission_epoch_ns`	`uint64_t` (ns)	Monotonic hardware timestamp when proposal was admitted	Baseline epoch for administrative lease duration T_{admin}
`expiration_deadline_ns`	`uint64_t` (ns)	Absolute hardware deadline $t_{\text{intent_exp}} = \min(t_0 + \tau_{\text{ev}}, t_{\text{adm}} + T_{\text{admin}}, t_{\text{deadline,stop}})$	Countdown timer revokes tracking authority upon expiry (equation 10.9)
`frame_ids`	`uint32_t[2]`	Base frame $\mathcal{F}_{\text{base}}$ and target affordance frame $\mathcal{F}_{\text{affordance}}$	Verified against active kinematic tree; prevents frame confusion
`target_pose_se3`	`double[7]`	Admitted nominal pose $[x, p_y, z, q_x, q_y, q_z, q_w]$ in $\mathcal{F}_{\text{base}}$	Target reachable within $\mathcal{W}$; full swept path checked downstream
`goal_region`	`double[3]` (m), `double` (rad)	Spatial semi-axes (r_x, r_y, r_z) and angular tolerance θ_{tol}	Defines $SE(3)$ goal set $\mathcal{G}_{\text{goal}}$ (equation 10.1); terminal boundary
`dynamic_limits`	`double[2]` (m/s, m/s^2)	Admitted TCP speed ceiling $v_{\max}$ and acceleration $a_{\max}$	Evaluated against thermal ratings; bounds transit lower bound (equation 10.6)
`max_wrench`	`double[6]` (N, N·m)	Admitted wrench ceiling $[F_x, F_y, F_z, \tau_x, \tau_y, \tau_z]$	Low-level impedance bounds; guards against crushing fragile items
`validated_predicates`	`uint32_t` (bitmask)	Bitmask of verified predicates $(P_{\text{approach}}, P_{\text{contact}}, P_{\text{clear}})$	Planner applies each predicate in its task-specified phase; checks full-path clearance
`fallback_policy_id`	`uint32_t` (enum)	Enforced terminal response (`HOLD`, `STOP`, `TORQUE_OFF`)	MCU-selected deterministic safe state matched to measured load and contact

By linking `parent_belief_digest` directly to the upstream belief record and emitting its own `intent_digest` to the downstream trajectory record, the intent lease schema (table 10.6) creates an unbroken, auditable custody chain extending from camera photons to actuator torque commands. Downstream trajectory planners can neither expand the admitted geometric goal set $\mathcal{G}_{\text{goal}}$ (equation 10.1) nor prolong tracking authority beyond `expiration_deadline_ns`.

↪ The trajectory record that embeds the lease's digest and answers to its bounds is developed in section 11.8.

Filled in for the red mug, the admitted lease links directly to the mug-handle belief record by its digest and sensor capture epoch. The target pose designates the 6-DoF mug-handle affordance

DRAFT

frame, where localization uncertainty is bounded by the belief record's 3 mm initial error envelope, well within the 15 mm task tolerance. The evidence horizon marks the temporal threshold where unobserved conveyor belt motion causes error growth to intersect this tolerance: 60 ms under open-loop conveyor drift, extending to 219 ms when tracking filters provide qualified updates under residual slip. Kinematically, the lease constrains the manipulator to a 1 m/s tool-center-point speed ceiling. Because the facility catalog registers no fragile payload profile for this mug, the wrench ceiling is the default profile's, and the controller enforces default joint impedance limits, relying on plant-level sorting rather than online compliance adaptation. A cataloged fragile payload would instead carry an item-specific ceiling, bounded below by the squeeze force that holds the payload through transit (section B.7.5) and above by its crush limit. Grasping and subsequent handover constitute the target objective, while the MCU retains exclusive authority over the fallback trajectory.

The lease expires at the earliest of the three terms of equation 10.9, and the mug record supplies a value for each. The scenario chooses an administrative lease of 100 ms, long enough that one dropped wrist-camera frame does not revoke authority, and a verified clearance of 300 mm ahead of the gripper. The stopping term needs a deceleration the arm can be relied on to deliver, which is not the controller's command limit. The arm's handbook bounds its worst-case stop at 552 ms with the full payload at maximum velocity, measured under the stopping test of EN ISO 10218-1 (Franka Emika GmbH 2021). The handbook states only "maximum velocity" and reports the stop in joint angles, so assuming that stop began at the 1.7 m/s Cartesian limit gives a derived credible deceleration of 3.1 m/s^2. At the 1 m/s ceiling, that deceleration and the 22 ms stop onset give a stopping distance of 184 mm, so the stopping deadline falls 116 ms after admission. With all three countdowns started together, as in figure 10.5, the 60 ms evidence horizon binds first when the mug is untracked. A tracker stretches the evidence horizon to 219 ms, and the 100 ms administrative lease then binds before the 116 ms stopping deadline. Subtracting the controller tracking reserve, which a deployment must still do, can only shorten the admitted target horizon and bring expiry earlier.

This explicit record structure establishes a concrete boundary for automated fault-injection suites. Systems engineers validate the safety controller by injecting unnormalized quaternions, stale capture timestamps, excessive wrench thresholds, and conflicting fallback requests into the IPC stream, verifying that the Safety MCU deterministically rejects invalid proposals across all operational states and timing margins.

↪ Negating each record's guarantees, intent lifetime among them, at its handoff to derive injected faults is developed in section 15.6.1.

Checkpoint 10.2: Expiring intent and fallback authority

Verify your understanding of how a proposal is refused or admitted, and how the lease granted from it is sized and revoked:

- ☐ **Ambiguity refusal**: Why does this station's singulation rule refuse a pick window holding two candidates, and why must that test run on a confident proposal as well as an uncertain one?
- ☐ **Wrong-object premise**: Which premise about the grasped object remains outside the permission path even when every coordinate, reachability, and force check passes, and where does the machine carry that premise instead?
- ☐ **Expiry bound**: Can you name which term of equation 10.9 only fresh evidence can extend, which one a silent host triggers, and which one a change in speed or clearance forces the MCU to recompute?
- ☐ **Clock domain**: Why must the MCU convert the belief record's evidence epoch into its own monotonic clock, with a bounded conversion error, before checking age and the requested expiry?
- ☐ **Fallback selection**: Can you explain why the MCU must select a feasible approved hold, deceleration, or torque-disable response from the measured load state rather than obey the proposal's requested terminal mode?

10.9 Fallacies and Pitfalls

Every failure pattern cataloged here stems from trusting an upstream message to mean more than it physically certifies. Real-time safety interlocks and local execution checks must refuse a proposed target, or revoke tracking authority over an active one, whenever its underlying sensory evidence expires or its spatial justification dissolves. Downstream execution monitors must evaluate evidence that the upstream proposer cannot falsify, enforcing safety invariants even while incoming inference streams remain syntactically valid and numerically confident.

Fallacy: *A renewal computed from the same stale frame is a valid renewal.*

In distributed computing and cloud infrastructure, lease renewals often function as software heartbeats. A client process demonstrates liveness and retains exclusive access by transmitting an uncorrupted keepalive packet before a timeout expires. In physical AI, however, software liveness implies nothing about physical evidence validity. If an upstream planner loops cleanly while the physical scene changes, keepalives succeed while the robot drifts blind.

Consider an intent model that repeatedly processes its last wrist-camera frame of a red mug, dispatching renewal requests with incremented sequence numbers, fresh issue timestamps, and identical target poses. Across the network, every field that a keepalive inspects appears healthy and up to date. No new photons, however, have reached the camera sensor, while the physical mug continues moving down the conveyor at 0.20 m/s. Because a sound intent lease dates its authority from the parent belief record's sensor capture epoch t_0 rather than packet arrival, the Safety MCU observes that the evidence epoch has stalled. As a result, it expires the target 60 ms after the original camera capture. A naive controller that evaluated renewals based on packet arrival time would permit a spinning software loop to retain tracking authority over an obsolete coordinate indefinitely. **Advancing software timestamps on stale sensory data creates an illusion of liveness while unobserved physical drift violates clearance.**

Architect's countermeasure: Anchor lease validity strictly to the sensor evidence epoch t_0 of the parent belief record; reject renewals that fail to supply a qualified newer capture record, including its error bound and bounded clock conversion.

Pitfall: *Allowing an unexpired temporal lease to continue commanding motion when target spatial bounds are violated.*

In distributed locking protocols, a lease grants exclusive, unconditional authority over a resource for the entire duration of its temporal grant. In physical AI, however, an intent lease is a coupled spatio-temporal contract:

$$\mathcal{J}_{\text{intent}} = \left(\mathcal{G}_{\text{goal}},\ [t_{\text{adm}}, t_{\text{intent_exp}}],\ \mathbf{w}_{\max}\right)$$

Temporal freshness ($t < t_{\text{intent_exp}}$) is a necessary condition for motion execution, but never a sufficient one.

Suppose a manipulator arm lowers toward the red mug under an admitted lease with a grasp tolerance of 15 mm. If an unexpected belt slip shifts the mug beyond that tolerance while time remains on the countdown, the lease is still temporally active, but the target has left the spatial goal region $\mathcal{G}_{\text{goal}}$ that justified the approach. Continuing until the countdown timer expires drives the arm toward an empty coordinate or provokes a collision. The runtime permission loop must continually compare the latest qualified target evidence and its age-dependent uncertainty bound against admitted limits. It revokes tracking authority the moment an update shows that the handle has left the goal set, $\|\mathbf{p}_{\text{target}}(t) - \hat{\mathbf{p}}_{\text{target}}\|_2 > r_{\text{tol}}$, where $\hat{\mathbf{p}}_{\text{target}}$ is the admitted target. Under a qualified tracker that target follows the tracked affordance frame along the belt, so the test catches slip beyond the tracker's prediction rather than the belt motion the tracker already cancels. Running the control loop faster cannot reveal an unobserved slip; sensing delay and bounded error growth must both be accounted for in the response budget. **A temporal lease confers authority only within declared spatial bounds; temporal freshness never excuses spatial divergence.**

Architect's countermeasure: Embed runtime spatial containment checks ($E(\Delta t) \le r_{\text{tol}}$) in high-rate control loops, revoking dependent authority when qualified evidence or its propagated bound no longer supports the tolerance mid-lease.

DRAFT

Fallacy: *A confident grounding needs no refusal path.*

In machine learning pipelines, a high detector score is often treated as definitive proof of identity. Engineers transitioning to physical robotics are frequently tempted to save latency with shortcut logic: `if confidence > threshold: skip_ambiguity_checks()`. That shortcut treats a model's score as an audit of the physical scene, and it fails across three distinct systems dimensions:

1. **Scores are not calibrated probabilities:** Neural networks trained with cross-entropy loss are often overconfident (Guo et al. 2017), and calibration fitted on one training distribution degrades under distribution shift (section A.2.3). An open-world detector can assign a high score to a transparent glass jar or a printed decal because it represents the closest feature match to the prompt.
2. **Per-box scores do not measure uniqueness:** Open-vocabulary detectors score each bounding box independently against the text prompt without normalizing across candidate proposals (Minderer et al. 2022; S. Liu et al. 2023). If two identical red mugs sit in the pick window, both score high. Downstream logic that naively keeps only the top-scoring box turns two valid candidates into an arbitrary choice, concealing real spatial ambiguity from all subsequent planning layers.
3. **The consequence is physical:** A score describes prompt alignment in representation space rather than confirming that the physical workspace contains exactly one manipulable entity. The two jar cases of section 10.3 mark the line. When the jar sits beside the mug, both enter the prediction set and refusal is mandatory however high either score is. When the jar stands in place of the mug, a confident singleton passes every check, which no score threshold can catch.

Workstation safety requires an independent singulation check on every intent proposal, drawing on evidence that the vision-language model cannot manipulate. An independent candidate-counting stage operating directly on calibrated spatial point clouds or voxel occupancy grids evaluates the physical workspace. If the pick window contains more than one candidate cluster, the station refuses the proposal with `ERR_GROUNDING_AMBIGUITY` before it reaches the Safety MCU, regardless of model confidence. Any earlier active record remains governed by its own evidence epoch, lease duration, and fallback strategy. Transitioning to a safe hold or operator handoff requires an admitted, physically feasible trajectory. **A detector score reflects the model's match to the prompt, not real-world uniqueness; keeping only the top box can select the wrong physical object.**

Architect's countermeasure: Enforce the selected station's singulation rule using qualified independent candidate evidence; treat `ERR_GROUNDING_AMBIGUITY` as a first-class diagnostic that can request a feasible hold or operator handoff without automatically revoking a still-valid active record.

Fallacy: *Neural networks can resolve bimodal spatial ambiguity by averaging candidate target locations.*

A continuous regressor trained with squared error converges toward the conditional mean of its targets (section 6.2.3). When demonstrations pick mug A half the time and mug B the other half, that mean settles on the midpoint $(\mathbf{y}_A + \mathbf{y}_B)/2$, which lies on the empty conveyor belt between two valid targets or directly on whatever obstacle separates them. Because the robot's collision-free operational space is not convex, the linear average of two feasible goals need not be feasible, and the gripper closes on empty air or collides with the inner edges of both mugs.

Suppose the perception system observes two identical mugs a few centimeters apart and submits their spatial mean as a grasp target. The fused estimate can appear deceptively sharp. Both individual detections may pass association and innovation gates (section 9.2.2), while an averaging estimator reports an artificially low variance that evades covariance expansion gates. However, the independent pick-window geometric check from section 10.7 still detects the presence of two distinct candidates, prompting the station's admission gate to reject the proposal regardless of what the fused estimate reports. That refusal does not revoke an active, unexpired lease; transitioning to a safe hold must itself remain physically feasible. Generative policies that explicitly represent multiple modes, such as diffusion policies, flow-matching models, or Gaussian mixture models (section A.5.1), avoid arithmetic averaging, but downstream execution contracts cannot rely on policy internals. Before crossing the intent boundary, the proposer must commit to a single goal set anchored to a single

tracked physical entity. **Averaging bimodal physical targets can replace two valid manipulation candidates with a location that satisfies neither task.**

Architect's countermeasure: Preserve explicit multi-hypothesis distributions at the reasoning boundary (via diffusion policies or Gaussian mixture models), and enforce discrete candidate selection backed by the independent pick-window ambiguity gate.

10.10 Summary

Grounded intent transforms an unverified proposal from a learned policy into a bounded, expiring physical target. In this architecture, a foundation model or vision-language-action (VLA) policy proposes a target pose in $SE(3)$, a spatial error envelope, and effort ceilings. The Safety MCU operates as an independent gatekeeper, evaluating the proposal against kinematic and physical limits before admitting it as an *intent lease*. This lease anchors directly to a parent belief record in spatial memory and remains valid only until the earliest of three deterministic deadlines: evidence decay (τ_{ev}, derived from the belief record after reserving controller tracking error), host silence (T_{admin}, guarding against communication stalls), and stopping clearance ($t_{\text{deadline,stop}}$, reserving the space needed to brake to rest). A hardware countdown timer enforces this boundary, revoking trajectory tracking authority without waiting for host confirmation. Because deceleration takes time, the worst-case response latency must be budgeted directly into the stopping clearance. Effort ceilings enforce mechanical safety alongside temporal deadlines. For example, when closing a cage-door latch, contact force continues to rise throughout the response delay of the contact-control loop. Stopping criteria must therefore account for the force already accumulating when the brake command issues, rather than assuming an instantaneous tripwire stop.

Tracking a red mug on a moving conveyor illustrates the multi-rate timing constraints that physical AI systems must reconcile. Under open-loop motion, target evidence remains valid for only 60 ms before conveyor drift carries the object outside the grasp tolerance. Meanwhile, the deliberative intent model executes at 2 Hz, updating its inferences every 500 ms. Because this deliberative period exceeds the evidence lifespan, the high-level policy cannot maintain an accurate target on its own. A qualified real-time tracker resolves this discrepancy by assimilating high-rate sensor observations to extend the evidence horizon to 219 ms, and its fresh captures, not the model's proposals, renew the lease on a goal set that follows the tracked handle. The deliberative model only reconfirms object identity at its slower cadence, so the arm need not hesitate, slow down, or abort between inferences. Guided by verified spatial corridors, continuous observation, and qualified tracking, the arm completes extended approach maneuvers across sequentially admitted segments, culminating in a grasp aligned with real-time state estimates. When a lease expires, the controller executes a stopping trajectory pre-validated for the current kinematic state, safely dissipating the mechanical momentum already present in the moving links.

In safe embodied architectures, refusal is a first-class operational outcome rather than an exceptional failure. When an instruction points to an ambiguous referent, the candidate set fails the calibrated prediction threshold and the station's singulation rule. When a proposed terminal motion cannot reach the target before evidence decays, the admission controller rejects the transit bound. Similarly, when a planned motion corridor intersects a coworker's forward occupancy set, the early screening filter denies permission. Screening the admitted prefix and its complete stopping fallback, rather than a speculative multi-second route, can reduce unnecessary refusal in narrow, shared workspaces. The screen must still cover response delay and deceleration after evidence expiry. Each refusal generates a structured diagnostic record that informs the proposer why the lease was denied, enabling informed re-planning. Symbolic task plans generated by language models integrate through this exact mechanism, mapping symbolic operators into physical preconditions and testable motion predicates. Nevertheless, physical admission gates cannot see past the wrong-object premise, because a model that confidently grounds an action to the incorrect object can satisfy every coordinate, reachability, and contact-force check. Validating that semantic premise requires task-level perceptual evidence and supervisory human oversight, while table 10.7 collects the equations that carry the physical decisions, what each bounds or decides, and where each is derived.

DRAFT

Table 10.7: Key equations of grounded intent: Each load-bearing equation of the chapter, the limit it bounds or the decision it settles, and the equation where it is derived.

Equation	What it bounds or decides	Derived in
$\lVert \mathbf{p} - \mathbf{p}_{\text{target}} \rVert_{\mathbf{E}} \le 1,\ \angle(\mathbf{R}, \mathbf{R}_{\text{target}}) \le \theta_{\text{tol}}$	Whether terminal pose tolerance is satisfied; task completion also requires its terminal predicates	equation 10.1
$\mathcal{C} = \{\, i : c_i \ge 1 - \hat{q}_{1-\epsilon} \,\}$	The calibrated candidate set: a singleton proceeds to remaining checks; a larger set triggers refusal	equation 10.3
$\tau_{\text{ev,untracked}} = (r_{\text{tol}} - e_0)/v_{\text{drift}};$ $\tau_{\text{ev,tracked}} = \sqrt{2(r_{\text{tol}} - e_0)/a_{\text{slip}}}$	How long target evidence stays inside the task tolerance, untracked and under a tracker	equation 10.5
$d/v_{\max} \le t_{\text{intent_exp}} - t_{\text{now,mono}}$	Whether a terminal move can finish on its current evidence; a necessary condition only	equation 10.6
$\lVert \mathbf{p} - \hat{\mathbf{p}}_k \rVert \le r_k + v_h \Delta t + k_\sigma \sigma_{\text{track}}(\Delta t)$	Where a moving person could be, and so which corridors the early screen refuses	equation 10.7
$t_{\text{intent_exp}} =$ $\min(t_0 + \tau_{\text{ev}},\ t_{\text{adm}} + T_{\text{admin}},\ t_{\text{deadline,stop}})$	When target-tracking authority lapses: evidence decay, host silence, or stopping clearance, whichever comes first	equation 10.9

Key Takeaways: Grounded intent at the proposal boundary

- **Leases grant bounded targets, not trajectories**: The host proposes a target pose, evidence epoch, error envelope, task tolerances, and effort ceilings. The lease the Safety MCU latches binds them to a goal set and motion predicates that the trajectory planner may not expand, and it leaves the path to the planner.
- **Expiry runs on the permission side's clock**: A hardware countdown ends authority at the earliest of the evidence horizon, the administrative lease, and the stopping deadline, so a hung host loses its target without sending anything. A renewal counts only when it carries a newer capture; a repeated frame with a fresh sequence number renews nothing.
- **Target evidence decays with unobserved drift**: At conveyor speed the mug's evidence lasts 60 ms while the current intent inference takes 336 ms, so this model cannot renew the target without another source of fresh evidence. Only fresh observations or a qualified tracker, which stretches the horizon to 219 ms, extend validity.
- **Evidence deadlines differ from braking deadlines**: Expiry is not rest. After the lease lapses the arm still needs 22 ms before braking begins and then its stopping distance, so the lease charges the stopping deadline as its own term rather than assuming the evidence horizon covers it.
- **Geometric feasibility does not guarantee semantic correctness**: A learned model can ground an action to the wrong physical object with high confidence and still satisfy every coordinate, reachability, and contact-force check. Because physical admission gates cannot evaluate semantic validity, task-level verification requires independent task evidence and operator oversight.
- **Refusal is a primary operational outcome**: Ambiguous object identity, expired evidence, dynamic reachability violations, and stopping distance constraints all trigger deterministic proposal rejections. Structured diagnostics let the proposer gather more evidence, choose a staged approach, or request operator assistance.

When a learned target misbehaves at the machine, the first question is which of its bounds was missing, not how accurate the model was. A target without an evidence epoch cannot be expired, one without an error envelope cannot be compared with a tolerance, and one without an effort ceiling cannot be stopped short of damage, so each omission turns a model error into motion. The

remedy is rarely a faster or more confident proposer. On the conveyor, no tuning lets a 336 ms inference hold a 60 ms target. The fixes are a tracker that renews evidence, a slower belt, or a refusal.

The intent lease is the third law, proposal is not permission (principle 3), written as a record for goals. The lease grants a target, never a path. It names where the gripper may end, how hard it may press, and until when, and it leaves the route to a planner whose motion must be admitted again on its own evidence. Authority a learned model obtains for a goal therefore never extends to the motion that reaches it, and it lapses on the permission side's clock whether or not the model is still running.

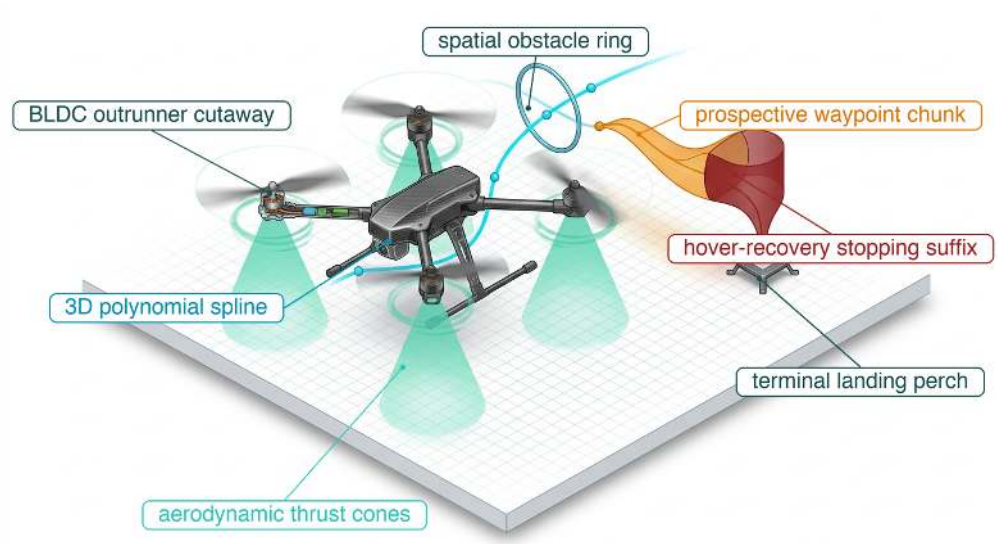
10.11 Historical Perspective and Further Reading

How a word comes to name a thing was a question long before robots acted on the answer. Gibson (1979) gave the thing its modern name, the affordance, what an object offers an agent able to act on it, and Harnad (1990) posed the grounding problem as a question about symbols that point only to other symbols. Robotics made the affordance quantitative long before learned models proposed one. Nguyen (1988) reduced a stable two-finger grasp to a geometric test on friction cones, and Ferrari and Canny (1992) turned force closure into a quality measure in wrench space. Learned grasp generators now propose such grasps directly from point clouds (Sundermeyer et al. 2021; Fang et al. 2023), but their scores estimate success on a training distribution and are not the analytic measures they replaced, which is why this chapter rechecks every survivor.

Symbolic planning began on a machine that moved. Fikes and Nilsson (1971) wrote the STRIPS operator language to plan for Shakey, a mobile robot whose actions did not always have the effects their operators listed (Nilsson 1984), and PDDL later standardized that language so that planners could be compared on common problems (McDermott et al. 1998). The geometric preconditions that STRIPS left to the robot returned as task and motion planning, which interleaves symbolic search with samplers that certify continuous facts (Kaelbling and Lozano-Pérez 2011; Garrett et al. 2021). Language models now write the symbolic half, by ranking skills (Ahn et al. 2022) or by translating a request into a planning problem (B. Liu et al. 2023), and neither step checks the geometry.

The lease comes from distributed systems. Gray and Cheriton (1989) bounded a client's authority over a cached file by time, so that a crashed holder could not block the others, and chose the term by weighing renewal traffic against the delay a conflicting write must wait. The calibrated refusal comes from statistics. Vovk et al. (2005) built conformal prediction on exchangeability alone, and Ren et al. (2023) carried it to a robot deciding when to ask for help. The motion lease adds a physical term: it is sized by how fast the evidence behind its target decays, not by clock skew or message cost, and its expiry is enforced on a processor that the proposer cannot stall. For further reading, six works trace the ideas this chapter composes:

- Harnad (1990) states the symbol grounding problem and argues that symbols acquire meaning only through their connection to sensorimotor categories, the premise behind carrying evidence with every proposal.
- Garrett et al. (2021) surveys task and motion planning, from operator languages and samplers to the planners that couple them, and shows where symbolic plans need geometric certificates.
- Gray and Cheriton (1989) introduces leases for file-cache consistency and analyzes how the lease term trades renewal traffic against availability, the analysis this chapter reworks with evidence drift as the term.
- Angelopoulos and Bates (2023) is a practical introduction to conformal prediction, with the coverage argument and its exchangeability assumption stated plainly, as equation 10.3 uses them.
- Ren et al. (2023) applies conformal prediction sets to a language-model planner, turning calibrated ambiguity into a request for help, the producer-side refusal of section 10.3.1.
- Trautman and Krause (2010) names the freezing robot problem and shows why independent forecasts that grow with time block every path in a crowd, the trade-off behind the forward occupancy screen of section 10.6.1.



What's Next: From intent leases to trajectory planning

When the next inference pass is late, an intent lease fixes the admissible target region, the effort ceilings, and the evidence deadline, but it specifies no timed velocity or acceleration profile. It cannot tell an arm already moving toward the mug how to continue while the proposer stalls. Chapter 11 begins from that moment. It turns the lease into a timed trajectory that joins the motion already under way without a step in acceleration, sizes its replacement deadline against the inference tail, and attaches a precomputed stop that runs even if no later pass returns. The trajectory record carries all three, bound to the lease's digest, and the permission path admits the complete bundle before execution, because a valid goal does not prove that a moving arm can still come to rest.

Purpose

Why must every motion a robot follows already contain the stop it will probably never use?

A moving robot cannot pause its momentum while a learned policy computes the next piece of its motion. Each new plan must take over from motion already under way. A plan that matches only the arm's position leaves a jump in velocity or acceleration, which the motors can meet only with a sudden step in torque. A real drive refuses such a step or converts it into vibration, wear, and a spilled load. A path that clears every obstacle can still ask for more joint speed, torque, or current than the body can supply, and the fastest timing along that path demands exactly the abrupt changes a drive cannot make. The next plan can also arrive late, because inference time has a long tail, and a machine that keeps moving while it waits spends the distance it needs to stop. Without trajectory planning, a correct decision about where to go becomes a command the body cannot follow, or motion that cannot be halted in the room that remains. Planning attaches timing, a smooth join to the present state, and a stop that runs without the proposer. Those three properties decide whether a command that crosses the causal boundary can still be brought to rest before its energy reaches something that cannot be undone.

Learning Objectives

- Distinguish prediction horizon, executed prefix, renewal cadence, and evidence age when budgeting trajectory replacement
- Map tool-space speed limits to joint rates through the manipulator Jacobian, explain why the mapping fails near a singularity, and bound an inverse-kinematics step there with damped least squares
- Evaluate a timed trajectory and its time parameterization against actuator torque, current-slew, and voltage limits, including reflected rotor inertia ($N_{\text{gear}}^2 J_{\text{rotor}}$)
- Synthesize closed-form quintic spline bridges, anchored at the projected seam state rather than a stale sampled pose, that eliminate acceleration steps and bound commanded jerk across replanning seams
- Size a jerk-limited C^2 stopping suffix from deceleration and jerk bounds and verify stopping clearance ($d_{\text{stop}} \leq D_{\text{clear}}$)
- Compare sampling-based search, trajectory optimization, and learned action chunking by the work each performs and the checks its output still requires
- Construct trajectory records whose two-tier deadlines (high-rate chunk lease and hardware commitment cutoff) keep motion out of inevitable collision states (ICS) and support independent per-tick permission decisions

11.1 Continuous Trajectory Generation

The arm of the warehouse mobile manipulator is reaching for a mug that drifts along a moving conveyor when an inference pass is delayed by operating-system scheduling contention. The intent lease still names the mug as a valid target, but a lease grants a target, never a path. A target coordinate paired with an expiration timestamp specifies neither velocity nor acceleration, so it cannot tell the arm what to do while the next pass is late. The arm cannot freeze abruptly, and it cannot extrapolate blind setpoints into space no check has covered. Planning must supply a concrete, time-parameterized path, an admissible transition from the motion already under way, and a precomputed stop that runs even if the next inference pass never returns.

↩ The intent lease, whose expiry bounds the validity window of every trajectory, is established in section 10.8.

Classical robotics split this problem into two stages. A search first finds a collision-free geometric path through a configuration space, and a time parameterization then assigns timing that respects kinematic and torque limits. Learned sensorimotor policies change both stages. Instead of searching a static, pre-mapped scene, a policy emits short chunks of future setpoints conditioned directly on live camera observations, and because it replans while the machine moves, each new trajectory must splice into motion already under way rather than start from rest. Neural inference also has variable, heavy-tailed latency, and the hardware keeps moving along its previous trajectory while it waits. Geometric clearance therefore does not settle a plan. A plan must also establish how long the proposed motion remains executable, how it joins the retiring trajectory, and how the machine comes to a controlled stop if later inference passes stall.

On this machine, the arm's low-level joint tracking loop evaluates feedback and setpoints at 1 kHz (datasheet; see the Reader Guide); however, this high-rate servo clock does not specify the physical stopping response. Above this loop sits the Brain, where learned policies such as Action Chunking with Transformers (ACT) (Zhao et al. 2023) or Diffusion Policy (Chi et al. 2025) process sensory observations on the host application processor to synthesize future reference paths.[1] The machine's chunk policy operates with an illustrative budget of 40 ms per pass at p99, vision included. Even so, memory contention, direct memory access (DMA) traffic, or thread preemption can stretch tail latency beyond 150 ms. The real-time controller therefore cannot block synchronously on policy execution; it requires both buffered nominal motion and an immediately dispatchable, pre-validated stop.

Whether candidate motions originate from sampling-based search, numerical trajectory optimization, or learned action chunking (section 11.6), the generator serves strictly as an unprivileged proposer. Time parameterization exposes instantaneous velocity, acceleration, and jerk to dynamic validation, and the independent safety permission path must verify that motor windings can gener-

[1] **Action chunking representations**: ACT and Diffusion Policy, the 2023-era chunk policies, carry no boundary-derivative constraints. Real-time chunking (Black, Galliker, et al. 2025) conditions each new chunk on the actions already committed, which makes a consistent join more likely without guaranteeing one, so the planner still proposes a transition bridge across each replanning seam and the permission path checks it before admission.

↩ The kinetic energy a trajectory commits, and the stopping distance that energy demands, are established in section 2.3.1.

ate the required torques under dynamic load and that sufficient clearance exists along the arm's swept stopping volume before any motion is admitted.

A multi-step action chunk delivers a finite horizon of future setpoints that the low-level tracking controller consumes sequentially while the proposer computes the next chunk. Splicing successive chunks introduces an **execution seam**: the temporal and kinematic boundary where the retiring setpoints hand off control to the incoming plan. Matching position alone across this seam leaves a discontinuous velocity step, and matching velocity while neglecting acceleration leaves an instantaneous acceleration step. Because physical links and payloads carry inertia, discontinuous accelerations demand instantaneous steps in motor torque, exciting mechanical vibrations and risking overcurrent faults. The trajectory generator must therefore enforce continuity through position, velocity, and acceleration (the C^2 continuity condition) while verifying that dynamic torques and swept clearance throughout the transition segment remain within safe physical envelopes.[2]

↪ The runtime gatekeeper that checks every admitted setpoint against live state is developed in section 12.1.

Decoupling the execution rate from the inference rate allows the low-level tracking controller to service motor loops on a rigid real-time clock while neural inference runs asynchronously. Setpoint buffering absorbs latency jitter, but buffered motion cannot remain valid indefinitely. Sensor observations age, dynamic obstacles shift, and localization drift accumulates over time. Consequently, the planner's replacement deadline must account for the worst-case inference tail, guaranteeing sufficient lead time to commit to a feasible, controlled stop before either the buffered trajectory drains or the supporting environmental evidence expires.

Every admitted proposal must therefore arrive as a self-contained bundle: the active trajectory segment continuous through acceleration (C^2), its explicit validity deadlines, and a pre-verified stopping suffix whose required deceleration distance fits within verified obstacle clearance ($d_{\text{stop}} \leq D_{\text{clear}}$). An isolated safety microcontroller (MCU) inspects and validates this bundle across the proposal boundary before arming actuator outputs, caching the emergency stopping continuation in local real-time memory so it can be autonomously dispatched if communications falter.

The machine meets these obligations in a fixed order. What the planner hands to the tracking controller and the permission path comes first, together with the map from tool coordinates to the joint limits the drives enforce. Replacement timing is then sized against the inference tail, a timed candidate and its seams are checked against what the actuators can follow, and the jerk-limited stop that every admitted plan must carry is sized. The generators that propose candidates, from sampling-based search to learned action chunks, can be compared only after those obligations are fixed.

11.2 The Planning Handoff and the Trajectory Record

If the planner hands over raw joint setpoints for the reach toward the mug without binding them to the obstacle geometry, the active intent lease, and a pre-checked stop, the arm can chase an expired target or coast past its clearance the moment the next inference cycle stalls. To prevent that failure, the planner consumes the belief record, which supplies obstacle geometry and clearance. It also consumes the intent lease, which supplies the grounded goal, task tolerances, effort ceilings, and the expiry time that bounds the lease ($t_{\text{intent_exp}}$). Throughout, the planner must respect the actuator and transmission limits of the physical body. The handoff connects those inputs to the checks that permit execution, and two things must be fixed before any replacement timing can be budgeted. The first is the map between the tool coordinates in which clearance is measured and the joint coordinates whose limits the drives enforce. The second is the record that carries a candidate across the proposal boundary, with the deadlines and the stop that bound its authority.

↩ The belief record and the state invariants it carries are established in section 9.3.

11.2.1 Mapping tool motion to joint limits

A path that keeps the tool inside its speed limit and clear of obstacles in workspace can still command a joint near a straightened elbow to spin faster than its drive allows, tripping a velocity fault mid-reach. Catching that mismatch requires translating workspace motion into the manipulator's joint coordinates. A configuration $(q_1, \ldots, q_n)$ collects the joint positions into a single point in the **configuration space**[3] $\mathcal{C}$, and removing configurations occupied by obstacles leaves the collision-free subset $\mathcal{C}_{\text{free}} = \mathcal{C} \setminus \mathcal{C}_{\text{obs}}$ (Lozano-Pérez 1983). Because a geometric path through $\mathcal{C}_{\text{free}}$ still lacks timing, an **executable trajectory** assigns physical timestamps to the path, generating continuous state references $\mathbf{x}(t) = [\mathbf{q}(t)^\top, \dot{\mathbf{q}}(t)^\top]^\top$ and acceleration profiles $\ddot{\mathbf{q}}(t)$ alongside feedforward torque profiles

2 | C^2 **continuity at the motor**: In permanent-magnet synchronous motors, electromagnetic torque couples directly to quadrature stator current ($\tau_{\text{motor}} = K_t i_q$). Under this model an acceleration step requires a finite step in torque and current, while a velocity step implies an ideal acceleration impulse, which no drive can supply.

3 | **Configuration space**: Lozano-Pérez (1983) shrank the moving body to a point by growing each obstacle by the body's shape, and in the same year Schwartz and Sharir (1983) treated the "piano movers' problem" as a search of exactly this space. The reduction turns a collision query into a membership test on $\mathcal{C}_{\text{obs}}$, but the space gains a dimension with every joint, which is why collision queries dominate the run time of the sampling planners in section 11.6.

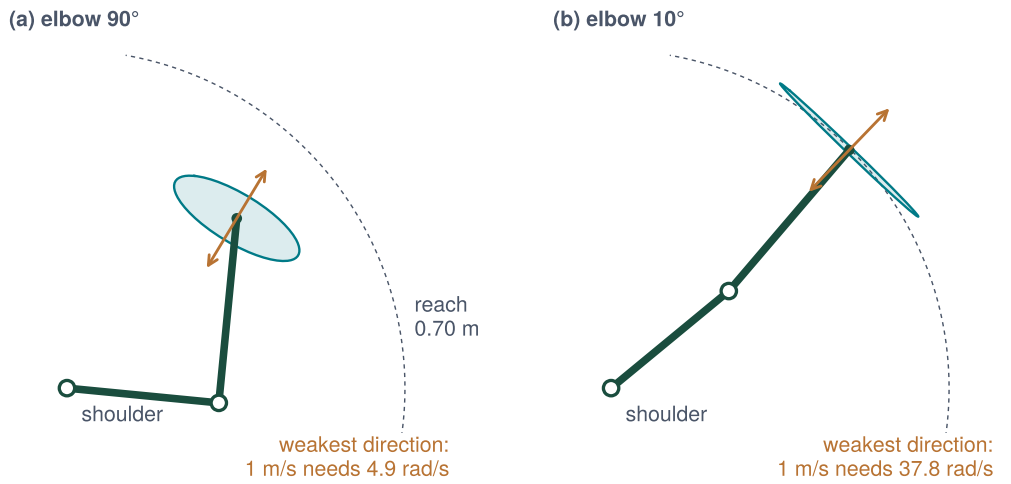

Figure 11.1: The same tool speed, two elbows: The planar two-link arm drawn to scale with its 0.316 m and 0.384 m links. Each ellipse is the set of tool velocities that a unit joint-rate vector can produce, drawn at one scale in both panels; its short axis is the weakest direction (arrow). At a right-angle elbow the ellipse is round enough that 1 m/s in that direction needs 4.9 rad/s of joint rate. Near the straight elbow the ellipse collapses toward a line across the arm, and the same tool speed along the arm needs 37.8 rad/s.

$\tau_{\text{ff}}(t)$. Whereas the kinematic references state the intended position, velocity, and acceleration, the feedforward terms supply the torque predicted by the rigid-body model. The complete candidate crosses the proposal boundary for independent checking, and only admitted actuator commands cross the causal boundary to the drives.

The drives track joint angles, but clearance is measured in the task space where the tool, the mug, and the conveyor guard sit. In a planar two-link abstraction of the arm's shoulder, elbow, and wrist with upper-arm length l_1 and forearm length l_2, **forward kinematics** gives the tool position directly as a function of the joint angles:

$$x = l_1 \cos q_1 + l_2 \cos(q_1 + q_2), \qquad y = l_1 \sin q_1 + l_2 \sin(q_1 + q_2) \tag{11.1}$$

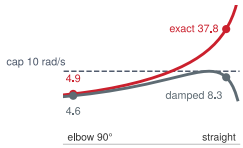
Differentiating equation 11.1 gives tool velocity $\mathbf{v}_e = \mathbf{J}(\mathbf{q})\,\dot{\mathbf{q}}$, where the manipulator Jacobian[4] $\mathbf{J} = \partial\mathbf{p}/\partial\mathbf{q}$ changes with configuration. It is the same map that showed, in section 5.9.2, why a Cartesian action label can force a different arm through a singularity; here it prices the arm's own reach. For the two-link arm its determinant is $l_1 l_2 \sin q_2$, which vanishes when the elbow straightens, the singular pose at which no joint motion moves the tool along the arm.

Consider the link lengths from the arm's published kinematic chain: 0.316 m and 0.384 m, which yield a 0.70 m planar reach (Franka Robotics GmbH 2023). The arm's weakest direction is the tool direction that a unit of joint rate moves least, set by the smallest singular value $\sigma_{\min}$ of $\mathbf{J}$, so that $\|\dot{\mathbf{q}}\| = v_{\text{TCP}}/\sigma_{\min}$. Moving the tool in that direction at the 1 m/s tool center point (TCP) limit requires a joint-rate vector of magnitude 4.9 rad/s at a 90° elbow. With two joints, the larger component of a vector is at least its norm divided by $\sqrt{2}$, so at least one joint must then turn at 3.5 rad/s, above the published 2.175 rad/s limit of the shoulder and elbow joints. Straightening the arm makes the demand far worse. The image of a unit joint-rate circle under $\mathbf{J}$, the manipulability ellipse of tool velocities, is broad at the 90° elbow and collapses into a narrow sliver across the links at 10° (figure 11.1). Sustaining 1 m/s along the arm, the ellipse's minor axis, then needs a joint-rate magnitude of 37.8 rad/s. A tool-speed limit bounds no joint speed near a singularity. Every tool-space quantity this chapter checks (the TCP limit, the stopping distance, and the swept clearance) must therefore be mapped back through $\mathbf{J}$ to the joint limits the drives enforce. This holds even on a seven-joint arm, whose extra degrees of freedom help the planner steer around singular poses that this planar abstraction omits.

[4] **Manipulator Jacobian**: It is the same object automatic differentiation builds, the matrix of first derivatives of an output with respect to its inputs, here tool position with respect to joint angles. Reverse-mode autograd never forms the matrix; it computes products $\mathbf{J}^\top\mathbf{v}$, and the manipulator equation uses that same transpose product to map a tool wrench into joint torques (equation 11.8). A planner is the unusual consumer that must *invert* $\mathbf{J}$, and it is the inverse, not the Jacobian, that fails at a singularity.

↪ Forward kinematics, the manipulator Jacobian, singularities, and the damped least-squares inverse are developed for n joints in section B.6.1.

The same map must also run in reverse. A proposal stated in tool space, whether a grasp pose from the intent lease or a Cartesian velocity from a policy or a teleoperation device, leaves the planner to find the joint motion that produces it, the **inverse kinematics** problem. The two-link arm has a closed-form inverse. A seven-joint arm replanning chunk by chunk is solved by differential steps instead: linearize at the current configuration and solve $\mathbf{J}\Delta\mathbf{q} = \Delta\mathbf{p}$ for the joint step that moves the tool by $\Delta\mathbf{p}$, then repeat from the new configuration. Where $\mathbf{J}$ is invertible the exact step is $\Delta\mathbf{q} = \mathbf{J}^{-1}\Delta\mathbf{p}$. Written along the singular directions of $\mathbf{J}$, this step divides the part of $\Delta\mathbf{p}$ along each tool direction by that direction's singular value σ. The weakest direction therefore receives the largest joint step, $1/\sigma_{\min}$ per unit of tool motion, which is exactly the joint-rate demand that figure 11.1 charts diverging along the minor axis as the elbow straightens. An exact inverse passes the singularity's arithmetic straight to the drives.



Damped least squares gives up exactness to bound the step (Wampler 1986; Nakamura and Hanafusa 1986). Instead of demanding $\mathbf{J}\Delta\mathbf{q} = \Delta\mathbf{p}$, it chooses the joint step that best trades tool error against joint motion, with a damping length λ that sets the exchange rate:

$$\Delta\mathbf{q}_\lambda = \arg\min_{\Delta\mathbf{q}} \left(\|\mathbf{J}\Delta\mathbf{q} - \Delta\mathbf{p}\|^2 + \lambda^2\|\Delta\mathbf{q}\|^2\right) = \mathbf{J}^\top\left(\mathbf{J}\mathbf{J}^\top + \lambda^2\mathbf{I}\right)^{-1}\Delta\mathbf{p} \tag{11.2}$$

Setting the gradient of the objective to zero gives $(\mathbf{J}^\top\mathbf{J} + \lambda^2\mathbf{I})\,\Delta\mathbf{q} = \mathbf{J}^\top\Delta\mathbf{p}$, and moving $\mathbf{J}^\top$ through the inverse yields the form in equation 11.2, which needs only a 2×2 solve for the planar arm. A reader who has trained a model will recognize ridge regression, with λ^2 as the weight-decay coefficient. Along each singular direction the gain changes from $1/\sigma$ to $\sigma/(\sigma^2 + \lambda^2)$. Far from the singularity, where $\sigma \gg \lambda$, the two agree. As σ falls toward zero the damped gain falls with it instead of diverging, and it never exceeds $1/(2\lambda)$, reached where $\sigma = \lambda$. The damping thus places a configuration-independent ceiling on the joint step, which no choice of pose can breach.

With an illustrative λ of 50 mm, the weakest-direction request at the 1 m/s TCP limit needs 4.6 rad/s of joint rate at the 90° elbow, against 4.9 rad/s undamped, and the tool still realizes 94.3 percent of the requested motion. At the 10° elbow the damped command is 8.3 rad/s instead of 37.8 rad/s, and no pose can demand more than 10 rad/s. The price is paid where the damping acts: the tool realizes only 21.9 percent of the requested motion along the arm, so the step lags its target in exactly the direction the arm cannot move well. That residual is a tracking error the planner must carry into the trajectory's timing and clearance checks rather than discard. A larger λ lowers the ceiling and enlarges the error everywhere, which is why practical solvers raise the damping only as $\sigma_{\min}$ approaches it.

Damping bounds the inverse-kinematics step; it does not make the step feasible. Even the damped 8.3 rad/s exceeds the 2.175 rad/s joint limit, so the planner must still slow the tool through time parameterization (section 11.4.5), and the permission path still checks every joint rate against the limits the drives enforce. Damped least squares is a better proposal, not a permission.

As the elbow straightens, the exact inverse climbs from 4.9 rad/s to 37.8 rad/s; damping caps it at 10 rad/s.

11.2.2 The trajectory record and its deadlines

If a candidate trajectory crosses from the planner to the controller without an immutable expiration time and a pre-checked stop, a hung host process leaves the drives tracking the last command into an obstacle. What the planner hands over is therefore a **trajectory record**, the ninth record in the record chain and the immutable proposal that the tracking controller follows and the permission path admits. The trajectory record consumes the geometric obstacle bounds from the belief record and the task target and lease window from the intent lease. It binds an untrusted sequence proposal to checked physical limits across the formal boundary between the unprivileged, asynchronous Brain and the deterministic, hard real-time Nervous System. Its header names its coordinate frame $\mathcal{F}$, evidence time t_0, initial reference state, and active intent lease expiry $t_{\text{intent_exp}}$. The header also carries four deadlines defined in the **MCU monotonic clock domain** (into which host and sensor timestamps are converted with a bounded synchronization error). Nominal tracking begins at t_{start}, the nominal setpoints end at $t_{\text{plan_exp}}$, the matched stop must physically begin at t_{commit}, and the admitted stop finishes at $t_{\text{stop_end}}$. Beside these header fields, an assumption sidecar declares the payload, friction, obstacle-map epoch, and other conditions under which the candidate was checked (section 11.8). Within the planner itself, each replacement is scheduled against an earlier internal milestone, the blend deadline t_{blend}, by which a preferred successor should clear validation. The

latest replacement-admission decision on the MCU precedes physical stop onset at t_{commit} by the reserved decision, transport, and actuator delay.

The permission path permits nominal **TRACK** only while the intent lease and trajectory record remain valid, so an expired intent lease terminates nominal tracking immediately, regardless of what the trajectory's own timestamps allow. To manage asynchronous inference latency tails and hardware faults without compromising safety, the architecture enforces a strict **two-tier deadline hierarchy**:

1. **Fast Nervous System periodic chunk lease (T_{lease}, 60 ms):** This high-rate heartbeat governs the real-time execution contract between Brain and Nervous System. The chunk policy proposes base velocity and arm joint targets together, so one chunk lease governs both bodies, and only an admitted replacement chunk renews it, with a desired admission interval of 50 ms on this machine. Qualification must bound successful-admission interarrival, not merely inference or request cadence. If an upstream inference pass hangs or communication drops, the lease lapses 10 ms after its expected renewal, immediately requesting a controlled stop whose onset follows the reserved response delay.
2. **Trajectory commitment deadline:** The record names the latest physical onset of its matched stop. Replacement admission must close early enough to dispatch that stop and absorb actuator response delay. This geometric limit does not replace the running machine's shorter chunk lease; the later worked timeline examines an explicitly different, longer-lease configuration.

↩ The chunk lease and its sizing from the stopping budget are established in section 4.4.

Two stopping responses back these deadlines. A matched stop suffix, latched at admission, begins at t_{commit} if no successor has been admitted; a state-matched fallback, built from the measured state, answers any earlier invalidation, such as a lapsed lease (section 11.5.1). Either stop remains authorized after nominal tracking expires, provided its own state, clearance, sensing, and drive-energy premises still hold.

Definition 11.1: Stopping suffix

Stopping suffix is the bounded continuation, checked and latched with a trajectory at admission, that brings the machine from a declared entry state to rest along the already-checked path, within the clearance that remains and without further input from the proposer.

1. **Significance**: It is the term that makes $d_{\text{stop}} \leq D_{\text{clear}}$ checkable before motion begins. From the arm's 1 m/s TCP limit, the worked suffix sized in section 11.5.2 travels 137.5 mm of an illustrative 300 mm of clearance, the free distance along the checked path between the tool and the nearest obstacle. The stop alone therefore claims nearly half the room before any response delay is charged.
2. **Distinction**: The matched suffix is anchored at the nominal state expected at t_{commit}; the state-matched fallback is built from the measured state when authority ends earlier. Both are controlled stops along the checked path, unlike a drive inhibit or brake, whose motion is not planned.
3. **Common pitfall**: Treating the last nominal setpoint, or a hold at the final position, as the stop. A hold is not a deceleration profile, and a suffix sized with constant deceleration understates the distance any drive that ramps its deceleration will travel.

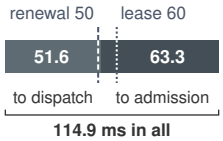
The two execution consumers read distinct subsets of the trajectory record. The downstream tracking controller interpolates admitted setpoints, timestamps, and feedforward torque terms to drive the motor inverters along a continuous profile fetched from the real-time execution jitter buffer. Simultaneously, the independent permission path inspects the record's lineage, timing bounds, dynamic assumptions, validity envelopes, and verified stopping continuation ($d_{\text{stop}} \leq D_{\text{clear}}$). The permission path monitors current limits and physical tracking error on every millisecond tick without inheriting the planner's feasibility claim as proof. An unmodeled obstacle, payload slip, or contact wrench immediately revokes TRACK authority and activates the state-matched fallback. Because every contract field maps to an explicit hardware or software gate, the Nervous System safely executes fast physical motion without presuming that subsequent neural inference cycles will

complete on schedule. A record of this kind is short-lived by design, so the next constraint is how often a successor must arrive and how long producing one takes.

11.3 Replacement Timing and the Planning Horizon

On the mug reach, the arm needs an admitted replacement every 50 ms and loses tracking authority 60 ms after the last one. Whether a replacement can arrive that often depends on how long it takes to produce one, and producing one is more than a single inference pass. The observation behind the candidate must be captured, the proposer must run, and the candidate must cross to the safety MCU and pass validation before it is admitted. Every generator, from numerical trajectory optimization to an autoregressive policy, pays for that pipeline. The timing questions therefore come before the choice of generator: how long a replacement takes, how deep into its latency tail the design must look, how much motion one record must cover, and from which state the next candidate must be planned.

11.3.1 Action chunk horizons and reaction lag



If a replacement chunk takes longer from camera capture to MCU admission than the active chunk's lease allows, the arm drops into its stopping fallback before the new plan arrives. If the executed prefix is stretched to hide that latency, the arm reacts too slowly when the mug or an obstacle shifts. Sizing the prediction horizon H therefore starts from an end-to-end latency budget for replacement, one that spans host accelerator memory, the inter-processor link, and real-time microcontroller firmware.

The scheduling metric that governs every handoff is **replacement latency** L: the total elapsed wall-clock time from the initial physical capture of the sensor observation on which a candidate trajectory proposal rests to the formal admission of that proposal into the real-time execution queue. Formulated in the event taxonomy of table 4.1, L spans the interval from capture to admission. It is the direct sum of two intervals. The first is the capture-to-dispatch perception age t_{age} established in section 8.4.1. The second is the dispatch-to-admission interval Δ_{da}, a design allocation whose stages are listed next and which section 13.6.2 later tests against the hardware:

$$L = \underbrace{t_{\text{age}}}_{\text{capture}\to\text{dispatch}} + \underbrace{\Delta_{\text{da}}}_{\text{dispatch}\to\text{admission}}, \qquad \Delta_{\text{da}} = t_{\text{infer}} + t_{\text{link}} + t_{\text{deser}} + t_{\text{validate}} + t_{\text{activate}} + t_{\text{wait}} \tag{11.3}$$

On the physical machine, sensor data is already 51.6 ms old when planning dispatches. The subsequent dispatch-to-admission allocation Δ_{da} of 63.3 ms accounts for the chunk policy's full 40 ms neural network forward pass and 18 ms of whole-plan kinematic validation. The balance is a few milliseconds of inter-board link transport, message deserialization, activation staging, and synchronization wait until the next discrete permission tick. Section 13.6.2 itemizes this balance when it tests the allocation on the selected hardware. These stages combine to yield an overall replacement latency L of 114.9 ms. L is a latency, not a period. It exceeds both the 50 ms renewal period and the 60 ms lease, so the renewal cadence can be sustained only by overlapping requests, several in flight at once, a throughput condition the timeline below returns to. Charging the entire neural inference pass after dispatch intentionally bills the visual encoding stage twice, since that stage is already inside t_{age}, which makes the budget deliberately conservative. When pipelined stages execute concurrently or contend for shared memory buses, the sum of independent stage percentiles does not equal the percentile of the sum (section 2.2.2). Sizing the planning horizon therefore demands evaluating the empirical end-to-end distribution of L, measured directly between physical sensor capture interrupts and microcontroller admission timestamps.

Trajectory validation represents the motion planner's dedicated compute contribution within this latency budget. The 18 ms validation allowance covers the combined elapsed contribution of host geometry validation and bounded local MCU admission, including scheduling delays, rather than overhead silently absorbed into the millisecond actuator tick. Its split between processors remains to be qualified. Formal admission requires bounded staging memory, candidate spline and stopping coefficients, and qualified local clearance evidence; the host processor's full, multi-gigabyte scene representation need not reside on the embedded MCU. The real-time scheduler must preserve deterministic per-tick enforcement while background admission executes, refreshing the seam

A 114.9 ms replacement path outlasts the 50 ms renewal, so requests must overlap.

DRAFT

boundary check immediately prior to commitment. System architects must allocate and qualify this compute and memory footprint under worst-case shared-bus interference. Because each term in equation 11.3 represents an illustrative design allocation, neither L nor its constituent stages serve as unverified static bounds; both intervals remain explicit qualification obligations on the physical hardware.

Prediction length and execution duration are separate architectural parameters. While the prediction horizon $H\Delta t$ specifies how far into the future the sequence proposer forecasts, the **executed prefix** represents only the initial slice dispatched to actuators before an admitted replacement plan supersedes it. Expanding the prediction horizon supplies candidate continuity well past the next planned handoff, but does not grant the robot authority to execute that trajectory unchecked. The production controller targets an admitted renewal every 50 ms, enforcing hard lease expiry at 60 ms following the most recent admission. The evidence horizon of the upstream target observation can be shorter still.

Compute amortization depends strictly on inference dispatch frequency rather than the raw number of future setpoints generated in a forward pass. Executing a longer trajectory prefix lowers invocation frequency and amortizes accelerator workload, yet it simultaneously inflates closed-loop reaction lag, delaying task corrections when the environment drifts. Conversely, predicting farther into the future while maintaining a high renewal rate increases proposer compute without reducing inference duty. Emergency protective stopping remains governed by an independent hardware permission path and its certified reaction latency. Sizing the prediction horizon therefore balances closed-loop reactivity, pipeline renewal throughput, sensor evidence freshness, and fallback transition rates under realistic system loads; no universal optimal horizon emerges from trajectory buffer capacity alone.

↩ Action chunking as a supply lever is established in section 3.5.1.

11.3.2 Tail latency budgeting across a mission

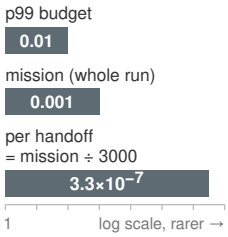
When the resident fallback works as certified, a late replacement costs availability rather than safety. A missed replanning deadline becomes a collision hazard only if the resident stop is kinematically infeasible, corrupted in memory, or delayed beyond its budgeted stopping distance. Over a long mission, however, the number of handoffs makes tail latency decide whether the mission completes,[5] even when a stopping profile safely absorbs every individual miss. The analysis below therefore bounds how often handoffs miss their deadlines, not how often the machine collides.

[5] **Tail at scale**: Dean and Barroso (2013) showed that a distributed request fanned out across many servers is bottlenecked by the slowest tail response, transforming rare single-server delays into frequent user-facing latencies. A continuous mission comprising thousands of sequential handoffs maps this same fan-out onto the time domain. Because every individual handoff must meet its admission deadline to avoid triggering a stop, the complete mission inherits the worst-case tail latency, rendering conventional per-handoff p99 benchmarks insufficient for assessing end-to-end mission reliability.

The component breakdown in equation 11.3 defines the latency of a single replacement cycle. Because an autonomous mission executes this handoff cycle repeatedly, the tail of the latency distribution dictates system behavior. A mission requiring K successive plan handoffs fails its continuous execution target if even one handoff misses its deadline. Partitioning a cumulative mission exceedance budget $\epsilon_{\text{mission}}$ uniformly across all K handoffs yields an upper bound on allowable per-handoff failure probability via the union bound:

$$\epsilon \leq \frac{\epsilon_{\text{mission}}}{K} \tag{11.4}$$

> Napkin Math 11.1: Handoff deadlines across a mission
>
> **Problem**: A generic replanner, slower than this machine's chunk renewal, meets a p99 replacement budget on each handoff. Over a ten-minute mission, how likely is it that every handoff arrives on time, and what per-handoff tail must the design target instead?
>
> **Variables**:
>
> - Mission length 600 s and replanning rate 5 Hz (illustrative)
> - Per-handoff exceedance of the p99 budget, $p = 0.01$ (definitional)
> - Mission exceedance target $\epsilon_{\text{mission}} = 1 \times 10^{-3}$ (chosen)
> - Independent misses (assumption)
>
> **Math**:



1. **Handoff count**: 600 s × 5 Hz gives $K = 3000$, and $Kp = 3000 \times 0.01 = 30$ handoffs are expected late.
2. **Every handoff on time**: $(0.99)^{3000} \approx 8 \times 10^{-14}$.
3. **Design tail** (equation 11.4): $\epsilon \leq \epsilon_{\text{mission}}/K \approx 3.3 \times 10^{-7}$, the p99.99997 quantile, deeper than the p99 budget by $0.01/(3.3 \times 10^{-7}) \approx 3 \times 10^4$.

Result: A mission almost never completes with every handoff inside a p99 budget, and the tail a mission target implies lies more than four orders of magnitude deeper.

Systems insight: The quantile a design must target is set by how many handoffs a mission makes, not by the per-handoff budget, and it lies beyond what a test campaign of practical size observes. A late handoff must degrade service availability, not safety clearance. Preserving $d_{\text{stop}} \leq D_{\text{clear}}$ relies on the resident stop profile (the pre-validated stopping suffix latched in MCU memory at admission and triggered without the host), not on optimistic assumptions about latency tails.

This per-handoff quantile functions as a **design quantile target**, a risk allocation across the software stack rather than an observed tail latency. In practice, resource contention across shared memory, PCIe buses, and hardware accelerators introduces temporal correlation, clustering deadline misses and violating independent-failure assumptions. Hardware-in-the-loop stress testing under maximum bus and memory saturation can expose deadline misses, but establishing this deep quantile requires a stated statistical model, sufficient observations, and evidence that the operating conditions match. The mission architecture must tolerate fallback frequencies that the available evidence cannot rule out without requiring human intervention.

To maintain continuous tracking, the client dispatches the next planning request at an offset no later than T_{request} after the active chunk begins executing. Plan admission must complete before a hard decision cutoff that precedes physical commitment t_{commit} by the actuator response allowance, rather than running up against the final nominal setpoint. Given a replacement-latency quantile target $Q_{1-\epsilon}(L)$ and a safety reserve T_{reserve}, a sufficient conservative timing requirement is $t_{\text{commit}} - t_{\text{start}} \geq T_{\text{request}} + Q_{1-\epsilon}(L) + T_{\text{reserve}}$. This requirement charges the complete capture-to-admission quantile after request dispatch, conservatively charging the preceding capture-to-dispatch age again. That extra age charge is separate from the visual-encoding overlap in equation 11.3. A tighter dispatch-relative requirement would use an independently characterized dispatch-to-admission distribution; subtracting marginal latency quantiles would not establish it. The reserve parameter T_{reserve} includes both scheduling slack before preferred admission and the physical decision-to-onset allowance. Furthermore, executing the resident stop requires an additional time window T_{stop} under dedicated MCU authority. Consequently, the time horizon T_{record} that an admitted trajectory record must cover, whether stored as dense setpoint arrays or polynomial splines, satisfies the corresponding conservative design requirement:

Spread over 3000 handoffs, a mission target demands a p99.99997 deadline, far past p99.

$$T_{\text{record}} \geq T_{\text{request}} + Q_{1-\epsilon}(L) + T_{\text{reserve}} + T_{\text{stop}} \tag{11.5}$$

In the baseline warehouse configuration, the chunk policy outputs a discrete setpoint every 25 ms across a 16-step horizon, producing 400 ms of nominal forward trajectory. Under nominal operation, an admitted replacement supersedes this trajectory after 50 ms. If renewal fails, the active lease lapses at 60 ms past the preceding admission tick. Unexecuted setpoints beyond that cutoff serve as candidate references for continuous handoffs rather than extended tracking authority.

On this running schedule the second tier, the record's commitment deadline, never acts, because a stalled proposer lets the 60 ms chunk lease lapse long before commitment arrives. To show how a record's own deadlines coordinate nominal motion with its stop, the worked timeline therefore uses an **alternate longer-lease schedule** for the same arm, one whose chunk lease is long enough not to lapse before the commitment cutoff. The commitment tier can then be seen on its own. On this schedule the planner issues its request 60 ms after the active chunk begins (later than the running machine's 50 ms renewal, which only a longer lease permits). It budgets 160 ms as its design-tail replacement latency $Q_{1-\epsilon}(L)$ above the 114.9 ms nominal sum, as a chosen stand-in for the deep quantile that equation 11.4 implies. It then adds 20 ms of scheduling slack to set a

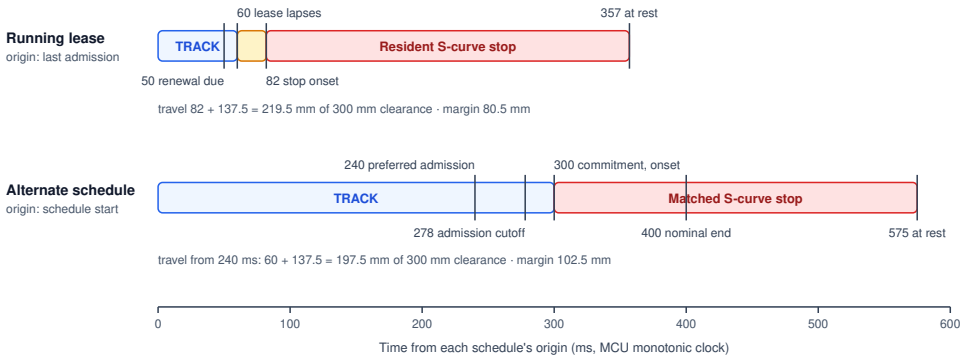


Figure 11.2: Two lease schedules for the arm: On the running lease (top), a stalled proposer lapses the lease 60 ms after the last admission, and the tick, bus, and onset allowance (amber) delays the resident stop to 82 ms. On the alternate schedule (bottom), admission must close by 278 ms so the matched stop begins at the 300 ms commitment; the unused nominal setpoints run to 400 ms. Each margin is charged against its own clearance check and still excludes sensing and model reserves.

preferred admission deadline at 240 ms. Adding the 22 ms decision-to-onset response allowance to the scheduling slack gives the 42 ms full reserve of equation 11.5 and a conservative minimum stop onset of 262 ms. Selecting a slightly later physical stopping onset at 300 ms leaves 60 ms between preferred admission and commitment. Replacement admission can therefore close as late as 278 ms (one 22 ms decision-to-onset delay before commitment). The pre-validated 275 ms stopping suffix (section 11.5.2) then brings the arm to rest at 575 ms, provided clearance holds through that entire window.

This alternate profile serves to contrast buffer structure with the production policy. Its window spans 23 setpoint periods, yet it stays compact in memory because the stop is stored as an analytical profile (jerk limits, acceleration limits, and phase durations) rather than as a dense array of setpoints. Set on one time axis, the two schedules spend clearance differently (figure 11.2). On the running lease, the lease lapses at 60 ms, the tick, bus, and onset allowance delays the resident stop to 82 ms, and the arm uses 219.5 mm of the 300 mm clearance, leaving 80.5 mm. On the alternate schedule, admission must close by 278 ms, after the preferred 240 ms, so that the matched stop begins at the 300 ms commitment and reaches rest at 575 ms with 102.5 mm to spare. The nominal setpoints that run on to 400 ms are never executed.

Sustaining the continuous 50 ms renewal cadence of the running lease requires verifying pipeline throughput alongside latency. Because the illustrative 114.9 ms replacement latency exceeds the 50 ms renewal period, the system must pipeline consecutive planning requests. Pipelining maintains real-time throughput only when intermediate hardware stages provide non-blocking queue capacity and bounded bus arbitration delay; pipelined concurrency cannot be established from latency sums alone. Until comprehensive load testing validates multi-request pipelining under peak bus contention, the specified resident fallback responds to missed renewal only under its stated state, clearance, sensing, energy, drive-response, deceleration, and jerk assumptions.

Both lease architectures remain bounded by the validity lifespan of upstream perceptual evidence. Even when employing a qualified local object tracker, the tracked evidence horizon derived in section 10.5 is shorter than the alternate commitment duration, so a single vision observation of a target object cannot justify that entire duration. Instead, the manipulator uses a staged perceptual approach. It follows an admitted prefix through a certified clear corridor, triggers fresh visual acquisition from a wrist-mounted camera at closer proximity, and re-anchors subsequent trajectory segments to updated state estimates. Embedded firmware then admits the terminal grasp maneuver only when the complete motion profile satisfies current target tolerances within an active validity envelope. Although an overall reaching motion may span several observation cycles, every executed trajectory slice requires fresh evidentiary support. Generating a new trajectory proposal cannot refresh stale sensor evidence, and losing perceptual tracking immediately transitions the robot into a state-matched stopping fallback.

On the Push-T manipulation benchmark (Chi et al. 2025), frequent closed-loop replanning lets an articulated planar arm recover from live disturbances as it guides a T-shaped block toward a designated pose. A diffusion policy generates $H = 16$ future steps and executes an initial prefix of $T_a = 6$ steps before replanning. It recovers dynamically from transient camera occlusions, external block displacements during approach, and perturbations near the terminal pose. However, these empirical trials demonstrate task-level reactive correction rather than certified derivative continuity or deterministic stopping under compute starvation. A safety-critical production system still requires an independently executable stopping suffix verified against known kinematic clearance bounds.

11.3.3 Conditioning on the state at splice time

While a joint rotates at 0.50 rad/s during an illustrative 80 ms compute and transport delay (somewhat longer than the 63.3 ms dispatch-to-admission allocation), a joint pose sampled when the replacement request was dispatched lags the advancing reference by 0.040 rad (2.29°). Mapped through the arm's forward kinematics (equation 11.1) at its 0.70 m maximum planar reach, that angular lag displaces the tool center point by up to 28 mm. This is more than the entire lateral swept-volume clearance budgeted for a reach past the conveyor guard (section 11.7.2). That clearance is a sideways allowance, distinct from the 300 mm of free path ahead of the tool that a stop consumes. Conditioning a motion plan on sensor feedback captured when inference begins therefore induces the **stale-state paradox**. By the time the generative policy completes its forward pass, the physical arm has already advanced along its prior trajectory. Initializing the new plan from the request-time state then commands the actuators to step backward across the distance traversed during computation, which injects step discontinuities into commanded position, velocity, and acceleration. To eliminate boundary discontinuities, the sequence proposer must instead condition its action generation on the forward-projected reference state[6] of the active trajectory at the designated replanning seam t_{seam}:

$$\Delta q_{\text{reference}} = \int_{t_0}^{t_{\text{seam}}} \dot{q}_A(t)\, dt, \qquad \hat{\mathbf{x}}_{\text{seam}} = \mathbf{x}_A(t_{\text{seam}}) \tag{11.6}$$

The left-hand integral is the joint-space gap that a stale anchor would leave, the 0.040 rad of the example, while the right-hand state is the anchor the proposer uses instead. Because the projected seam state $\hat{\mathbf{x}}_{\text{seam}}$ in equation 11.6 exists strictly in reference trajectory space, external contact forces, mechanical compliance, and closed-loop tracking errors invariably displace the physical plant from this nominal point. Rather than presuming an unobservable future measurement, admission verification prior to the seam evaluates a bounded reachable-state envelope, confirming that feasible polynomial bridges and certified stopping profiles exist across all reachable states within that set. At activation, embedded MCU firmware reads fresh optical encoder measurements and state-estimator error bounds to validate the actual boundary discrepancy $(\Delta q, \Delta \dot{q}, \Delta \ddot{q})$ against that certified envelope. It then instantiates the bounded fifth-degree C^2 bridge of section 11.4.4 and checks its joint-space derivatives against actuator velocity, torque, and jerk limits within the reserved real-time tick before dispatching motor commands. If measured tracking errors or bridge derivatives exceed admitted bounds, the MCU rejects the replacement and maintains the active plan only while its tracking error, target evidence, lease duration, and stopping clearances satisfy safety invariants; otherwise, it triggers the pre-latched fallback profile. Matching two *reference* profiles guarantees derivative continuity across reference commands, but it never eliminates physical tracking errors in the underlying mechanical hardware.

Recent generative imitation learning architectures incorporate delay compensation directly into their sampling algorithms. Real-time chunking (Black, Galliker, et al. 2025) computes upcoming action sequences concurrently with active chunk execution. Because setpoints scheduled to run during the inference delay window are already committed to the actuator queue, the model fixes those initial steps to their committed values and samples subsequent actions conditioned on this prefix, applying decaying consistency weights across the overlap window. Although empirical evaluations show that control throughput remains stable under artificial latency injection, the formulation provides no formal continuity or stability guarantees. In contrast, bidirectional decoding (Y. Liu et al. 2024) samples a diverse candidate batch of trajectory chunks, scoring and selecting the proposal whose trajectory matches the previously executed actions most smoothly. Conditioning generation on the committed trajectory prefix promotes smooth kinematic transitions and reduces

6 **Smith predictor**: Smith (1957) handled known dead time in feedback control loops by projecting a plant model forward across the delay interval rather than closing feedback against delayed measurements. Future-state conditioning adapts this idea to trajectory planning by anchoring prospective trajectories to the reference state expected at the handoff seam. It also inherits the weakness of any dead-time predictor: external disturbances during the delay interval go uncompensated until physical feedback arrives, which is why the MCU must check measured joint states against strict error bounds at activation.

DRAFT

boundary tracking discrepancies, yet it cannot substitute for formal safety verification. Embedded microcontroller logic must still evaluate actual physical states against the admitted safety envelope before committing any new chunk to execution.

Definition 11.2: Future-state conditioning

Future-state conditioning is the practice of generating candidate motion plans anchored to the anticipated state at execution time rather than the stale state measured at plan initiation.

1. **Significance**: Offsets computational and transport latency Δt_{plan}, eliminating boundary step discontinuities at trajectory handoffs without forcing zero-velocity pauses between consecutive chunks.
2. **Distinction**: Differs from state estimation or Kalman filtering; it is a forward reference-planning technique that propagates an admitted nominal trajectory rather than filtering sensor noise.
3. **Common pitfall**: Conflating forward-projected reference states with actual physical plant positions. If external contact forces or tracking lag displace the mechanism during planning, activation remains contingent upon the MCU verifying actual encoder feedback and bridge feasibility at the handoff seam.

Trajectory replacement therefore comes down to three sizing decisions. The prediction horizon must be long enough to carry kinematically feasible motion together with a certified stopping profile, the executed prefix short enough to keep closed-loop responses to a changing environment fast, and the renewal cadence one that the pipelined compute can sustain deterministically. Perceptual evidence freshness dictates the maximum lifespan over which any target estimate justifies physical motion. Even when replacement plans arrive strictly within latency budgets, timely delivery alone cannot guarantee that physical joint actuators can track the synthesized trajectory or bridge seamlessly from their measured state.

Checkpoint 11.1: Action chunk horizon and tail latency

Verify your understanding of replacement timing budgets, tail latency exposure, and delay compensation mechanisms before examining kinodynamic feasibility:

- ☐ **Mission length and tail quantiles**: In the stated independent-handoff illustration, what is the probability that one or more missed p99 handoff deadlines occur across 3000 consecutive cycles, and why does this represent an allocation target rather than an empirical mission collision rate?
- ☐ **Horizon sizing trade-offs**: Why can a long prediction horizon coexist with a short executed prefix, and which scheduling parameter dictates accelerator inference duty?
- ☐ **Projected seam state**: Why must a trajectory synthesized from a forward-projected reference still undergo reachable-set verification at admission and measured state bridge validation at activation?

11.4 Kinodynamic Feasibility

A candidate trajectory that clears every obstacle in workspace and arrives before its deadline will still fault on the hardware if it asks a joint for more speed, torque, or current slew than the drive can supply. What an embodied model generates is a geometric and timed proposal, not permission to move. While high-level motion planners and learned policies navigate free configuration space $\mathcal{C}_{\text{free}}$, physical actuators operate under fixed electromotive, thermal, and structural limits. Kinodynamic feasibility bridges geometric intent and mechanical reality, ensuring that reference trajectories respect actuator torque limits, velocity boundaries, and transmission dynamics before the low-level controller dispatches setpoints to motor drives.

Definition 11.3: Kinodynamic feasibility envelope

Kinodynamic feasibility envelope is the set of initial states from which the machine can track a candidate trajectory, including its transition seams and terminal stop, while every joint remains within its configured position, velocity, acceleration, jerk (the rate of change of acceleration), torque, and stator current limits.

1. **Significance**: Obstacle clearance in configuration space is necessary but insufficient. At the 1 m/s TCP speed limit, a collision-free reach in the arm's weakest kinematic direction at a right-angle elbow demands 3.5 rad/s from a single joint against its 2.175 rad/s ceiling. The spatial geometry succeeds while the timing fails. The envelope defines the state region where dynamic models predict trackable motion, which admission and runtime monitors must continuously verify.
2. **Distinction**: Kinematic reachability evaluates whether a mechanism can geometrically achieve a configuration. Kinodynamic feasibility introduces time and momentum: the time derivatives that a trajectory profile implies, the dynamic torques produced through the manipulator equation, the effective inertia reflected through gear trains, and the physical stopping distance required to brake safely.
3. **Common pitfall**: Evaluating feasibility solely at discrete waypoints. The continuous-time interpolant between discrete samples can overshoot velocity bounds or demand severe torque steps even when every discrete sample satisfies constraints.

11.4.1 Rigid-body dynamics and continuous collision checks

A trajectory can stay completely clear of obstacles in $\mathcal{C}_{\text{free}}$ and still fail on the physical machine because it demands actuator torques that saturate motor inverters, induces base accelerations that tip the platform, or drives current slew rates that trip motor protection circuits. Classical kinematic motion planning checked only whether the swept volume avoided obstacles; a moving body with momentum must satisfy configuration-space clearance and time-domain dynamic limits together.

On a single joint, such as the manipulator's shoulder lifting a grasped payload, the balance of torques obeys the scalar equation of motion:

$$\tau = J_{\text{eff}}\,\ddot{q} + mgr\cos q + \tau_{\text{fric}} \tag{11.7}$$

where J_{eff} represents the effective inertia driven by the joint, m is a concentrated mass whose center of gravity lies at distance r from the joint axis, q is the joint angle measured from the horizontal plane, and τ_{fric} is friction torque opposing motion. Mechanical inertia resists angular acceleration, while gravity exerts a static load proportional to the horizontal moment arm $r\cos q$. Holding the rated 3 kg payload horizontally at the manipulator's full 0.70 m planar reach requires 20.6 N·m of static holding torque, which consumes 23.7 percent of the joint's 87 N·m torque limit before motion begins (Franka Robotics GmbH 2023). The actuator's reflected rotor inertia is the N_{gear}^2-amplified rotor term of section 2.4.3, which the seam analysis below prices for a Panda-class joint. Adding it to the payload inertia produces an effective joint inertia of 1.65 kg·m² that every commanded acceleration must accelerate. Structural link mass and distributed inertia add to this baseline. Because manufacturer datasheets rarely provide link mass distributions, empirical evaluations rely on published identified parameters (Gaz et al. 2019); an operational deployment requires system identification on the physical arm and attached tooling.

In multi-degree-of-freedom manipulators, dynamic coupling interconnects the joints. The scalar terms generalize into the matrix terms of the **manipulator equation**, derived from the Euler-Lagrange equations of motion (Craig 2005; Lynch and Park 2017):

$$\tau(t) = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) - \mathbf{J}^{\top}(\mathbf{q})\mathbf{F}_{\text{ext}} \tag{11.8}$$

Here, the symmetric, positive-definite inertia matrix $\mathbf{M}(\mathbf{q})$ generalizes scalar inertia J_{eff} from equation 11.7. Off-diagonal elements capture cross-joint inertial coupling (accelerating the elbow induces reaction torques at the shoulder), and matrix values vary continuously as the arm articulates.

The quadratic velocity term $\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}}$ aggregates centrifugal and Coriolis torques, which scale quadratically with joint velocity, while the gravity vector $\mathbf{g}(\mathbf{q})$ generalizes $mgr\cos q$ to represent configuration-dependent static holding torque. The geometric Jacobian from equation 11.1 maps an external wrench $\mathbf{F}_{\text{ext}}$ acting on the end effector into equivalent joint torques via the transpose $\mathbf{J}^{\top}(\mathbf{q})$; external contact wrenches that assist motion reduce actuator torque demands, while resistive loads increase them. Evaluating equation 11.8 along a prospective trajectory $\mathbf{q}(t)$ is the problem of **inverse dynamics**. The recursive Newton-Euler algorithm computes inverse dynamics for an n-joint serial arm in $\mathcal{O}(n)$ arithmetic operations per trajectory sample (Luh et al. 1980; Lynch and Park 2017). An admission filter scanning an N-sample candidate trajectory therefore performs $\mathcal{O}(Nn)$ operations whose worst-case execution time must fit within the system's admission latency allowance.

Before dispatching a proposed trajectory chunk, the planning runtime screens it against the kinodynamic feasibility envelope, verifying that the physical state at the handoff seam satisfies position, velocity, torque, stator current, contact force, and collision boundaries over the planning horizon. For robotic arms, the rigid-body model maps joint trajectories $\mathbf{q}(t)$, $\dot{\mathbf{q}}(t)$, and $\ddot{\mathbf{q}}(t)$ to joint torques $\tau(t)$ via equation 11.8. Those torques convert to quadrature-axis motor currents $i_{q_i}(t) = \tau_i(t)/K_{t_i}$ using the joint-effective torque constant K_{t_i}. (When using motor-side torque constants, the conversion must explicitly incorporate gear ratios and transmission mechanical efficiencies.) Initial screening by an unprivileged planner, however, does not constitute system admission. The real-time safety MCU executes an independent, deterministic verification check, admitting a bounded trajectory chunk only if configured dynamic limits and certified stop clearances hold for the verified initial state. Once admitted, the MCU monitors control tracking error, plan freshness, and stopping distance margins on every servo cycle.

Numerical optimizers can smooth geometric paths and expand obstacle clearance, but motion permission resides strictly in the admitted trajectory chunk and its resident stopping suffix. For example, the cuRobo motion-generation framework uses massively parallel GPU compute to generate collision-free, minimum-jerk trajectories across kinematic configurations (Sundaralingam et al. 2023). Its collision pipeline evaluates signed distance fields across sampled swept-sphere volumes under a linear-motion approximation, leaving continuous inter-sample swept volume evaluation as an open requirement. Following trajectory optimization, cuRobo identifies the limiting time step where joint velocity, acceleration, or jerk encounters actuator bounds, rescaling trajectory duration before re-optimizing. This uniform temporal scaling represents an initial form of the rigorous time parameterization developed in section 11.4.5. Because cuRobo's algorithmic formulation focuses on kinematic derivatives rather than full multi-body dynamics, torque boundaries, winding thermal accumulation, continuous swept-volume containment, and admission deadlines remain external system-level requirements. Under this systems architecture, the GPU trajectory generator operates as an unprivileged proposer, while the real-time safety MCU independently validates prospective trajectories and seam constraints within a strict admission deadline, latching an executable stopping continuation before authorizing motion.

11.4.2 Overshoot between samples and contracted limits

When the admission filter checks a candidate only at discrete waypoints spaced T_s apart, two consecutive joint samples $t_k = kT_s$ that sit just below the velocity ceiling $v_{\max}$ can still bracket an overspeed fault midway between them. The reason is that physical actuators track a continuous interpolant across (t_k, t_{k+1}). If that interpolator can command accelerations up to $a_{\max}$ within a sample period, an acceleration sign reversal across the midpoint lets continuous velocity rise above the values recorded at both endpoints.

Under acceleration-bounded interpolation, the maximum velocity excursion between two consecutive samples sharing equal velocity arises from a bang-bang acceleration reversal: $+a_{\max}$ applied over $[0, T_s/2]$, followed immediately by $-a_{\max}$ over $[T_s/2, T_s]$ to restore endpoint velocity. The velocity excursion reaches its maximum at the midpoint, corresponding to the integrated area of the initial acceleration phase:

$$\Delta\dot{q} = a_{\max} \cdot \frac{T_s}{2} = \frac{1}{2} a_{\max} T_s \tag{11.9}$$

As equation 11.9 demonstrates, two consecutive waypoint samples evaluated just beneath velocity ceiling $v_{\max}$ can bracket an interior velocity peak that exceeds the limit, tripping drive overspeed

protection between individually valid samples. To ensure continuous-time velocity compliance without evaluating an infinite continuum of points, the admission filter tests discrete waypoints against an analytically contracted velocity threshold:

$$|\dot{q}_k| \leq v_{\max} - \frac{1}{2} a_{\max} T_s \tag{11.10}$$

The shaded acceleration area in figure 11.3 becomes the velocity rise between the sampled endpoints. Placing both endpoints one full rise below the physical ceiling keeps the continuous peak at that ceiling.

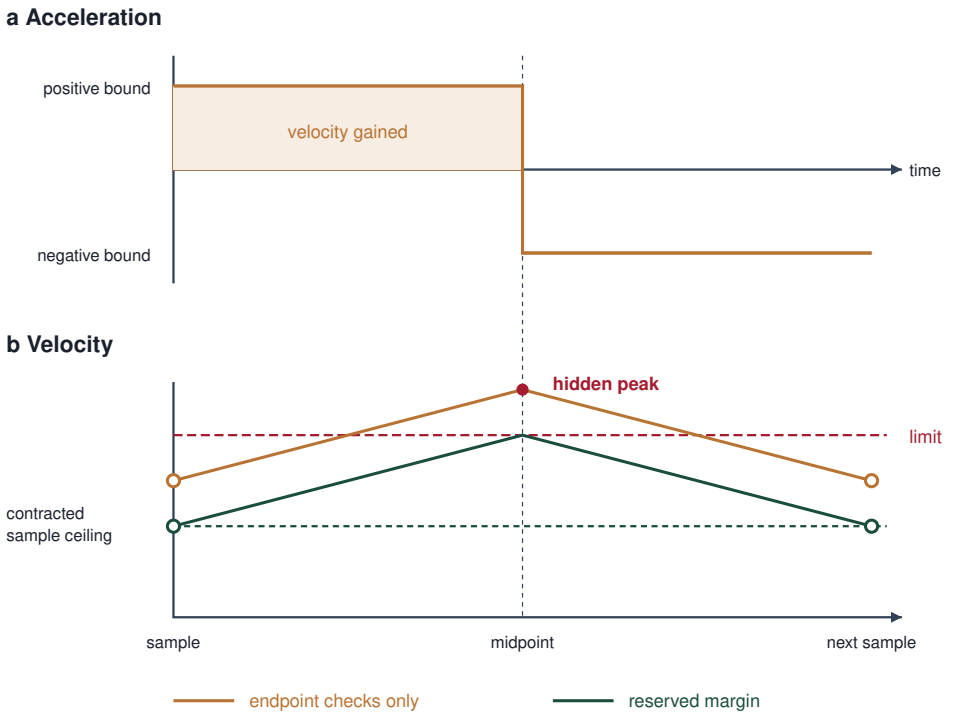

Figure 11.3: A Velocity Peak Between Valid Samples: Positive acceleration over the first half of a sample interval raises velocity; the equal negative phase restores the original endpoint velocity. The bronze trajectory passes both endpoint checks but crosses the velocity limit. The pine trajectory uses the contracted sample ceiling, leaving the reserve derived in equation 11.9. The schematic assumes an acceleration bound and an instantaneous sign reversal; it does not impose a finite jerk bound.

The endpoint check succeeds only when the interpolant obeys the assumptions used to reserve the margin. A sampled value below the physical ceiling alone supplies no such guarantee.

This contraction creates a safety margin that absorbs the worst-case overshoot any acceleration-bounded interpolator can generate across a sample period T_s. A smaller reserve requires additional boundary conditions. If consecutive samples have equal velocity and zero acceleration, and the interpolator enforces $j_{\max} \leq 4a_{\max}/T_s$, the extremal reversal consists of a positive triangular acceleration pulse followed by its negative counterpart, each of base $T_s/2$. Their peaks reach $a_{\max}$ only at equality in the jerk condition, so $\frac{1}{4} a_{\max} T_s$ is a conservative velocity reserve for this restricted interpolation. A jerk bound alone does not justify that reserve when endpoint accelerations are nonzero. For polynomial spline interpolants, the admission filter can instead compute exact interior extrema analytically before certifying continuous-time feasibility.

11.4.3 Seam acceleration jumps and reflected rotor inertia

When the arm hands off from one action chunk to the next while moving, two chunks that are each feasible in isolation can still form an infeasible seam between them. Matching joint positions alone

(C^0 continuity) leaves an unconstrained velocity step across the boundary. Matching both position and velocity (C^1 continuity) eliminates velocity jumps but leaves an instantaneous acceleration discontinuity, which demands an immediate step in joint torque. Under a rigid-inertia approximation, commanding a velocity step $\Delta\dot{q}$ across a single servo period T_s requires an inertial torque of:

$$\tau_{\text{request}} = J_{\text{eff}} \frac{\Delta\dot{q}}{T_s} \tag{11.11}$$

where $J_{\text{eff}} = J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}$ in equation 11.11 represents the total effective inertia referenced to the joint output. This term adds link and payload inertia J_{load} to the reflected rotor inertia established in section 2.4.3, the motor rotor inertia J_{rotor} seen through gear reduction ratio N_{gear}. Because the rotor turns N_{gear} times faster than the joint, its kinetic energy, written in joint velocity, carries the factor N_{gear}^2:

$$E_k = \frac{1}{2} J_{\text{rotor}} \omega_m^2 = \frac{1}{2} J_{\text{rotor}} (N_{\text{gear}} \dot{q})^2 = \frac{1}{2} (N_{\text{gear}}^2 J_{\text{rotor}}) \dot{q}^2$$

In precision robotic manipulators equipped with high-ratio strain-wave gearing[7] ($N_{\text{gear}} = 50$–100), reflected rotor inertia is magnified by a factor of $2{,}500$ to $10{,}000$. It can then rival or exceed link inertia, most often for an unloaded arm or a folded pose, although a rated payload held at full reach outweighs it. In the one-joint example the payload supplies most of the 1.65 kg·m² total, against 0.18 kg·m² from the rotor. Either way, the reflected term sits in every joint's J_{eff} regardless of payload, and on its own it makes seam torque spikes large. At a C^0 boundary, an instantaneous velocity step implies an idealized Dirac acceleration impulse $\delta(t)$, which no physical motor drive can supply. At a C^1 boundary, an acceleration jump $\Delta\ddot{q}$ demands a step change in electromagnetic torque, $\Delta\tau = J_{\text{eff}} \Delta\ddot{q}$. Such abrupt torque transients excite structural resonance in flexible transmissions, accelerate mechanical wear, and degrade control tracking. On the strain-wave joint priced in the notebook below, an unblended one-tick velocity step of 0.2 rad/s asks the reflected rotor inertia for a 36.7 N·m torque pulse, while a 50 ms C^2 quintic bridge closing the same gap peaks at 1.1 N·m (figure 11.4). Commercial industrial arms enforce this exact discipline at their low-level control interfaces. For example, the Franka Research 3 arm samples setpoints at 1 kHz, comparing each incoming command against the previous cycle. If inter-cycle setpoint differences exceed factory derivative thresholds, the drive immediately aborts motion with an unrecoverable discontinuity fault (such as `joint_motion_generator_velocity_discontinuity`) (Franka Robotics GmbH 2026, 2023). An unblended seam can therefore abort nominal tracking before repeated transitions accumulate mechanical fatigue. Physical stopping still requires the drive's qualified response delay and deceleration profile.

When the arm carries an open cup of liquid, steady velocity does not spill the contents, whereas rapid acceleration transitions and high jerk provoke sloshing and spillage (section 11.5.2 models this deceleration threshold directly). A trajectory interface that continuously matches position, velocity, and acceleration constitutes a C^2 **spline seam**. Enforcing C^2 continuity eliminates reference acceleration steps and prevents the associated torque jump $\Delta\tau = J_{\text{eff}} \Delta\ddot{q}$. Concurrently, bounding trajectory **jerk** ($j_{\text{joint}} = \dot{a} = \dddot{x}$) limits the rate at which joint acceleration changes. Neither mathematical property alone guarantees payload stability or mechanical longevity, however; an interpolating bridge that matches boundary conditions perfectly can still violate velocity, jerk, actuator torque, or obstacle clearance limits in its interior.

Mechanical transmissions govern how actuator torque couples into physical link motion. In a standard two-inertia drivetrain comprising load inertia J_{load}, reflected rotor inertia $J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$, and torsional coupling stiffness K_{joint}, the antiresonance and resonance frequencies (P. Li et al. 2024) are:

$$f_{\text{anti}} = \frac{1}{2\pi} \sqrt{\frac{K_{\text{joint}}}{J_{\text{load}}}}, \qquad f_{\text{res}} = \frac{1}{2\pi} \sqrt{K_{\text{joint}} \left(\frac{1}{J_{\text{load}}} + \frac{1}{J_{\text{ref}}} \right)}$$

In robot joints constructed with strain-wave gearing, large reflected inertia coupled with flexspline torsional compliance amplifies high-frequency setpoint harmonics. An admission checker must therefore verify prospective bridges against the joint's identified, load-dependent vibrational modes, evaluating derivative extrema, peak torques, and drive current limits against empirical structural

[7] **Strain-wave (harmonic) gearing**: In the mechanism Musser (1959) patented, an elliptical wave generator flexes a thin toothed cup, the flexspline, so that it meshes with a rigid ring carrying two more teeth, and each turn of the generator advances the cup by only that difference. The result is a high reduction in one compact stage with almost no backlash. The flexspline is also the joint's main compliance, so the same gearing that multiplies rotor inertia by N_{gear}^2 supplies the compliant coupling of the two-inertia model below.

DRAFT

parameters. The two frequencies reach the checker through the bridge duration. A short bridge can excite these modes, but duration alone does not determine its spectral content or the joint's response. Identified modal frequencies and damping therefore inform qualified bridge-duration and derivative limits alongside the torque-rate limit. Structural stiffness, resonance modes, and admissible jerk envelopes never transfer between robot platforms without direct system identification.

11.4.4 Quintic splines and C^2 boundary matching

Closing the position, velocity, and acceleration gap between retiring chunk A and incoming chunk B over a finite blend duration T_{blend} requires online C^2 trajectory spline blending. The blend duration is a physical execution interval, distinct from the computational blend deadline t_{blend}. Blending synthesizes a dedicated polynomial bridge $q_{\text{blend}}(t)$, which must undergo the exact same kinodynamic feasibility checks as the primary chunks rather than acting as a cosmetic filter.[8] A localized seam bridge must satisfy position, velocity, and acceleration constraints at both boundary states, which gives six independent boundary conditions. A cubic polynomial has only four degrees of freedom and cannot satisfy them. A fifth-degree quintic polynomial provides the six required coefficients. This localized endpoint-matching formulation differs from fitting a globally continuous cubic spline across an entire offline sequence of knots.

[8] **Minimum jerk**: Flash and Hogan (1985) found that unconstrained human reaching follows the trajectory that minimizes integrated squared jerk, which for a rest-to-rest reach is a quintic polynomial in time. The jerk term of equation 11.20 inherits that smoothness but not a bound, so a minimum-jerk bridge can still exceed the drive's limits, and its extrema are checked through equation 11.13.

The six boundary conditions are

$$q(0) = q_0, \quad \dot{q}(0) = \dot{q}_0, \quad \ddot{q}(0) = \ddot{q}_0$$
$$q(T_{\text{blend}}) = q_1, \quad \dot{q}(T_{\text{blend}}) = \dot{q}_1, \quad \ddot{q}(T_{\text{blend}}) = \ddot{q}_1$$

where $(q_0, \dot{q}_0, \ddot{q}_0)$ is the terminal physical state of chunk A at the seam instant, and $(q_1, \dot{q}_1, \ddot{q}_1)$ is the target state on incoming chunk B at $t = T_{\text{blend}}$. The six conditions fix the six coefficients $(a_0 \dots a_5)$ of the fifth-degree polynomial:

$$q(t) = a_0 + a_1 t + a_2 t^2 + a_3 t^3 + a_4 t^4 + a_5 t^5$$

Evaluating boundary conditions at $t = 0$ directly yields the first three coefficients: $a_0 = q_0$, $a_1 = \dot{q}_0$, and $a_2 = \frac{1}{2}\ddot{q}_0$. The remaining three coefficients $[a_3, a_4, a_5]^\top$ satisfy the 3×3 linear system evaluated at duration $T = T_{\text{blend}}$:

$$\begin{bmatrix} T_{\text{blend}}^3 & T_{\text{blend}}^4 & T_{\text{blend}}^5 \\ 3T_{\text{blend}}^2 & 4T_{\text{blend}}^3 & 5T_{\text{blend}}^4 \\ 6T_{\text{blend}} & 12T_{\text{blend}}^2 & 20T_{\text{blend}}^3 \end{bmatrix} \begin{bmatrix} a_3 \\ a_4 \\ a_5 \end{bmatrix} = \begin{bmatrix} q_1 - \left(q_0 + \dot{q}_0 T_{\text{blend}} + \frac{1}{2}\ddot{q}_0 T_{\text{blend}}^2\right) \\ \dot{q}_1 - \left(\dot{q}_0 + \ddot{q}_0 T_{\text{blend}}\right) \\ \ddot{q}_1 - \ddot{q}_0 \end{bmatrix} \tag{11.12}$$

Analytically inverting equation 11.12 yields closed-form expressions for $[a_3, a_4, a_5]^\top$, given in section B.5, that require deterministic arithmetic operations per joint. Differentiating $q(t)$ three times produces the continuous commanded jerk profile:

$$j_{\text{joint}}(t) = \dddot{q}(t) = 6a_3 + 24a_4 t + 60a_5 t^2 \tag{11.13}$$

Because $j_{\text{joint}}(t)$ in equation 11.13 is a quadratic function of time, its extrema over the interval $[0, T]$ occur exclusively at the domain boundaries ($t = 0$ or $t = T$) or at the interior stationary point $t^* = -a_4/(5a_5)$. The interior point applies when $a_5 \neq 0$ and $t^* \in (0, T)$. If $a_5 = 0$, jerk varies linearly or remains constant, and evaluating the boundaries alone suffices. The safety microcontroller can therefore compute exact peak jerk $|j_{\text{peak}}|$ analytically in $\mathcal{O}(1)$ operations without executing iterative numerical line searches. An identical principle governs lower derivatives: acceleration extrema occur at the roots of the quadratic jerk, and velocity extrema occur at the roots of cubic acceleration, both solvable in closed form.

Evaluating coupled joint torques across the bridge presents an entirely different challenge. Along a polynomial trajectory $\mathbf{q}(t)$, the right-hand side of equation 11.8 is non-polynomial because the inertia matrix $\mathbf{M}(\mathbf{q})$, Coriolis matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$, and gravity vector $\mathbf{g}(\mathbf{q})$ contain transcendental trigonometric functions of joint positions. Consequently, peak torque possesses no closed-form analytic solution. The safety monitor therefore evaluates torque at discrete sample waypoints and bounds inter-sample torque variation using the contraction principles established in section 11.4.2.

DRAFT

Bounding trajectory jerk directly protects actuator health, preserves motor inverter voltage headroom, and prevents premature transmission wear. When a trajectory generator outputs time-parameterized splines, it transforms kinematic waypoints into continuous reference functions whose derivatives map directly onto physical electrical and mechanical states. In permanent-magnet synchronous motors operated under field-oriented control, joint torque rate couples to jerk through the time derivative of the manipulator equation: $\dot{\tau}(t) = \mathbf{M}(\mathbf{q})\dddot{\mathbf{q}}(t) + \dot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}}(t) + \ldots$. For a single joint with constant effective inertia $J_{\text{eff}} = J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}$, neglecting changing gravity, friction, and external-load torques reduces the output torque rate to $\dot{\tau} = J_{\text{eff}} j_{\text{joint}}(t)$. Defining a joint-effective torque constant K_t such that output torque satisfies $\tau = K_t i_q$, commanding an output torque rate $\dot{\tau}$ demands a proportional quadrature-axis stator current slew rate:

$$\frac{di_q}{dt} = \frac{J_{\text{eff}}}{K_t} j_{\text{joint}}(t)$$

Here, K_t incorporates both the gear reduction ratio and transmission mechanical efficiency; directly substituting a raw motor-side torque constant without gear scaling would incorrectly pair motor torque with output-side inertia. Motor winding inductance L_{phase} and available DC bus voltage impose hard electrical limits on current slew rate. During positive motoring operations with resistive and back-electromotive force (back-EMF) drops, a simplified necessary condition for voltage headroom is:

$$V_{\text{bus}} \geq L_{\text{phase}} \frac{di_q}{dt} + R_{\text{phase}} i_q + K_e \omega_e \tag{11.14}$$

where R_{phase} represents phase winding resistance, K_e is the motor back-EMF constant, and ω_e denotes motor electrical speed. In operational motor drives, space-vector pulse-width modulation limits the maximum usable quadrature-axis voltage to a fraction of the total DC bus voltage. A complete electrical feasibility check must evaluate available voltage against the fully coupled, signed motor equations, including regenerative braking and inductive flyback, rather than treat a scalar approximation as sufficient qualification.

↩ Phase inductance, back-EMF, and the current-slew limits they impose are established in section 2.4.2.

An acceleration discontinuity in a motion plan demands an instantaneous step in electromagnetic torque and stator current. Because finite bus voltage and nonzero winding inductance prevent physical inverters from supplying infinite current slew rates (di_q/dt), the physical actuator lags the commanded reference. The resulting tracking error, inverter saturation, and thermal protection response depend on drive gains and mechanical compliance. An unbounded mathematical jerk demand does not instantly cause an overcurrent shutdown, but it induces severe tracking lag, mechanical vibration, and drive stress. A valid bridge must satisfy both continuous mathematical derivative bounds and the physical bandwidth limits of the actuator drive.

Satisfying the six boundary conditions guarantees acceleration continuity at chunk interfaces, but it does not guarantee that interior jerk, torque, or current slew rates remain within actuator ratings. The admission filter evaluates closed-form derivative extrema from equation 11.13 against the electrical constraints of equation 11.14, checks sampled multi-body torques against inter-sample contraction bounds, and rejects any bridge violating physical thresholds. Evaluating a fixed-degree polynomial requires bounded arithmetic operations per joint. Spline coefficient synthesis and trajectory extrema verification take place prior to trajectory dispatch; the qualified worst-case execution bound, accounting for memory access latency and register operations, must remain strictly within the configured admission deadline.

While a local quintic bridge resolves seam continuity through explicit boundary matching, global trajectory representations provide alternative verification properties. **Uniform B-splines**[9] parameterize joint trajectories as $\mathbf{q}(t) = \sum_{i=0}^{L} \mathbf{p}_i B_{i,p}(t)$, where $\mathbf{p}_i$ represent geometric control points, $B_{i,p}$ are polynomial basis functions of degree p, and ξ_i denote knot timestamps. Using simple knot sequences, uniform B-splines ensure C^{p-1} continuity by construction. Furthermore, the **convex hull property** ensures that the continuous trajectory lies entirely within the convex hull formed by its control points, enabling spatial collision checkers to prune entire collision volumes without dense sampling. Differentiating a B-spline yields a derivative spline whose control points are $\mathbf{v}_i = \frac{p}{\xi_{i+p+1} - \xi_{i+1}}(\mathbf{p}_{i+1} - \mathbf{p}_i)$, allowing difference operations on control points to establish conservative upper bounds on velocity, acceleration, and jerk. These geometric bounds accelerate screening,

[9] **Spline** (a draftsman's bending strip): The word named the thin flexible strip that shipwrights and draftsmen bent through fixed points, held in place by lead weights, to draw a fair curve. Schoenberg (1946) borrowed it for piecewise polynomials, and Boor (1978) made B-splines practical to compute with a stable recursion. The convex-hull property that construction supplies is what lets a checker bound a whole segment's derivatives from a few control-point differences.

though they do not replace full dynamic inverse dynamics or swept-volume collision checks. In streaming replanning architectures, the trajectory representation must also support rapid coefficient joining within the real-time admission deadline; table 11.1 separates the continuity supplied by each representation from the dynamic checks still required before execution.

Table 11.1: Trajectory representations and required checks: Smooth parameterization helps form a candidate but does not by itself prove dynamic feasibility.

Representation	Native seam property	Checks before execution
Cubic polynomial (C^1)	Matches $q, \dot{q}$; adjoining acceleration need not match.	Check acceleration matching and interior limits; position and velocity matching alone are insufficient.
Quintic bridge (C^2)	Matches $q, \dot{q}, \ddot{q}$ at both ends; jerk is quadratic within each bridge.	Check interior extrema, torque rates, inverter headroom, and clearance.
Septic polynomial (C^3)	Can match derivatives through jerk at both endpoints.	Check interior derivatives and actuator limits; endpoint matching does not bound their magnitudes.
Uniform B-spline (degree p)	C^{p-1} continuity; convex hull bounds spatial curve.	Constrain control point differences for velocity/jerk; check global knot system.
Neural action chunk (ACT, Diffusion)	Discrete samples; continuity depends on interpolation and seam constraints.	Project onto feasibility manifold via numerical solver or C^2 quintic bridge; latch stop.
Online jerk-limited generator	Reaches a target $(q, \dot{q}, \ddot{q})$ from any current state within per-axis v_{max}, a_{max}, j_{max} bounds; the generator picks the duration.	Check coupled torque, clearance, evidence age, and the configured limits themselves; kinematic feasibility by construction is not admission.

Napkin Math 11.2: The seam spike

Problem: At a replanning seam the incoming chunk's reference runs 0.2 rad/s faster than the active one. Should the joint close that gap in one servo tick or over a C^2 bridge, and what does each ask of the drive?

Variables:

- Joint: a CSG-25-50 strain-wave gear driven by a TQ-RoboDrive ILM 70x18 motor, a Panda-class stand-in because Franka does not publish the Panda's joint internals (datasheet parts); reflected rotor inertia $J_{\text{eff}} = N^2_{\text{gear}} J_{\text{rotor}} = 0.18$ kg·m² (derived; link and payload inertia excluded, so here J_{eff} is the reflected inertia J_{ref} of section 2.4.3 alone)
- Ratings 51 N·m rated and 127 N·m repeated peak (datasheet); the arm's torque-rate limit 1,000 N·m/s (datasheet)
- Velocity gap $\Delta\dot{q} = 0.2$ rad/s (illustrative) and servo tick $T_s = 1$ ms (chosen)
- Bridge duration $T_{\text{blend}} = 50$ ms (illustrative), zero acceleration at both ends, ending on chunk B's reference, a position residual $\Delta\dot{q} T_{\text{blend}}/2 = 0.005$ rad (chosen)

Math:

1. **One tick** (equation 11.11): $J_{\text{eff}} \Delta\dot{q}/T_s = 36.7$ N·m, below the rating. Reaching it within the tick needs at least 36.7 N·m per 1 ms, or 36,700 N·m/s, 36.7× the torque-rate limit.
2. **Quintic bridge** (equation 11.12): Because a symmetric velocity transition from $\dot{q}_0$ to $\dot{q}_0 + \Delta\dot{q}$ averages $\dot{q}_0 + \frac{1}{2}\Delta\dot{q}$ across the bridge, the joint advances by $\Delta\dot{q} T_{\text{blend}}/2$ beyond chunk A's constant-velocity extrapolation; with that position residual and zero boundary accelerations, the system gives $a_5 = 0$, $a_4 = -\Delta\dot{q}/(2T^3_{\text{blend}}) = -800$ rad/s^4, and $a_3 = \Delta\dot{q}/T^2_{\text{blend}} = 80$ rad/s^3.
3. **Bridge peaks**: Acceleration peaks at mid-bridge at $1.5\Delta\dot{q}/T_{\text{blend}} = 6$ rad/s², a torque of 1.1 N·m. Jerk (equation 11.13) peaks at both ends at $6a_3 = 480$ rad/s^3, a torque rate $J_{\text{eff}} j_{\text{joint}}$ of 88.1 N·m/s, 8.8 percent of the limit.

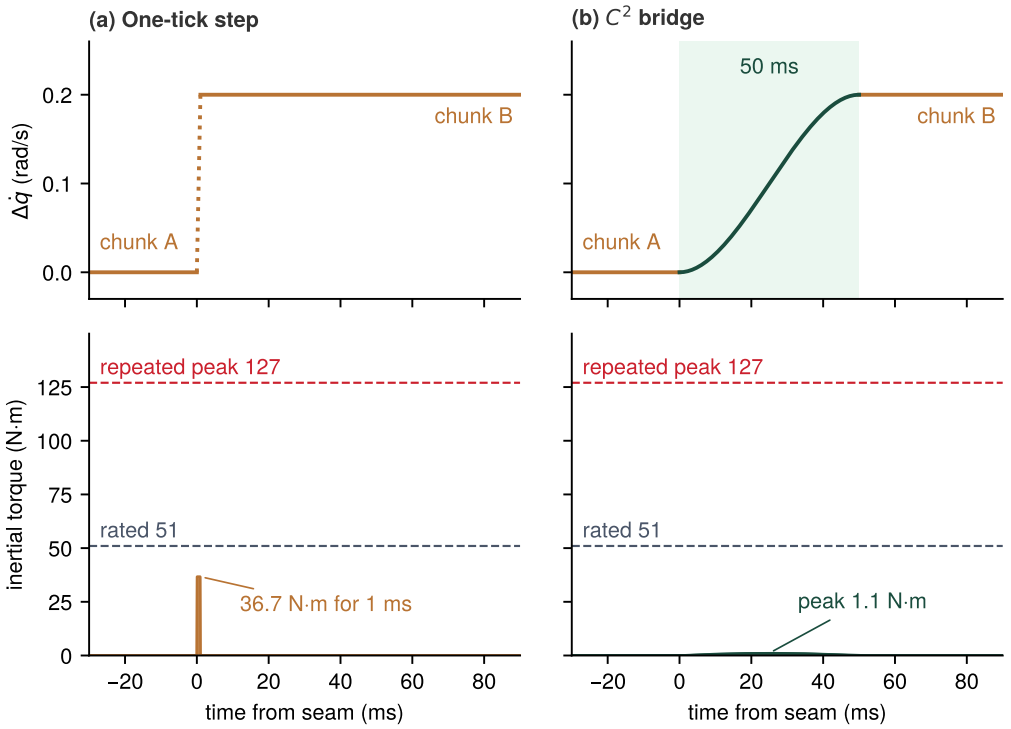

Figure 11.4: Seam demand and checked bridge: Both columns close the same 0.2 rad/s reference velocity gap on the notebook's strain-wave joint, with torque drawn to one scale against its datasheet ratings. The one-tick step (left) asks the reflected rotor inertia for 36.7 N·m, below the 51 N·m rating, so the torque-magnitude check alone passes. The notebook's torque-rate calculation rejects the transition, and the drive also rejects its discontinuity. The 50 ms C^2 bridge (right) peaks at 1.1 N·m, but its interior jerk, full joint torque, and response still require checking.

4. **Half the duration**: Peak torque scales as $1/T_{\text{blend}}$ and jerk as $1/T_{\text{blend}}^2$, so a bridge half as long needs 2.2 N·m, 1,920 rad/s^3, and 352.3 N·m/s, still inside the limit.

Result: The one-tick step passes a torque check and asks for 36.7× the torque-rate limit; the bridge passes both with a 33.3× smaller torque peak.

Systems insight: Evaluating torque magnitude alone is an inadequate feasibility screen at a trajectory seam. Actuator drives fail on the rate of change of torque, which grows quadratically ($1/T_{\text{blend}}^2$) as blending duration compresses. When late trajectory admission forces the system to compress bridge duration T_{blend}, required jerk and torque slew rates increase fourfold for every twofold reduction in duration. An admission monitor must explicitly re-evaluate the compressed bridge rather than inheriting validity from the uncompressed nominal profile. Furthermore, link inertia, payload mass, gravity, and joint friction compound this inertial baseline, requiring independent peak torque and thermal budget verification. The torque verdict of step 1 depends on that exclusion. With the payload inertia of equation 11.7 included, 1.65 kg·m^2 in place of 0.18 kg·m^2, the one-tick request grows by the same ratio and exceeds even the 127 N·m repeated peak, so the one-tick step fails the torque check as well.

High-frequency chatter in learned policy outputs represents an identical physical hazard under a different guise. Stochastic sampling policies, such as diffusion policies or action-chunking transformers, often generate consecutive trajectory chunks where individual waypoints satisfy static position and velocity limits, yet commanded accelerations reverse sign erratically between steps. Each acceleration reversal demands an immediate torque reversal from the actuator, triggering

rapid current transitions and severe $i_q^2 R_{\text{phase}}$ resistive heating in the motor windings. In physical AI systems, engineers must treat this high-frequency variance as a direct cause of thermal rise and transmission fatigue rather than cosmetic jitter. A trajectory candidate that excites structural resonances or exceeds drive thermal dissipation limits is infeasible, regardless of how closely its geometric path resembles demonstration data.

11.4.5 Time parameterization under torque and jerk bounds

A collision-free curve through configuration space says where the arm goes. It says nothing about how fast the arm may travel along that curve without saturating a joint's torque limit on the way up or demanding an impossible torque step when it switches to braking. Geometric search and neural proposal generators determine only the spatial path of motion: a curve $\mathbf{q}(s)$ parameterized by scalar path coordinate $s \in [0, 1]$. The timing law $s(t)$ governs the physical motion, determining every joint velocity, acceleration, and torque required along the trajectory. Establishing a valid timing profile $s(t)$ subject to physical actuator limits is the problem of **time parameterization**. Applying the chain rule to the joint coordinates yields:

$$\dot{\mathbf{q}} = \mathbf{q}'(s)\,\dot{s}, \qquad \ddot{\mathbf{q}} = \mathbf{q}'(s)\,\ddot{s} + \mathbf{q}''(s)\,\dot{s}^2$$

where primes denote differentiation with respect to path coordinate s ($d\mathbf{q}/ds$ and $d^2\mathbf{q}/ds^2$). Substituting these path derivatives into the unconstrained manipulator equation from equation 11.8 expresses joint torque as a function of three path-dependent terms:

$$\tau = \mathbf{a}_\tau(s)\,\ddot{s} + \mathbf{b}_\tau(s)\,\dot{s}^2 + \mathbf{g}(s) \tag{11.15}$$

with vector coefficients $\mathbf{a}_\tau(s) = \mathbf{M}(\mathbf{q})\mathbf{q}'(s)$, $\mathbf{b}_\tau(s) = \mathbf{M}(\mathbf{q})\mathbf{q}''(s) + \mathbf{C}(\mathbf{q}, \mathbf{q}')\,\mathbf{q}'(s)$, and $\mathbf{g}(s) = \mathbf{g}(\mathbf{q})$. Each actuator torque bound $|\tau_i| \le \tau_{\max_i}$ translates into an admissible interval of path acceleration, $\ddot{s}_{\min}(s, \dot{s}) \le \ddot{s} \le \ddot{s}_{\max}(s, \dot{s})$, at every coordinate of the **phase plane** $(s, \dot{s})$. Actuator velocity and acceleration limits introduce equivalent bounding intervals. As path velocity $\dot{s}$ increases, the centrifugal and Coriolis term $\mathbf{b}_\tau(s)\dot{s}^2$ grows quadratically until the admissible acceleration interval closes entirely ($\ddot{s}_{\min} = \ddot{s}_{\max}$). The locus of phase-plane points where this interval collapses defines the maximum velocity curve, representing an upper speed envelope that no feasible parameterization can exceed.

Because total motion duration is $T = \int_0^1 \frac{1}{\dot{s}}\,ds$, the minimum-time profile maintains the highest permissible path velocity $\dot{s}$ at every point along the path. Under torque constraints alone, the time-optimal solution takes a bang-bang form (Bobrow et al. 1985). The system accelerates along the upper bound $\ddot{s}_{\max}$ until its phase-plane trajectory encounters a braking curve integrated backward from the goal at lower bound $\ddot{s}_{\min}$. It then decelerates along $\ddot{s}_{\min}$ to reach the target at rest. Switch points mark the phase-plane coordinates where the trajectory transitions between maximum acceleration and maximum braking. The TOPP-RA algorithm (Pham and Pham 2018) solves this phase-plane parameterization efficiently by transforming it into a convex optimization problem. By substituting squared path velocity $x = \dot{s}^2$ and path acceleration $u = \ddot{s}$, the torque constraints in equation 11.15 and the differential step equation $x_{i+1} = x_i + 2\,\Delta s\,u_i$ become linear across a grid of N_{grid} path waypoints. (This linear step relation follows from $dx/ds = 2\dot{s}\,(d\dot{s}/ds) = 2\ddot{s}$, matching the kinematic equation $v^2 = 2ad$). A backward integration pass computes the controllable interval of x at each grid point from which the terminal state remains reachable, solving a single linear program per point. A subsequent forward pass selects the largest admissible acceleration u at each step. The complete pass runs in $\mathcal{O}(N_{\text{grid}})$ time, and an empty feasible interval at any point provides constructive proof that no parameterization satisfies the bounds on that grid. Kinematic variants that constrain only joint velocity and acceleration compute this timing structure with lower overhead (Kunz and Stilman 2012). The Kunz and Stilman algorithm serves as the default time-parameterization method in MoveIt 2, which can apply a downstream jerk-limiting filter (MoveIt 2 Documentation 2026).

Napkin Math 11.3: Time-optimal swing of one joint

Problem: The shoulder lifts the rated payload at full planar reach through 0.5 rad, from rest to rest. How fast can it swing, and what does the fastest timing ask of the drive?

Variables:

- Swing $\Delta q = 0.5$ rad (illustrative), with the joint angle itself as the path parameter ($s = q$, measured from the start)
- Inertia $J_{\text{eff}} = 1.65$ kg·m² and payload gravity torque $\tau_g = 20.6$ N·m, held at its horizontal value (derived, payload only)
- Joint limits: torque $\tau_{\max} = 87$ N·m, acceleration 7.5 rad/s², velocity 2.175 rad/s, torque rate $\dot{\tau}_{\max} = 1000$ N·m/s (datasheet (Franka Robotics GmbH 2023))

Math:

1. **Binding acceleration**: The torque limit allows $(\tau_{\max} - \tau_g)/J_{\text{eff}} = 40.2$ rad/s² upward and $(\tau_{\max} + \tau_g)/J_{\text{eff}} = 65.1$ rad/s² braking, an asymmetry that gravity creates. The published 7.5 rad/s² is tighter than both, so it binds in both directions.
2. **Time-optimal swing**: The accelerating curve $\dot{s}^2 = 2a_{\max}s$ meets the braking curve at mid-swing, where speed peaks at $\sqrt{a_{\max}\,\Delta q} = 1.94$ rad/s, below the velocity limit. The swing takes $2\sqrt{\Delta q / a_{\max}} = 516.4$ ms.
3. **Switch-point step**: Acceleration reverses from $+a_{\max}$ to $-a_{\max}$, a torque step $2J_{\text{eff}}a_{\max} = 24.8$ N·m, which needs at least 24.8 ms at the torque-rate limit. That limit bounds jerk at $\dot{\tau}_{\max}/J_{\text{eff}} = 604.8$ rad/s³.
4. **Jerk-limited swing**: A rest-to-rest double-S profile with no cruise covers $\Delta q = a_{\max}\,T_{\text{acc}}\,(T_{\text{acc}} + a_{\max}/j_{\max})$ in $T = 2(T_{\text{acc}} + a_{\max}/j_{\max})$. Because the accelerating half of the swing consists of a constant-acceleration hold framed by two jerk ramps of duration $a_{\max}/j_{\max}$ (one ramping acceleration up to $a_{\max}$ and one ramping it back to zero at mid-swing), $T_{\text{acc}} = T/2 - a_{\max}/j_{\max}$ is half the swing less one jerk ramp (the constant-acceleration hold plus one ramp), giving the trapezoidal acceleration pulse an area equal to the peak speed $a_{\max}T_{\text{acc}}$. With $a_{\max}/j_{\max} = 12.4$ ms, the swing needs $T_{\text{acc}} = 252.1$ ms and takes 528.9 ms.

Systems insight: Enforcing the torque-rate limit incurs an execution penalty of 12.6 ms, a modest 2.4 percent increase in motion duration, while eliminating the instantaneous torque step entirely. For the payload alone, torque was not the binding constraint; the published kinematic limits governed the trajectory, though identified link inertia would narrow this torque headroom. A valid time parameterization must incorporate every constraint capable of binding in practice. The theoretical time-optimal profile without a jerk bound is an unexecutable mathematical abstraction that physical drives reject.

In the phase plane the two profiles differ only near their corners (figure 11.5). The torque limits alone would permit steeper accelerating and braking parabolas, but the published 7.5 rad/s² acceleration limit contracts both arcs, and the bang-bang path rides them to its 1.94 rad/s switch point, well below the velocity limit. The jerk-limited path rounds the start, the apex, and the finish just inside those arcs. That rounding is where its extra 2.4 percent of duration goes, and it is what removes the 24.8 N·m torque step at the switch point.

The time-optimal bang-bang solution produces precisely the derivative discontinuities that safe seam execution forbids. Every transition between maximum acceleration and maximum braking represents a step change in acceleration, demanding an instantaneous step in electromagnetic torque that actuator drives cannot deliver within finite voltage and current slew limits. Incorporating an explicit jerk bound transforms the problem into a third-order trajectory formulation. As the shoulder swing notebook shows, the time cost of bounding jerk is small next to the torque step it removes. Modern motion pipelines therefore parameterize paths under coupled torque and velocity limits and enforce explicit jerk bounds downstream, or constrain jerk directly during parameterization.

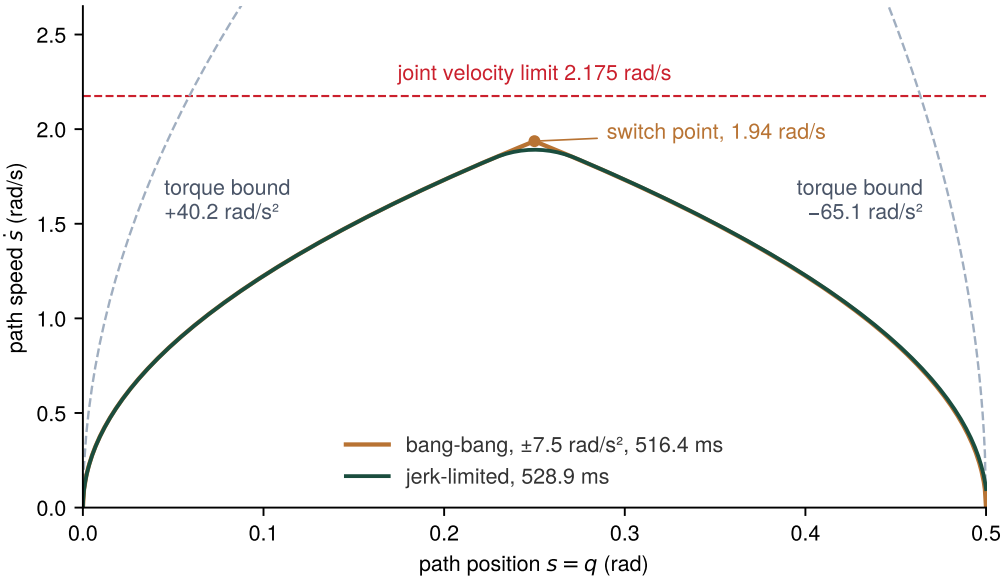

Figure 11.5: Phase plane of the shoulder swing: Path speed $\dot{s}$ against path position s for the 0.5 rad rest-to-rest swing. The joint's 7.5 rad/s² acceleration limit, tighter than either torque-derived bound, sets both the accelerating and braking curves; the bang-bang path follows them to the switch point at 1.94 rad/s, below the velocity limit, in 516.4 ms. The jerk-limited path stays inside it and takes 528.9 ms, 2.4 percent longer, with no torque step at the switch.

An identical jerk-limited profile, synthesized from the robot's verified state, resolves both seam blending and safe stopping. An **online trajectory generator** receives the instantaneous position, velocity, and acceleration of each joint together with a target boundary state, returning a time-optimal profile that satisfies per-axis velocity, acceleration, and jerk limits (Kröger and Wahl 2010). For example, the Ruckig algorithm (Berscheid and Kröger 2021) evaluates arbitrary initial and target states across seven distinct constant-jerk phases, calculating profile durations analytically for most trajectory classes and using a bounded polynomial root solver for asymmetric edge cases. In published benchmarks, Ruckig achieved an average execution latency of 19.8 µs and a worst-case latency of 123 µs for 7 axes on a desktop processor, making it fast enough to re-solve within a 1 kHz control cycle. This formulation differs structurally from the fixed-duration quintic bridge in section 11.4.4. The quintic approach fixes blending duration T_{blend} upfront and risks exceeding joint limits during aggressive maneuvers, so downstream extrema checks must reject invalid solutions. An online trajectory generator instead solves for minimum duration as an optimization variable, which guarantees that kinematic derivative bounds hold by construction. The S-curve stopping trajectory examined in section 11.5.2 represents this exact profile structure evaluated toward a zero-velocity terminal state.

Kinematic feasibility by construction, however, does not grant permission to move. An online generator guarantees only the mathematical bounds explicitly configured in its parameters. Single-axis velocity, acceleration, and jerk bounds cannot account for multi-joint dynamic coupling in equation 11.8, spatial swept-volume collisions, or stale perception data. Furthermore, configuration errors or numerical solver faults can directly compromise the guarantees the generator claims to provide. Real-time benchmarks reported on high-performance desktop CPUs also do not represent execution latency on a constrained safety MCU. Online generators produce higher-quality proposals that satisfy kinematic constraints by design, but the deterministic safety controller must independently validate dynamic feasibility, collision margins, and temporal deadlines before granting execution permission. Even a candidate trajectory that passes every internal dynamic and seam continuity check remains unsafe without an admitted contingency. The system must therefore continuously maintain a certified stopping suffix to handle replacement chunks that fail to arrive before the admission deadline.

Checkpoint 11.2: Followable motion and the seam

A collision-free candidate becomes followable only after its joint rates, its seams, and its timing fit the body's limits.

Mapping and sampling

- ☐ **Singularity cost**: Explain why the 1 m/s TCP limit bounds no joint speed near a straightened elbow, and what damped least squares gives up to bound the inverse-kinematics step there.
- ☐ **Contracted limit**: Explain why two velocity samples inside their limit can bracket an interior over-speed, and when the smaller reserve of a jerk-bounded interpolant may be used.

Pricing the seam

- ☐ **Bridge estimate**: If the 50 ms bridge of notebook 11.2 must shrink to 10 ms to fit a late admission, estimate its peak inertial torque and peak torque rate, and decide whether it still fits the arm's 1,000 N·m/s torque-rate limit.
- ☐ **Executable timing**: Why does the time-optimal swing ask the drive for a step it refuses, and what does a jerk bound cost the shoulder swing in time?

11.5 Behavior at the Seam

When the replacement does not arrive, because inference stalls on scheduling interference, a bus fault, or an unhandled exception, the arm reaches the end of its authority with no successor in hand. The runtime must then bring it to rest without violating the limits derived above or exhausting its stopping clearance. Three things decide the outcome: which deadline has passed, which stop the MCU runs, and how much clearance that stop consumes.

11.5.1 Replacement deadlines and commitment cutoffs

A single timeout cannot protect both a fast control loop against a hung proposer and a moving arm against overrunning its obstacle clearance. A lease short enough to catch a dropped packet fires long before the geometric point of no return. A cutoff placed at the point of no return leaves a stalled policy coasting blind in the meantime. The two tiers named with the trajectory record in section 11.2, the periodic chunk lease and the commitment cutoff, therefore answer different questions: whether a replacement has renewed tracking authority recently enough, and whether the reserved stop can still begin in time. The planner also uses a soft *blend deadline* (t_{blend}), a scheduling target for a smooth replacement. Missing that target need not end tracking if the current lease and evidence remain valid and a checked replacement can still arrive before the admission cutoff that precedes physical commitment (t_{commit}). The earlier admission cutoff leaves the response interval needed for the matched stopping suffix to begin at commitment, before its reserved clearance is spent.

The two deadlines call for two different stops:

- **Matched stop suffix (planned termination at $t = t_{\text{commit}}$):** A pre-computed, jerk-limited C^2 slowdown along the admitted path, anchored specifically at the nominal state expected at t_{commit}, checked at admission to satisfy $d_{\text{stop}} \le D_{\text{clear}}$. If no successor is admitted before the earlier admission cutoff, the controller dispatches the stop early enough that the body smoothly transfers to this pre-latched suffix at commitment, decelerating to rest without requiring runtime replanning.
- **State-matched fallback (reactive termination at $t < t_{\text{commit}}$):** If the high-rate chunk lease lapses, the parent intent expires, or a runtime safety monitor detects an unmodeled obstacle or torque fault *before* reaching t_{commit}, the robot cannot use the matched stop suffix (which is anchored at the future state t_{commit}). Instead, the MCU selects or constructs a validated state-matched fallback from current state estimates $(q, \dot{q}, \ddot{q})$ within reserved clearance. Encoder-derived velocity and acceleration have their own error bounds; bounded polynomial evaluation does not eliminate sensing, dispatch, or actuator response delay.

Both are the stopping suffix that every admitted trajectory carries (definition 11.1), differing only in the entry state from which they start. For the running mug reach, a stalled proposer expires the shared lease 60 ms after the last admission. The MCU then requests its state-matched fallback; physical onset follows the separately budgeted response delay. All timeout checks use the MCU monotonic clock. The longer-lease comparison isolates the geometric limit: even with tracking evidence continually renewed, the controller must dispatch the matched stop early enough to begin at commitment. A host progress report changes neither cutoff. Both stops also inherit the seam's continuity requirement, and that requirement fixes their shape and therefore their length.

11.5.2 The C^2 stopping suffix and jerk-limited braking

A moving robot carries continuous momentum. If an emergency brake uses an idealized constant-deceleration profile ($\ddot{q}_{\text{stop}}(t) = -a_{\text{brake}}$), the commanded acceleration steps discontinuously from zero to $-a_{\text{brake}}$ at t_{commit}, and steps discontinuously back to zero when velocity reaches zero. This instantaneous switch demands an infinite jerk impulse ($\dddot{q}_{\text{stop}} = \infty$) and an instantaneous step jump in actuator braking torque ($\Delta\tau = J_{\text{eff}} a_{\text{brake}}$). A real drive can only approximate that step. Whether the response loses traction, disturbs the payload, or exceeds structural limits depends on the load and controller, so the worked design chooses an explicitly smooth profile.

Two bounds describe what the load and the drive tolerate during that stop: a peak deceleration $a_{\max}$ and a peak jerk $j_{\max}$, the rate at which deceleration may change. A C^2 stop keeps position, velocity, and acceleration continuous at both ends, so it must ramp its deceleration up from zero and back down to zero, and the jerk bound limits how quickly it can do either. Within those bounds, the shape of the profile decides how far the machine travels. Consider a cruise entry with position $q_{\text{stop}}(t_{\text{commit}}) = q_c$, cruise speed $v_c > 0$, and zero entry acceleration. One smooth candidate is the lowest-order polynomial that matches position, velocity, and acceleration at both ends, written in the normalized time $u = (t - t_{\text{commit}})/T_{\text{stop}} \in [0, 1]$:

$$q_{\text{stop}}(u) = q_c + v_c T_{\text{stop}} \left(u - u^3 + \frac{1}{2} u^4 \right), \qquad \ddot{q}_{\text{stop}}(u) = -\frac{6 v_c}{T_{\text{stop}}} u(1-u), \qquad \dddot{q}_{\text{stop}}(u) = -\frac{6 v_c}{T_{\text{stop}}^2}(1-2u) \tag{11.16}$$

Its deceleration is an inverted parabola that peaks at the midpoint, $a_{\text{peak}} = 1.5\, v_c / T_{\text{stop}}$, and its jerk is largest at the two ends, $6 v_c / T_{\text{stop}}^2$. Holding the peak at $a_{\max}$ gives $T_{\text{stop}} = 1.5\, v_c / a_{\max}$ and a distance of $\frac{1}{2} v_c T_{\text{stop}} = 0.75\, v_c^2 / a_{\max}$, which is 1.5 times the constant-deceleration distance $v_c^2 / 2a_{\max}$. That factor is a property of this polynomial, not of smooth stopping. The polynomial touches its peak deceleration only at the midpoint and spends half the stop below three quarters of it, so it gives away distance that its own bounds would allow it to use.

The profile that uses those bounds fully is the **jerk-limited S-curve** (trapezoidal acceleration, the "double S" velocity profile) (Biagiotti and Melchiorri 2008). It ramps deceleration from zero to $a_{\max}$ at the jerk limit, holds $a_{\max}$, and ramps back to zero at the jerk limit just as velocity reaches zero. Each ramp lasts $a_{\max}/j_{\max}$. The velocity profile is point-symmetric about its midpoint, so the distance is half the entry speed times the duration:

$$d_{\text{stop}}(v) = \begin{cases} \dfrac{v^2}{2a_{\max}} + \dfrac{v\, a_{\max}}{2 j_{\max}}, & v \geq a_{\max}^2 / j_{\max} \\ v\sqrt{v / j_{\max}}, & v < a_{\max}^2 / j_{\max} \end{cases} \qquad T_{\text{stop}}(v) = \begin{cases} \dfrac{v}{a_{\max}} + \dfrac{a_{\max}}{j_{\max}}, & v \geq a_{\max}^2 / j_{\max} \\ 2\sqrt{v / j_{\max}}, & v < a_{\max}^2 / j_{\max} \end{cases} \tag{11.17}$$

Above the threshold speed $a_{\max}^2 / j_{\max}$, the stop costs constant-deceleration braking at $a_{\max}$ plus cruise over half of one jerk ramp, $a_{\max}/2j_{\max}$, so a finite jerk limit acts like extra reaction time. Below the threshold the stop is too short to reach $a_{\max}$, and its deceleration peaks at $\sqrt{v j_{\max}}$. Among stops that respect both bounds and never reverse, this profile reaches rest in the least time and the least distance. The shape of the stop, not physics, sets the distance beyond $v^2 / 2a_{\max}$, and for given deceleration and jerk bounds the S-curve spends the least. A slower profile remains admissible, but it must be charged at its own distance.

The jerk bound belongs to the load. The loaded tote rack and the mug tolerate a deceleration only if it is reached gradually, and the registry does not yet hold a measured jerk tolerance for either.

The worked design therefore sets each body's $j_{\max}$ to the peak jerk of equation 11.16 at that body's peak deceleration and top speed, a jerk the polynomial already asked the load to accept. A loaded stopping trial that measures the tolerable jerk would replace this stipulation, and equation 11.17 would then give the distance directly.

The stop is also a slowdown along the admitted path, not a new path. The planner fixes the geometry $\mathbf{q}(s)$ it checked for clearance, and the S-curve governs only the speed $\dot{s}(t)$ along that geometry. The stop therefore sweeps no volume outside the corridor already checked, and the one-dimensional comparison $d_{\text{stop}} \le D_{\text{clear}}$ applies along the path. A stop computed separately for each joint would leave that path and would need its own swept-volume check. A nonzero measured entry acceleration requires a profile matched to the actual $(q, \dot{q}, \ddot{q})$ at entry with zero terminal velocity and acceleration; the permission path checks its interior speed, acceleration, jerk, torque, and clearance.

In the alternate longer-lease arm case, the blend deadline is 240 ms, matched commitment 300 ms, nominal setpoint end 400 ms, and stop end 575 ms, so the stop lasts 275 ms. At the arm's 1 m/s TCP speed limit, the S-curve suffix with a 5 m/s² deceleration bound and a 66.7 m/s³ jerk bound travels 137.5 mm, compared with 150 mm for the polynomial of equation 11.16 with the same peaks. Because the blend deadline is the preferred admission instant on this schedule, the last scheduled validation and clearance evidence finish at 240 ms. The 60 mm of cruise between 240 ms and physical brake onset at 300 ms must therefore be charged against that clearance alongside the stop. Together they consume 197.5 mm in all, leaving 102.5 mm of the 300 mm obstacle clearance before sensing and model error are deducted. Because 300 ms is **physical suffix onset**, the MCU must close replacement admission and pretrigger any communication or actuator delay δ by that instant minus δ. Otherwise, the arm travels an extra $v_c\delta$, shifts the stop end later, and shrinks the 102.5 mm margin. Nominal setpoints end at 400 ms while MCU STOP continues to 575 ms, assuming fresh target evidence keeps TRACK valid until stop dispatch (section 11.3).

On the running machine, as the alternate schedule's introduction noted, a stall never reaches commitment because the chunk lease lapses first, so its stop is the state-matched fallback. From zero-acceleration cruise the S-curve matches the arm at whatever instant it starts, and it slows the tool along the path already checked, so the state-matched fallback travels the same distance as the matched stop suffix. On the arm, as on the base, the chunk lease is a term of the stopping budget, the rule established in section 4.4; the arm's own speed, stop, and clearance set what that term costs.

DRAFT

Napkin Math 11.4: The stall runway

Problem: The proposer stalls while the arm reaches at its TCP limit, and no replacement is admitted. How much of the obstacle clearance does the arm use between its last admission and rest, and how much remains?

Variables:

- Chunk lease $T_{\text{lease}} = 60$ ms (chosen); permission tick 1 ms (derived) and bus cycle 1 ms (illustrative); onset 20 ms (illustrative, the base's registered brake onset charged conservatively to the arm)
- Speed $v = 1$ m/s (chosen, TCP limit)
- Deceleration bound $a_{\max} = 5$ m/s² (illustrative) and jerk bound $j_{\max} = 66.7$ m/s³ (derived, the peak jerk of equation 11.16 at the same peak)
- Clearance $D_{\text{clear}} = 300$ mm (illustrative)

Math:

1. **Response path**: 60 ms + 1 ms + 1 ms + 20 ms = 82 ms from last admission to stop onset, which is 82 mm at v.
2. **Branch test** (equation 11.17): $a_{\max}^2 / j_{\max} = 0.375$ m/s, below v, so the stop reaches $a_{\max}$.
3. **Stop**: $v^2/2a_{\max} + v\,a_{\max}/2j_{\max} = 100$ mm + 37.5 mm = 137.5 mm, in $v/a_{\max} + a_{\max}/j_{\max} =$ 200 ms + 75 ms = 275 ms.
4. **Clearance**: 82 mm + 137.5 mm = 219.5 mm of 300 mm.

DRAFT

Result: The stall leaves 80.5 mm of geometric margin, before sensing and model reserves.

Systems insight: The travel before the stop begins is 59.6 percent of the stop itself, and at this speed every millisecond of lease costs a millimeter. The remaining margin equals only 80.5 ms of further lease, so the lease length is a term of $d_{\text{stop}} \le D_{\text{clear}}$ exactly as the deceleration bound is.

While hardware qualification must establish the arm's actual response in place of the charged onset allowance, the two schedules leave different geometric margins because they date their clearance evidence differently (figure 11.2). The running lease charges travel from the last admission (82 mm) plus the 137.5 mm stop, which keeps 80.5 mm. The alternate schedule charges only the cruise from its blend deadline, when clearance was last checked, to commitment (60 mm) plus the same stop, which keeps 102.5 mm. The alternate schedule's 278 ms admission cutoff is therefore an offset on its own time axis rather than a lease length that the running clearance could support. Any lease, whatever its length, must fit its own evidence age, response travel, stop, and uncertainty reserve, just as the running lease does in the notebook above.

Although the free-space deceleration bound suits the empty-gripper reach toward the mug, it is too aggressive once the arm carries an open mug of liquid away from the conveyor, because container acceleration tilts the free surface and excites sloshing (Mayer and Krechetnikov 2012). Under a steady deceleration a, the free surface settles perpendicular to the effective gravity, tilting by $\tan\theta_{\text{tilt}} = a/g$ and raising the liquid at the wall by $R\,a/g$ for inner radius R. In an illustrative mug of 40 mm inner radius filled to 10 mm below the rim, the free-space stop's 5 m/s² deceleration raises the liquid 20.4 mm at the wall, well past the rim. Keeping even the steady tilt inside the freeboard h_f (a necessary condition, since dynamic sloshing overshoots the steady tilt) limits deceleration to $g\,h_f/R$, or 2.45 m/s². At that gentler bound, with the jerk the polynomial reaches at the same peak, the stop from the 1 m/s TCP limit lengthens to 280.4 mm and, together with the running lease path, demands 362.4 mm of the 300 mm clearance. The loaded carry must therefore run slower than the empty reach. Before sensing and model reserves are deducted, the highest speed whose lease path and stop fit that clearance is 0.89 m/s. The trajectory record's assumption sidecar must declare which payload regime and measured slosh limit (or lid) the record assumes.

At the TCP limit, the open mug's gentler stop overruns the clearance the empty reach fits.

The commitment deadline forbids waiting. In the alternate arm schedule, commitment preserves the 102.5 mm margin computed from clearance dated at 240 ms. Missing the 278 ms admission cutoff and delaying stop dispatch by 200 ms would delay physical stop onset that far past commitment. Cruise at the TCP limit would add 200 mm before the same stop and breach the 300 mm clearance by 97.5 mm. A later stop must still match its actual entry state; this counterfactual holds cruise speed constant only to show the lost clearance. An arm that waits that long may already occupy a state from which no admissible control avoids the obstacle.

11.5.3 Inevitable collision states

An arm or base that is still clear of every obstacle at the current millisecond can already be doomed to hit one if its speed and remaining distance leave no control input inside its drive and traction limits that can bring it to rest in time. Classical path planning misses this trap when it treats obstacle avoidance as a static geometric query that asks only whether the robot's configuration overlaps an obstacle volume at the current instant. Because a mobile manipulator moving with momentum and finite braking torque cannot halt instantaneously, its dynamic state (position, velocity, and acceleration, under its traction limits) can cross a boundary beyond which every admissible control trajectory leads to collision long before geometric contact occurs. Such states are inevitable collision states (ICS)[10] (Fraichard and Asama 2004).

10 **Inevitable collision states and viability**: Within the free states, the complement of the ICS set is what Aubin (1991) calls the viability kernel, the states from which some admissible control keeps the system inside its constraints forever. Planning must therefore keep the commitment state inside that kernel, not merely outside the obstacle, and against static obstacles a verified stop to rest is the witness that it is there.

Definition 11.4: Inevitable collision state

Inevitable collision state (ICS) is any dynamic plant state $\mathbf{x}(t) \in \mathcal{X}$ from which every physically admissible future control trajectory $\mathbf{u}_{[t,\infty)} \in \mathcal{U}_{\text{adm}}$ inevitably produces collision with an obstacle or constraint boundary:

$$\mathbf{x} \in \text{ICS}(\mathcal{X}_{\text{obs}}) \iff \forall \mathbf{u}(\cdot) \in \mathcal{U}_{\text{adm}},\ \exists t' \geq t \text{ such that } \mathbf{x}(t') \in \mathcal{X}_{\text{obs}}$$

where $\mathcal{U}_{\text{adm}}$ denotes the admissible control input set bounded by actuator torque, traction, and deceleration limits.

1. **Significance**: Sets the commitment deadline t_{commit} in receding-horizon planning; continuing nominal motion past it without an admitted successor can carry the plant into an ICS, and no later replanning can bring it back out.
2. **Distinction**: Unlike static geometric collision checks that evaluate only instantaneous spatial overlap ($\mathbf{x} \in \mathcal{X}_{\text{obs}}$), an ICS identifies dynamically trapped states where current momentum and finite braking torque make future boundary breach physically unavoidable.
3. **Common pitfall**: Delaying emergency braking in the expectation that an overdue neural planner will complete an evasive path, ignoring that moving mass enters an ICS long before geometric contact occurs.

The commitment deadline t_{commit} and the admission-checked stopping suffix are co-designed precisely so that the machine initiates braking *before* its dynamic state enters an inevitable collision state, ICS($\mathcal{X}_{\text{obs}}$). If an action chunk's stopping suffix requires distance $d_{\text{stop}} > D_{\text{clear}}$, that suffix cannot justify admitting the chunk. Failure of this particular stop does not establish that every admissible maneuver collides, as the definition of an inevitable collision state requires. The architecture nevertheless refuses the proposal because it lacks the independently executable stop on which its permission depends. The safety microcontroller therefore enforces the hard admission invariant:

$$d_{\text{stop}}(t_{\text{commit}}) \leq D_{\text{clear}}(t_{\text{commit}}) \tag{11.18}$$

If the controller delays braking past commitment in the hope that an overdue neural replanner will deliver an evasive path, physical momentum can carry the machine into an ICS from which no admissible control input can prevent impact. The commitment deadline is the deadline form of this boundary, fixed at planning time. Its set form, the recoverable set of plant states from which the resident stop still succeeds, is the stopping envelope that section 12.3 develops for the runtime check.

These deadlines and the stop they protect are fixed at admission, before motion begins. The candidate declares payload, contact, effort, and obstacle assumptions. The MCU first validates its fixed header and lineage. It then checks the complete bounded trajectory and suffix, including the seam $(q, \dot{q}, \ddot{q})$ against the reachable state envelope from its current estimate, interior extrema, clearance, stopping distance, and a feasible response from every state reachable through physical stop onset. A scan over N setpoints is $\mathcal{O}(N)$, even with a fixed maximum N and measured worst-case execution time; after admission, a distinct $\mathcal{O}(1)$ per-tick check reads the current state and local reference. A replacement received after the blend deadline passes the same check with a compressed bridge, whose higher acceleration and torque its extrema must still clear. If the check cannot finish before the earlier admission cutoff, the MCU retains the current record only while its own lease, evidence, and fallback remain valid. A candidate received after commitment cannot restore the spent runway.

The planner proposes the suffix. The MCU latches the validated payload and stop profile into protected memory **before** enabling TRACK, and it dispatches that resident path before commitment without reading host DRAM. A host crash, bus stall, or corrupted shared packet therefore cannot erase the stop. If the measured state falls outside the latched suffix's entry region, the MCU uses the state-matched fallback. Torque disable or a spring brake is not a universal substitute for a controlled stop, especially with a suspended load (section 12.9).

11.5.4 Base stopping budget under jerk-limited deceleration

On the mobile base approaching the rack end at its 1.5 m/s drive limit, the loaded tote rack tolerates the machine's credible 2 m/s² deceleration only when that deceleration is ramped gradually rather than applied as an abrupt step. The base's stop is therefore the S-curve of equation 11.17 with $a_{\max}$ at 2 m/s² and a jerk bound of 7.11 m/s³. That jerk bound is the peak jerk of the polynomial stop from the 1.5 m/s drive limit and the stop jerk bound already listed on the machine card (table 1.2). Under it, every speed above 0.5625 m/s reaches the deceleration plateau. At the drive limit, this suffix lasts 1,031.25 ms and travels 773.44 mm, compared with 562.5 mm for constant-deceleration braking in equation 2.2 and 843.75 mm for the polynomial with the same peaks. Because the jerk ramps cost the equivalent of 140.6 ms of cruise, the suffix adds 210.94 mm to the budget that section 8.4.1 left at 912.9 mm. This raises the running total to 1,123.84 mm and exceeds the 1.10 m rack-end clear distance by 23.84 mm. Because this partial total still omits the unqualified dispatch-to-admission interval, which can only add travel, the 23.84 mm overrun is a conditional design deficit rather than a complete measured response bound.

Plotted as velocity against time, the area under each curve is its stopping distance, and the jerk ramps appear as the rounded start and finish that stretch the S-curve and the polynomial past the constant-deceleration line (figure 11.6). Stacked onto the budget's other terms, only the constant-deceleration stop, which no drive can execute, ends inside the 1.10 m rack-end clearance.

Even the shortest stop under the stipulated bounds leaves a 23.84 mm deficit at the 1.5 m/s drive limit, so the robot cannot cruise at that limit in this aisle under the stated deceleration and jerk bounds. The deficit is narrow and it rests on a stipulated jerk bound, so a measured jerk tolerance could move it in either direction. The machine must either derate its operating speed or detect the boundary with more usable clearance ahead; a longer prediction or evidence lifetime alone creates no stopping room. This is the first law's stopping condition (principle 1) with one more term, because a stop the load can tolerate is a longer stop and the distance it adds comes out of the same clear distance. This calculation concerns the fixed rack-end boundary. A person entering the aisle requires separately qualified moving-actor bounds and crossing control or an operating restriction; this static clearance calculation does not establish that protection. Under the selected body and aisle constraints, reducing speed can recover clearance. Section 12.3 adds the tracking allowance and derives a candidate speed; permission to operate still requires complete capture-to-admission timing, positive stopping reserve, and qualification under the declared conditions.

↩ The intrusion distance an approaching pedestrian adds to the stopping budget, and the site controls it demands, are established in section 9.7.

For either body, the admission and fallback decisions in table 11.2 are distinct from an emergency power cut. The mug reach and the aisle approach now have a complete execution argument: a timed prefix, a checked seam, and a stop reserved under stated conditions. With those obligations fixed, trajectory generators can be compared by the candidate work they perform rather than by treating their outputs as permission.

Table 11.2: Tracking and fallback decisions: A host crash does not remove a latched stop. TRACK is the nominal mode; STOP is the stop rung of the fallback ladder in section 12.9.1.

State	Trigger	MCU action and required evidence
TRACK, ordinary handoff	Replacement passes the complete admission check before the admission cutoff preceding commitment.	Latch the new nominal path and its own stop, then transfer at a checked C^2 seam.
TRACK, late candidate	Candidate arrives after the blend deadline but before the admission cutoff preceding commitment.	Admit only if the compressed bridge, full path, stop, and timing still fit; otherwise retain the current record only while its own permission remains valid.
STOP, matched suffix	No successor admitted by the earlier cutoff.	MCU follows its protected suffix from the validated entry state; nominal tracking may end while STOP continues.
STOP, earlier invalidation	Lease lapse, intent expiry, contact, state mismatch, or fault before physical stop onset.	MCU selects the state-matched fallback with reserved clearance.
Fault response	Controlled stop cannot be assured from measured state.	Use the machine-specific risk response (which may include drive inhibit, brake, or compliance) only under its validated load and timing assumptions.

DRAFT

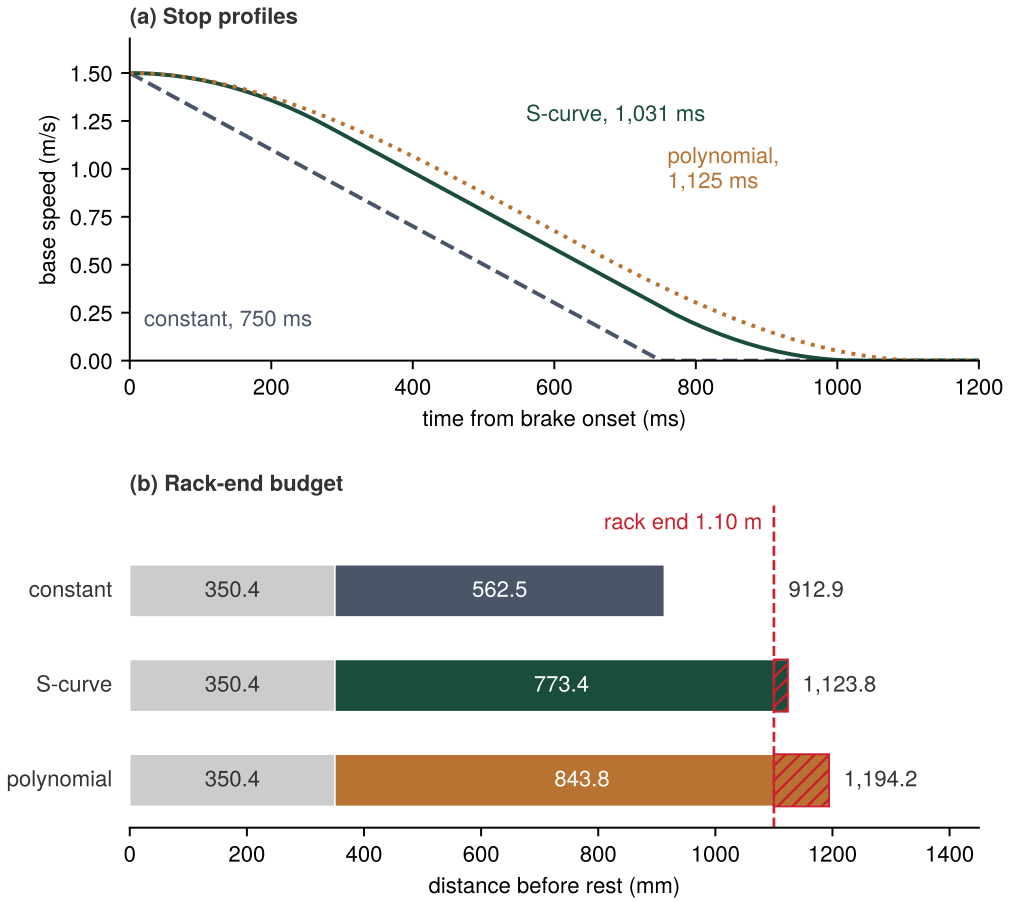

Figure 11.6: Three stops from the drive limit: Velocity against time for the base's stop from 1.5 m/s under the same 2 m/s² deceleration bound (a), and each stop added to the budget's other terms against the 1.10 m rack-end clearance (b). The area under each velocity curve is its stopping distance. Constant deceleration, which no drive can execute, fits with 562.5 mm of braking; the jerk-limited S-curve, the shortest stop under the stipulated bounds, needs 773.44 mm and passes the clearance by 23.84 mm; the polynomial with the same peaks needs 843.75 mm.

Checkpoint 11.3: Commitment and full stopping clearance

Before committing an autonomous machine to an action chunk, verify your understanding of commitment deadlines, stopping budgets, and trajectory continuity:

- ☐ **Deadline distinction**: Distinguish nominal setpoint end, physical stop completion, and the end of the evidence horizon.
- ☐ **Continuous entry**: Why would a constant-deceleration switch fail C^2 matching at zero-acceleration cruise entry?
- ☐ **Clearance and latency**: The arm's 102.5 mm margin already charges cruise from the blend deadline to commitment. Where must an unreserved delay δ beyond it be charged, and how much of that margin does $v_c\delta$ consume?

11.6 Choosing a Trajectory Generator

When a mobile manipulator reaches around a conveyor guard, a planner that searches configuration space can run out of time before finding a route. A local trajectory optimizer can get trapped in a

non-convex pocket behind the guard. A learned action-chunk policy can propose a smooth reach that clips the guard or exceeds a joint's torque limit. The three algorithmic families that propose motion, geometric search, continuous optimization, and learned action chunking, each fail in a different way if treated as self-certifying. In all three paradigms, deciding where the body can travel geometrically remains separate from determining how quickly actuators can safely traverse that path. Regardless of which family generates a proposal, the resulting trajectory remains an unverified candidate that requires exhaustive dynamic validation before the execution engine commits it to the hardware.

The conveyor reach also fixes what each family can afford. A replacement must be admitted every 50 ms, and 18 ms of every replacement's dispatch-to-admission allocation is already reserved for whole-plan validation, while a chunk policy spends another 40 ms of it on inference. To sustain the intended renewal cadence, the generation pipeline must provide both the allocated latency and the throughput that overlapping requests require. A solver without a bounded completion time needs a timeout that leaves the resident fallback executable; it can also run outside the renewal loop, planning the route around the guard and handing the loop a corridor to follow. That deadline, more than the quality of the motion, sorts the three families below.

Sampling-based geometric planners explore configuration space without requiring an explicit algebraic representation of obstacles. Probabilistic Roadmaps (PRM) (Kavraki et al. 1996) construct multi-query roadmaps by sampling collision-free configurations and connecting nearby neighbors with local collision-free segments, amortizing graph construction costs across multiple tasks. Conversely, Rapidly-exploring Random Trees (RRT) (LaValle 1998) target single-query problems by growing a space-filling tree from the initial configuration toward unexplored territory. Its asymptotically optimal counterpart, RRT* (Karaman and Frazzoli 2011), continuously rewires parent connections within local neighborhoods as samples accumulate, ensuring that the discovered path cost converges almost surely to the theoretical optimum (Karaman and Frazzoli 2011). These methods resolve geometric routes through complex obstacle geometry, yet their completeness guarantees remain strictly probabilistic: the probability of discovering a feasible path approaches one only as the number of samples approaches infinity. When a sampling planner exhausts its computation budget without finding a path, its timeout provides no proof that the route is obstructed. The admission logic must therefore treat planner silence as an unresolved proposal rather than a verified safety determination. Furthermore, evaluating configuration samples and connecting edges requires repeated collision queries against environment geometry, usually accelerated by enclosing the manipulator links in bounding spheres or capsules, and these queries dominate the planner's run time. Even when successful, search yields only an un-timed geometric path with discontinuous derivative transitions. The system must still apply time parameterization, smooth corner blends, joint torque verification, and a valid stopping continuation before dispatching the trajectory to physical actuators.

The complementary classical formulation is **constrained continuous trajectory optimization**, exemplified by Covariant Hamiltonian Optimization for Motion Planning (CHOMP) (Ratliff et al. 2009), TrajOpt (Schulman et al. 2014), and receding-horizon Model Predictive Control (MPC) (Tedrake 2023; Lynch and Park 2017). Rather than evaluating discrete graph nodes, continuous trajectory optimization represents motion as a continuous, time-indexed curve $\mathbf{q}(t)$ and minimizes an objective functional that balances dynamic smoothness against obstacle proximity:

$$\min_{\mathbf{q}(t)} \quad \mathcal{U}[\mathbf{q}] = \int_0^T \left(\frac{1}{2} \|\ddot{\mathbf{q}}(t)\|^2 + \lambda_{\text{obs}} c_{\text{obs}}(\mathbf{q}(t)) \right) dt$$

subject to physical boundary conditions and actuator invariants:

$$\mathbf{q}(0) = \mathbf{q}_0, \quad \dot{\mathbf{q}}(0) = \dot{\mathbf{q}}_0, \quad \ddot{\mathbf{q}}(0) = \ddot{\mathbf{q}}_0$$

$$\mathbf{q}(T) = \mathbf{q}_{\text{goal}}, \quad \dot{\mathbf{q}}(T) = \mathbf{0}, \quad \ddot{\mathbf{q}}(T) = \mathbf{0}$$

$$|\dot{\mathbf{q}}(t)| \leq \dot{\mathbf{q}}_{\max}, \quad |\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})| \leq \tau_{\max}$$

While CHOMP performs functional gradient descent and TrajOpt solves sequential convex subproblems using signed-distance collision constraints, both rely on local optimization. Consequently, non-convex obstacle geometry can trap the solver in infeasible local minima or geometric dead ends. Graphs of Convex Sets (GCS) resolve this susceptibility when the collision-free configuration space

can be partitioned beforehand into convex regions. Finding the global sequence of regions and optimizing the polynomial spline within them then formulates as a mixed-integer convex program whose convex relaxation can be solved efficiently (Marcucci et al. 2023). Because generating these convex decompositions requires substantial offline computation, GCS suits static structures such as the conveyor guard far better than dynamic, rapidly shifting environments. Although geometric search or learned policies can propose alternative routes around unforeseen obstructions, any candidate motion must still undergo explicit verification against dynamic torque limits and actuator constraints.

Repeatedly re-optimizing from an updated state estimate forms the operational foundation of classical **Model Predictive Control (MPC)**[11]. In this receding-horizon paradigm, an optimizer computes an optimal trajectory over a finite horizon T, dispatches an initial prefix to the actuator controllers, and re-solves the problem from the newly observed state on the subsequent cycle. The objective functional ranks candidate motions by performance, while hard constraints eliminate trajectories that exceed physical limits. Classical discrete-time MPC frames this trade-off as a constrained numerical optimization problem over steps $k = 0, \dots, N_{\text{mpc}} - 1$ (Tedrake 2023; Lynch and Park 2017):

$$\begin{aligned} \min_{\mathbf{u}_{0:N_{\text{mpc}}-1}} \quad & \sum_{k=0}^{N_{\text{mpc}}-1} \ell(\mathbf{x}_k, \mathbf{u}_k) + \ell_f(\mathbf{x}_N) \\ \text{subject to} \quad & \mathbf{x}_{k+1} = f(\mathbf{x}_k, \mathbf{u}_k), \quad k = 0, \dots, N_{\text{mpc}} - 1 \\ & \mathbf{x}_k \in \mathcal{X}_{\text{safe}}, \quad \mathbf{u}_k \in \mathcal{U}_{\text{adm}}, \quad k = 0, \dots, N_{\text{mpc}} - 1 \\ & \mathbf{x}_N \in \mathcal{X}_f \end{aligned} \tag{11.19}$$

The variables in equation 11.19 decouple the predicted state sequence $\mathbf{x}_k$ from the selected control inputs $\mathbf{u}_k$. The dynamic transition map $f(\mathbf{x}_k, \mathbf{u}_k)$ propagates the system state forward, requiring every intermediate step to remain admissible. The stage cost $\ell(\mathbf{x}_k, \mathbf{u}_k)$ penalizes tracking error and control effort, while the safe state set $\mathcal{X}_{\text{safe}}$ enforces collision margins derived from the spatial perception pipeline. The admissible control set $\mathcal{U}_{\text{adm}}$ bounds actuator torques and voltages according to verified hardware limits.

The terminal constraint forces the horizon endpoint into a **terminal invariant set**, $\mathbf{x}_N \in \mathcal{X}_f$. In classical control theory, *recursive feasibility* guarantees that if a feasible solution exists at control cycle i, a feasible solution remains provably discoverable at cycle $i+1$. Establishing this property requires an accurate dynamic model and a terminal set $\mathcal{X}_f$ within which an invariant fallback control law maintains safety indefinitely. In an embodied robotic system, this terminal invariant is implemented through a validated braking continuation that brings the machine to rest within verified spatial clearance ($d_{\text{stop}} \leq D_{\text{clear}}$). Bringing the machine to a standstill does not guarantee indefinite safety on its own, because dynamic obstacles can move into the workspace of a stationary robot unless external interlocks preserve the boundary.

Continuous-time optimal control problems are typically transcribed into finite-dimensional nonlinear programs through **direct shooting** or **direct collocation**.[12] Direct shooting forward-integrates the control trajectory $\mathbf{u}(t)$, yielding a compact optimization problem that can nonetheless become ill-conditioned over long horizons. Direct collocation parameterizes both states and controls using piecewise polynomial splines, enforcing dynamic defect constraints $\mathbf{f}(\mathbf{x}_k, \mathbf{u}_k) - \dot{\mathbf{x}}_k = \mathbf{0}$ at interior knots to generate large, sparse nonlinear programs that converge rapidly near smooth trajectories (Hargraves and Paris 1987). However, theoretical MPC guarantees hold only when the dynamic model is accurate, constraints are satisfied, and the numerical solver finishes before its real-time deadline. Contact transitions, stick-slip friction, and unexpected loads degrade solver convergence, often causing iterations to time out. Learned action chunking eliminates online numerical solves during inference, but neural policies do not enforce the terminal invariant constraint $\mathbf{x}_N \in \mathcal{X}_f$. An unvalidated action chunk can easily end at high velocity where the robot lacks adequate braking room.

Decoupling generation into a learned proposer and a constrained optimizer reconciles statistical representation with physical safety. The learned policy acts as a proposer, generating behavioral candidates conditioned on raw visual tokens and task semantics. A constrained trajectory generator

[11] **Model predictive control**: MPC began in the process industries of the 1970s, in refineries and chemical plants whose slow dynamics left seconds to minutes for each solve; Qin and Badgwell (2003) trace its industrial lineage from the first IDCOM and dynamic matrix control installations. Moving the same receding-horizon loop onto an arm tracked at 1 kHz shrinks that time to milliseconds, which is why a solver's deadline, and not its optimum, decides what reaches admission.

[12] **Direct collocation defects in real-time solvers**: Direct collocation, introduced for trajectory optimization by Hargraves and Paris (1987), turns a continuous-time control problem into a finite nonlinear program by requiring the defect $\Delta_k = \dot{\mathbf{x}}(t_k) - \mathbf{f}(\mathbf{x}_k, \mathbf{u}_k) = \mathbf{0}$ at each collocation point. Contact transitions and unmodeled friction make the problem non-smooth, and the solver then loses its fast local convergence and needs more iterations than a fixed control deadline may allow.

DRAFT

then adjusts the proposed trajectory to satisfy boundary conditions, actuator limits, and spatial clearances. Because this numerical projection can become infeasible or miss its real-time deadline, it operates entirely on the untrusted proposal side of the architecture, upstream of independent safety admission.

Mathematically, this dual-stage architecture formulates trajectory generation as a constrained projection operator $\Pi_{\mathcal{K}}(\hat{\mathbf{a}}_{\text{learned}})$:

$$\mathbf{q}^*(t) = \Pi_{\mathcal{K}}(\hat{\mathbf{a}}_{\text{learned}}) = \arg\min_{\mathbf{q}(t)} \int_0^T \|\mathbf{q}(t) - \hat{\mathbf{q}}_{\text{learned}}(t)\|^2_{\mathbf{W}_q} dt + \int_0^T \|\ddot{\mathbf{q}}(t)\|^2_{\mathbf{W}_j} dt \tag{11.20}$$

The projection begins at the planned activation seam, so its initial-state constraints refer to that seam rather than to the state measured when the planning request begins. Upstream synthesis uses the projected reference and its reachable-state envelope; at activation, the MCU instantiates and checks the bounded bridge against measured state. The candidate remains subject to physical boundary conditions and safety invariants across the execution interval $t \in [0, T]$:

$$\mathbf{q}(0) = \mathbf{q}_{\text{actual}}, \quad \dot{\mathbf{q}}(0) = \dot{\mathbf{q}}_{\text{actual}}, \quad \ddot{\mathbf{q}}(0) = \ddot{\mathbf{q}}_{\text{actual}}$$

$$\mathbf{q}(t) \in \mathcal{C}_{\text{free}}, \quad |\dot{\mathbf{q}}(t)| \leq \dot{\mathbf{q}}_{\max}, \quad |\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})| \leq \tau_{\max}$$

$$d_{\text{stop}}(\mathbf{q}(t_{\text{commit}}), \dot{\mathbf{q}}(t_{\text{commit}})) \leq D_{\text{clear}}(t_{\text{commit}})$$

In equation 11.20, the primary term penalizes tracking deviation from the learned nominal trajectory $\hat{\mathbf{q}}_{\text{learned}}(t)$ using positive semidefinite state weights $\mathbf{W}_q$, while the regularization term penalizes joint jerk $\|\ddot{\mathbf{q}}(t)\|^2_{\mathbf{W}_j}$ to minimize mechanical vibration and wear. The weighted quadratic norm is defined as $\|\mathbf{z}\|^2_{\mathbf{W}} = \mathbf{z}^\top \mathbf{W}\mathbf{z}$, and $\mathcal{K}$ denotes the feasible set of trajectories satisfying the displayed physical constraints. These constraints enforce the dynamic invariants that unconstrained learned models cannot guarantee: C^2 continuity with the currently executing state, collision avoidance within the free configuration space $\mathcal{C}_{\text{free}}$, kinematic joint speed bounds, full rigid-body inverse dynamics torque limits, and certified stopping viability at the commitment horizon t_{commit}. Even when the optimizer finds a feasible trajectory, that solution remains contingent on model assumptions regarding payload mass and obstacle positions; the independent admission gate must verify those assumptions before granting hardware permission.

Altering the proposer modifies the computational budget and latency profile, but leaves the physical safety obligations unchanged. Action Chunking with Transformers (ACT) (Zhao et al. 2023) infers an entire chunk of future joint setpoints in a single forward pass and smooths replanning boundaries by ensembling overlapping temporal chunks. However, simple coordinate averaging across predictions fails to enforce higher-order boundary derivatives, which can induce severe acceleration transients at chunk transitions. Diffusion policies (Chi et al. 2025) capture complex, multimodal behavioral distributions through iterative score-based denoising, but the multiple neural network evaluations required during inference add substantial latency to the replacement planning path. Alternatively, a neural model can warm-start a numerical trajectory optimizer by providing initial collocation knots. While a good warm-start drastically reduces sequential quadratic programming iterations, an out-of-distribution observation can seed the optimizer in an infeasible basin of attraction, causing solver divergence and missed execution deadlines. Generator selection therefore balances configuration-space exploration, constrained local tracking, and multimodal perceptual synthesis against the strict temporal deadlines required to validate and admit candidate trajectories. Table 11.3 compares the inputs, constraints, and seam obligations of these synthesis methods. Its sampling-based MPC row, model predictive path integral control (MPPI), rolls many sampled control sequences through the dynamics model and returns their cost-weighted average. MPPI reappears as a base controller in section 11.6.1.

DRAFT

Table 11.3: Comparison of trajectory generation paradigms: Search, optimization, and learned proposals perform different candidate-generation work. Solve time and supported constraints depend on the implementation and problem; every selected pipeline still needs checked dynamics, seams, and stopping clearance.

Trajectory paradigm	Input representation	Dynamic and safety guarantees	Dominant workload	Boundary continuity across replanning
Sampling-Based Graph Search (PRM, RRT*)	Configuration samples $\mathbf{q} \in \mathcal{C}_{\text{free}}$	Route quality depends on the search; dynamics need separate checks	Collision queries	Piecewise-linear (C^0); discontinuous $\ddot{\mathbf{q}}$
Classical Numerical MPC	Low-dimensional state vector $\mathbf{x} \in \mathbb{R}^n$	Constraint and stability guarantees depend on model and assumptions	Constrained solve	Continuity requires explicit boundary constraints
Sampling-Based MPC (MPPI)	State vector and a Euclidean signed distance field (ESDF)	Constraint treatment depends on the formulation and solver	Rollouts or optimization	Requires spline smoothing or terminal costs
Generative Action Chunking (ACT, Diffusion)	High-dimensional multimodal tokens (vision, text)	Empirical demonstration distribution; no formal safety guarantee	Model inference	Discrete samples; requires checked interpolation and seam

The mechanisms in this chapter are durable; the systems that implement them change quickly. Table 11.4 records the named systems a practitioner meets today, each tied to the mechanism it implements. Its final row shifts from the seven-joint arm to the wheeled mobile base, whose rolling wheels constrain the velocity space directly.

Table 11.4: Trajectory generation in practice, as of 2026: Each system implements a mechanism this chapter teaches and remains a proposer in this architecture. Figures come from each system's own paper, measured on its authors' hardware, and are not admission evidence for this machine.

Job in this chapter	System	Mechanism	Reported figure
Time parameterization	TOPP-RA (Pham and Pham 2018)	Reachability analysis over a path grid (section 11.4.5)	$\mathcal{O}(N_{\text{grid}})$ small linear programs for N_{grid} grid points
Online jerk-limited generation	Ruckig (Berscheid and Kröger 2021)	Time-optimal constant-jerk phases from an arbitrary state	19.8 µs mean, 123 µs worst case for 7 axes on a desktop processor
Parallel trajectory optimization	cuRobo (Sundaralingam et al. 2023)	Parallel optimizer seeds, sphere collision model, time step rescaled to the limits	Kinematics and position derivatives only; full dynamics left open
Learned chunk proposals	π_0 (Black et al. 2024)	Flow-matching action chunks executed open loop	50-action chunks; 50 Hz robots re-infer after 25 actions (0.5 s)
Chunk-boundary conditioning	Real-time chunking (Black, Galliker, et al. 2025)	Freeze the actions that run during inference, generate the rest to agree with them	No continuity guarantee stated
Mobile-base local control	Nav2 DWB and MPPI controllers (Macenski et al. 2023)	Velocity-space arcs scored by plugin critics, or sampled control sequences by cost	Both ship in the ROS 2 navigation stack

11.6.1 Mobile-base planning under nonholonomic constraints

Unlike the seven-joint arm, the mobile base cannot follow a straight line interpolated between two poses in the warehouse aisle, because its two coaxial drive wheels roll without slipping and therefore cannot slide sideways along their axle. Expressed in terms of heading angle θ_{head}, forward linear speed v, and yaw rate ω_z, the differential-drive (unicycle) kinematics satisfy

$$\dot{x} = v\cos\theta_{\text{head}}, \qquad \dot{y} = v\sin\theta_{\text{head}}, \qquad \dot{\theta}_{\text{head}} = \omega_z, \qquad \dot{x}\sin\theta_{\text{head}} - \dot{y}\cos\theta_{\text{head}} = 0 \tag{11.21}$$

The non-integrable relation in equation 11.21 forms a **nonholonomic constraint**,[13] restricting the instantaneous velocity space without diminishing the dimension of the reachable configuration space $SE(2)$ (Siciliano et al. 2009). The base can reach any planar pose in the aisle, but not with

[13] **Holonomic** (Greek *holos*, whole, and *nomos*, law): Hertz (1894) introduced the term for systems whose constraints obey integral laws, relations among positions alone, in contrast to material systems in general, which obey only differential laws. A wheel's no-slip rule is a differential law that cannot be integrated into such a relation. The distinction decides the planner's search space, since a holonomic arm can be planned as a path through configuration space while the base must be planned through its controls.

DRAFT

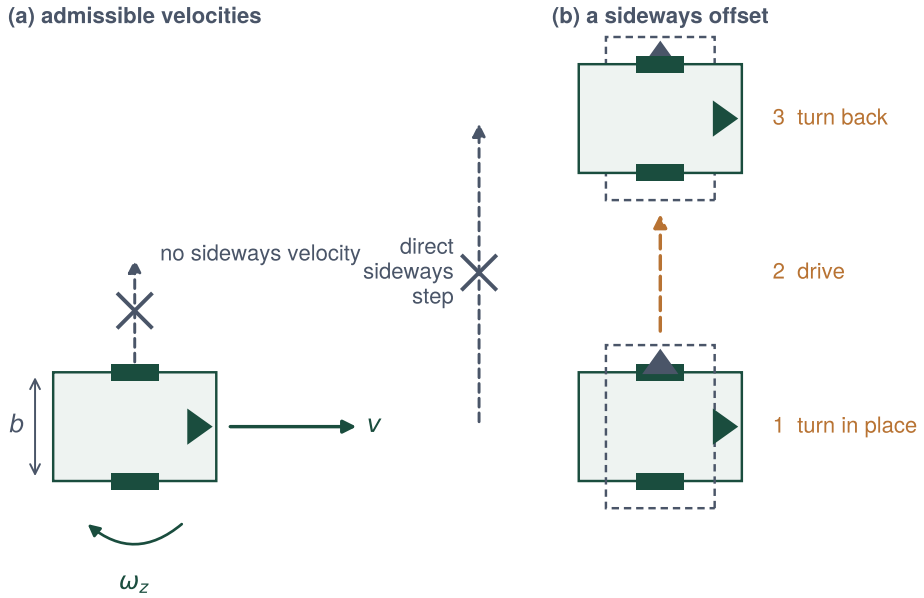

Figure 11.7: What the wheels allow: (a) A differential-drive base with track width b can move forward at v and turn at ω_z about the center of its axle, but its wheels cannot roll sideways. (b) A pure sideways offset is still reachable, as a maneuver rather than a step: turn in place, drive, and turn back. Proportions are schematic.

any velocity. It can drive forward at v and turn at ω_z about the center of its axle, while the no-slip condition forbids translation along the axle (figure 11.7). A pure sideways offset is therefore reached as a maneuver rather than a step: turn in place, drive along the new heading, and turn back. A base planner must therefore search directly over kinematically admissible control trajectories rather than straight geometric paths in configuration space. Furthermore, each wheel's tangential speed equals $v \pm \omega_z b/2$ for track width b, so hardware motor limits constrain linear velocity and turning rate jointly.

Local base planners enforce nonholonomic constraints by planning directly in velocity space over a receding time horizon. The dynamic window approach (DWA) (Fox et al. 1997) maps each control pair (v, ω_z) to a circular trajectory arc and evaluates candidate pairs through two nested dynamic criteria. *Reachable velocities* comprise pairs achievable within actuator acceleration limits over the replanning window. With the mobile manipulator's base acceleration limit of 2 m/s² and a 50 ms chunk renewal interval, this dynamic window spans 0.1 m/s on either side of the current forward velocity. *Admissible velocities* select the subset from which the base can decelerate to a complete stop before reaching the nearest obstacle along that arc, satisfying $v \leq \sqrt{2\, d_{\text{arc}}(v, \omega_z)\, a_{\text{brake}}}$. From these admissible candidates, DWA selects the control pair maximizing an objective that balances target heading alignment, obstacle clearance, and forward speed. MPPI (Williams et al. 2017), the sampling-based MPC of table 11.3, replaces this deterministic velocity grid by rolling forward thousands of stochastic control sequences through the dynamic model on a GPU, synthesizing an optimal control action as a cost-weighted trajectory distribution. Production navigation frameworks such as ROS 2 Nav2 incorporate both controller families (Macenski et al. 2023).

The admissibility test applies the core stopping requirement across candidate arcs, yet its classical textbook formulation assumes instantaneous, constant-deceleration braking. On a straight trajectory with 1.10 m of rack-end clearance, this simplified test admits forward speeds up to 2.10 m/s, well above the physical drive limit of 1.5 m/s. However, when evaluated against the conditional stopping subtotal derived in section 11.5.4 (which accounts for sensor latency, communication delays, localization uncertainty margins, and jerk-limited deceleration), that same clearance fails to guarantee safety even at the nominal drive limit. A mobile-base trajectory generator, whether

a classical DWA planner or a learned chunk policy, is therefore a proposer of candidate velocities. The real-time permission path must also charge dispatch-to-admission travel before validating each proposed trajectory against the full stopping budget.

The choice of trajectory generator governs how candidate motions are discovered and determines the computational burden placed on downstream verification. However, the system's safety enforcement mechanisms must respond consistently regardless of how a proposal was generated. In particular, the execution architecture must cleanly differentiate between rejecting an invalid replacement candidate and responding to unexpected environmental changes. Rejecting an unvalidated proposal leaves the active trajectory in control only while its state, evidence, lease, and stopping reserve remain valid, whereas detecting an unexpected obstacle incursion along the executed path demands an immediate transition to verified braking.

11.7 Trajectory Planning Failure Modes and Infeasible Seams

On the mug reach, a replacement trajectory can fail in three distinct regimes: within the candidate itself, along the boundary where it joins the executing motion, or during execution when the environment changes. The point where a failure first manifests dictates which subsystem has the sensory evidence to reject the trajectory, as well as how much time and clearance remain to bring the machine to a safe stop. Pre-execution candidate and boundary checks intercept the first two failure modes before setpoints can reach actuator registers, whereas runtime monitoring guards against the third.

11.7.1 Checking limits and boundaries before execution

If an unvalidated chunk reaches actuator registers directly, a single out-of-bounds waypoint or an unblended velocity step at the splice instant will fault the drive before feedback monitoring can react. Before any proposed trajectory setpoint can influence actuator registers, a deterministic safety MCU therefore screens the candidate record through two independent admission gates within a measured worst-case execution budget. Fixed-degree seam calculations require bounded compute per axis, whereas checking a complete setpoint sequence scales with the candidate horizon length:

1. **Pre-execution Bound Checker:** Evaluates the proposed neural action chunk in isolation across the full candidate horizon $[t_{\text{start}}, t_{\text{plan_exp}}]$ against intrinsic kinematic, dynamic, and stopping invariants. The checker evaluates margin functions $M(t) = L_{\text{limit}} - |x(t)|$ across the signals it checks. Joint positions $q(t)$ are checked against their limits. Joint velocities are checked against contracted limits $|\dot{q}(t)| \le v_{\max} - \frac{1}{2} a_{\max} T_s$ (equation 11.10, or the $\frac{1}{4}$ reserve under the equal-velocity, zero-acceleration endpoint conditions and jerk bound of section 11.4.2). Free-space inverse-dynamics joint torques are sampled with a bound on their inter-sample variation and checked against the rated torque, $|\tau(t)| = |\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})| \le \tau_{\text{rated}}$. The checker also enforces the binding stopping invariant: the candidate's matched stopping suffix must satisfy $d_{\text{stop}} \le D_{\text{clear}}$ throughout observed free space. If any knot point or interior interval yields $M(t) < 0$ or causes the stopping runway to breach available clearance, the gate immediately rejects the candidate and logs a diagnostic fault record containing the joint index, timestamp, and negative margin. Gate rejection causes neither mechanical shudder nor physical pause, because the low-level tracking controller continues along the previously admitted trajectory as long as that trajectory's state, sensor evidence, lease, and stopping reserve remain valid. A rejected replacement simply fails to renew that lease.
2. **Boundary Checker:** Evaluates the transition seam between the currently executing trajectory A and the candidate replacement B at transition time t_{seam}. Because unconstrained sequence decoders predict open-loop action tokens without terminal derivative matching, concatenating raw chunks frequently produces sharp acceleration steps. The boundary checker addresses this in two stages. During early admission, it screens the reachable seam-state envelope projected from trajectory A. At activation, it incorporates real-time encoder estimates $(\mathbf{q}_{\text{meas}}, \dot{\mathbf{q}}_{\text{meas}}, \ddot{\mathbf{q}}_{\text{meas}})$ and their error bounds to calculate the physical seam gap $(\Delta\mathbf{q}, \Delta\dot{\mathbf{q}}, \Delta\ddot{\mathbf{q}})$. It then evaluates whether an analytical C^2 quintic bridge (equation 11.12) can reconcile the boundary without violating torque limits or the motor drive's voltage and current-slew constraints. A fast one-tick estimate, $\tau_{\text{request}} = J_{\text{eff}} \frac{\Delta\dot{q}}{T_s}$, diagnoses the demand of an unblended one-tick transition. Failure

of that estimate cannot reject a finite bridge by itself; admission checks the bridge at its actual duration, with its endpoint states, interior derivatives, torque and electrical bounds, and swept clearance.

For the CSG-25-50 joint in the seam analysis, an idealized calculation accounts solely for its 0.18 kg·m² reflected rotor inertia over a single 1 ms tick and allocates the entire 127 N·m repeated-peak rating purely to acceleration. It yields an *idealized ceiling* of 0.69 rad/s on that hypothetical one-tick step $\Delta\dot{q}$, not on a finite-duration bridge. In practice, the available torque margin is substantially smaller once link and payload inertia, gravity, friction, feedforward torque commands, coil current rise times, and thermal or DC-bus limits are deducted. The admission path must evaluate the finite bridge against this state-dependent torque margin and the drive's measured step response. The gate nevertheless rejects a step velocity discontinuity outright, even one whose idealized single-tick torque falls below that ceiling, because continuous physical motion requires a smooth, bounded C^2 bridge that satisfies its own interior limit checks.[14]

[14] **Drive and resonance response**: A sharp command can excite a joint's *identified* flexible modes, but their frequencies and damping depend on the transmission and load. Current limiting, desaturation detection, DC-bus response, and shutdown depend on the selected driver and its configuration; one vendor's desaturation-protection design note shows how such trip thresholds are set (Chen and Ramachandran 2025).

↪ The cyclic checking that enforces these trips on every tick, and the independence the monitor needs from the proposer, are developed in section 12.8.

11.7.2 Runtime tracking monitors and unexpected contact

When the arm reaches past the conveyor guard with 0.020 m of budgeted swept-volume clearance, a slipping payload or an unexpected contact after admission can invalidate the dynamic and geometric assumptions under which the plan was cleared. Independent **runtime monitors** must detect this divergence while remaining obstacle clearance still allows a controlled stop. They track four primary signals on every tick: joint state divergence, tracking error velocity, unexpected contact wrenches, and violations of the geometric assumptions declared in the trajectory record's sidecar (section 11.8). This monitoring relies on **spatial margin budgeting**, in which geometric obstacle clearance is not simply awarded to control tracking error. Mechanical compliance under load, structural deflection, and drivetrain backlash consume physical clearance before any feedback tracking error becomes observable at the encoders. The tracking error allowance ϵ_{pos} therefore equals the total swept-volume clearance minus the structural deflection and gearbox compliance allowance δ_{deflect}.

On the conveyor-guard reach, once payload deflection and gearbox compliance claim an allowance δ_{deflect} of 0.005 m, the nominal tracking allowance ϵ_{pos} drops from 0.020 m to 0.015 m. This remainder represents an upper ceiling on allocatable margin rather than a direct trip threshold, because latencies across detection, dispatch, and actuator response, along with state-estimation uncertainty and the swept motion of the fallback maneuver, all require dedicated clearance reserves. The arm tracker's validated tracking bound, the arm's counterpart to the base tracking bound ϵ_{track} that section 12.2 derives, must fit within these 0.015 m and is checked by the real-time safety loop on every control tick. If the measured Cartesian tool-position error $\|\mathbf{p}_{\text{meas}}(t) - \mathbf{r}(t)\|$ exceeds ϵ_{track}, or if a wrist-mounted six-axis force-torque sensor detects an unmodeled 10 N contact during free-space transit, the monitor immediately revokes nominal tracking and commands the validated state-matched fallback. Active physical deceleration begins once the measured detection, communication, and actuator-onset delays elapse.

A trajectory plan can also exhaust its nominal setpoints before a subsequent candidate passes admission. The safety MCU cannot simply allow the execution pointer to overrun the trajectory buffer, nor can it treat a stationary position-hold setpoint as an active, verified stop. Instead, the two deadline tiers of section 11.5.1 end the window of validity on the MCU's monotonic clock, whichever fires first. Furthermore, computing stopping clearance requires accounting for the full physical chain: sensing and detection delays, dispatch latency, actuator torque rise times, and the swept volume across the deceleration profile. Elementary calculations assuming instantaneous or constant deceleration fail to model the true physical trajectory of a smooth C^2 stopping suffix.

Every checker and monitor described here depends on an explicit execution contract between the upstream trajectory generator and the downstream real-time controller. If a planner delivers only a raw sequence of Cartesian or joint waypoints, without its validity lease, clearance margins, boundary derivative bounds, and certified stopping suffix, the low-level permission path has no principled way to distinguish safe nominal motion from dangerous dynamic drift. Safe autonomous execution requires that geometry, dynamics, and timing be verified together before setpoints ever reach actuator registers.

11.8 The Trajectory Record

Suppose the planner hands the low-level controller a bare array of 16 joint setpoints for the reach toward the mug, without the obstacle epoch, payload assumption, and pre-checked stopping suffix under which those setpoints were cleared. The MCU then has no way to tell whether the plan is still safe to run when the host stalls or the load changes. The trajectory record, handed over immutably at every replanning cycle, lets the low-level permission path decide whether to admit those setpoints without consulting the high-level planner again. The record carries the header, four deadlines, two deadline tiers, and assumption sidecar defined with the planning handoff in section 11.2.2. It works as a cyber-physical contract rather than a passive message format. Every field encodes a physical invariant that the downstream runtime can verify before a command crosses the causal boundary.

By pairing a staged admission check with the latched stopping profile of section 11.5.3, the record lets the MCU evaluate safety independently of the host planner. Even if the host operating system crashes mid-motion, the resident emergency stop profile remains intact on the real-time controller. Bringing the physical machine to rest still demands operational sensors, DC bus energy, and mechanical braking authority. The belief record and intent lease consumed at the planning handoff remain embedded in the record's lineage. The completed record binds these physical assumptions directly to the proposed motion before forwarding them to the runtime enforcer, where live sensor feedback governs per-tick tracking permission.

Every field in the contract captures an explicit condition of admission. Kinematic boundary derivatives define how the trajectory must mesh with ongoing motion at the seam. Real-time deadlines dictate exactly when nominal tracking must yield to a safe stop. The accompanying sidecar documents the precise geometric and inertial assumptions under which the validator certified the plan. Instead of taking the planner's assertion of feasibility on faith, the execution runtime uses the record to hold the motion accountable to physical reality.

Hierarchically, the trajectory record answers to the intent lease. The cryptographic digest binds the record to the exact parent lease whose target and effort ceilings the permission path must check against the proposed motion. The motion itself is stored as discrete setpoint arrays or continuous spline coefficients, parameterized by an explicit sample cadence (a 25 ms timestep Δt_{step} on the running machine, a 40 Hz stream). The record also carries the nominal trajectory expiration $t_{\text{plan_exp}}$ (400 ms for a single chunk) and canonical SI units. Pairing this explicit cadence and unit specification with the reference coordinate frame and evidence timestamp established in section 11.2 allows the joint controller to interpolate setpoints and evaluate higher-order derivatives cleanly, eliminating coordinate-frame ambiguities and any reliance on unsynchronized host clocks.

Physical feasibility is never unconditional; it holds only under the environmental geometry and dynamic loads assumed during planning. The immutable sidecar captures these conditions, recording the obstacle-map epoch, payload mass, surface friction coefficients, kinematic limits, validator software version, certified clearance margins, and the source observation identifiers. A cryptographic digest in the fixed header immutably binds this sidecar to the setpoint payload. Because safety proofs cannot extrapolate beyond validated boundaries, the payload and friction values declared in the sidecar must fall strictly within the target operational design domain (ODD) declared in section 7.8. If live sensor feedback indicates that the robot has drifted outside these operating assumptions, the permission path immediately revokes the TRACK state, recognizing that clearance margins computed for one world state do not hold in another. Diagnostic metadata, such as random solver seeds and neural model weight hashes, belongs in this audit sidecar for offline postmortem analysis, keeping the per-tick servo loop lean and deterministic.

On this machine, the chunk policy generates only the nominal motion profile, which the planning runtime then packages into a self-contained record by appending the seam state, the four operational deadlines, and a matched stopping suffix. Inside the fixed header, lineage fields record a monotonic sequence number, the evidence timestamp t_0, and the digest of the parent intent lease, while timing fields encode the four deadlines from section 11.2.2. Seam fields then define the reference frame, each joint's initial state $(q, \dot{q}, \ddot{q})$ at handoff, and the representation of an admission-checked stopping profile satisfying $d_{\text{stop}} \leq D_{\text{clear}}$. Content fields specify the payload format, byte length, and an integrity digest spanning both the setpoint payload and the sidecar.

↪ Conditional permission, the per-tick safe-set test that holds a clearance margin valid only for the live state, is developed in section 12.5.

Both the variable-length setpoint sequence and the immutable assumption sidecar sit immediately outside the fixed header. The MCU verifies their composite digest before running the admission

checks described in section 11.5. This dual-digest design decouples integrity from provenance: the payload digest validates contents, while the parent digest anchors lineage. Because the permission path admits a motion proposal based entirely on whether its physical invariants check out rather than on the identity of the process that generated it (section 4.4.1), the record deliberately omits cryptographic signatures or origin tags.

↪ **Byte layout:** Section C.15.3 illustrates a record carrying a single polynomial stopping suffix; it does not encode the worked piecewise S-curve.

Instantiated for the warehouse reach toward the mug, the record carries its own deadlines, which are those of the alternate timeline, while the running chunk lease decides how long tracking actually continues. Its parent digest points directly to the mug-acquisition intent lease, its coordinates are expressed in the robot base frame, and every timestamp references the MCU's monotonic clock. Measured relative to t_{start}, the timing fields record the commitment deadline at 300 ms, the nominal trajectory end at 400 ms (derived from 16 setpoints spaced at 25 ms), and the final safe-stop horizon at 575 ms. The 240 ms blend deadline remains a planner scheduling target outside the fixed header. Four candidates can end tracking authority: the admission cutoff at 278 ms, the lease timeout 60 ms after the last admitted chunk, the intent lease expiry, and evidence staleness. On the running machine the lease timeout binds first. The commitment fields then serve as a backstop that acts only under a lease long enough to outlast the cutoff.

The worked seam specifies a 275 ms, jerk-limited C^2 stopping suffix bounded by peak acceleration 5 m/s^2 and jerk 66.7 m/s^3. It is anchored at the commitment state and brings the arm safely to rest from its 1 m/s TCP velocity limit within 137.5 mm. Serializing and admitting this analytical S-curve requires a specified bounded profile encoding and decoder, bound to the admitted path and stop-entry state, with decoding and validation included in the admission budget (a representation not supplied by the illustrative single-polynomial wire layout). Under the running lease, a lease timeout triggers the state-matched fallback built from the measured state. From zero-acceleration cruise that fallback follows the same S-curve and travels the same distance (section 11.5.2), so the lease path and stop together consume 219.5 mm of the available 300 mm clearance. The 278 ms commitment cutoff never extends the lease. In the sidecar, the planner asserts a payload mass bounded by 3 kg, unobstructed free space leading up to the grasp contact, and operating conditions inside the target ODD. The real-time permission path evaluates all of these upon admission and audits them on every control cycle.

In this concrete trajectory, the temporal ordering strictly satisfies $t_{\text{start}} \leq t_{\text{commit}} < t_{\text{plan_exp}} < t_{\text{stop_end}}$, and the MCU enforces these timing boundaries according to the TRACK and STOP transition rules developed in section 11.2. Because safety requires both temporal validity and physical realizability, a well-formed timestamp in the header cannot compensate for an unviable stopping suffix. To make latency and timing jitter auditable, the system logs the timestamps for evidence capture, plan request, validation completion, admission, activation, control transfer, and stop completion in a synchronized time domain, exposing the end-to-end response delay of the entire perception-planning-control pipeline.

Every artifact in this runtime chain, from the observation contract and the belief record through the intent lease to the trajectory record itself, declares its physical dependencies and its expiration deadline. The trajectory record proves only what the planner could verify at plan time: that a collision-free stop remains physically feasible from any state the robot might reach before commitment, given the obstacle scene and dynamic payload asserted in its sidecar. Common design pitfalls often mistake this bounded, conditional guarantee for unconditional safety, overlooking what happens when physical reality deviates from the planner's model.

11.9 Fallacies and Pitfalls

A planned trajectory remains physically feasible only as long as its environmental, dynamic, and computational assumptions hold true. In embodied systems, failures rarely stem from minor mathematical errors along the nominal interior of a path. Instead, they emerge at operational and physical seams: when dynamic obstacles intrude into an active swept volume, when concatenated action chunks excite mechanical resonances, when host inference pipelines miss scheduling deadlines, or when controllers attempt to stop faster than actuator dynamics permit. Both the trajectory admission gate and the real-time execution monitor must defend against these five failure modes.

Fallacy: *Static admission checks protect a machine against obstacle displacements during active execution.*

Static geometry confirms clear space only at admission time; dynamic workspaces demand continuous runtime monitoring. Consider a robotic manipulator reaching toward an assembly target. When the trajectory is first admitted, the swept volume between the end-effector and the target is completely clear. Halfway through execution, however, an operator slides a storage tote into the arm's path. Although the admission check was mathematically correct when computed, the physical workspace has changed. Static pre-screening guarantees only that a trajectory was safe in the past; it cannot guarantee that the path remains clear as time elapses. Execution monitoring must continuously track obstacle clearances and initiate deceleration while adequate stopping distance remains. Systems architects must explicitly budget sensor bus latency and vision pipeline transit times, reserving enough spatial stopping margin to ensure the machine can halt before an encroaching obstacle breaches its swept volume.

Architect's countermeasure: Pair high-level spatial screening on the host with low-latency local clearance sensing processed directly by the MCU. Explicitly allocate the sensing refresh rate, bus transit latency, and MCU memory footprint. If an unmodeled obstacle breaches the reserved spatial safety margin δ_{margin}, immediately abort nominal tracking and engage the pre-validated, state-matched fallback trajectory.

Pitfall: *Checking each action chunk alone without examining the motion the chunks compose.*

Individual chunk feasibility does not guarantee smooth motion across seams; stochastic neural chatter can overstress a mechanical transmission. When generative sequence policies (such as diffusion models or action-chunking transformers) are sampled stochastically, successive chunks frequently disagree in direction or mismatch acceleration at their boundary. While every individual chunk satisfies kinematic position and velocity bounds in isolation, concatenating them without boundary constraints induces rapid torque reversals $\Delta\tau = J_{\text{eff}}\Delta\ddot{q}$. Amplified by the reflected rotor inertia ($N_{\text{gear}}^2 J_{\text{rotor}}$), this high-frequency chatter excites flexible structural modes, accelerates gearbox wear, and causes severe Joule heating ($i_q^2 R_{\text{phase}}$) in the stator windings. The admission pipeline must evaluate derivative continuity across every chunk boundary seam, enforce C^2 quintic smoothing, and track recent motion history to reject oscillating command sequences before they reach the motor drives.

Architect's countermeasure: Enforce multi-chunk frequency and reversal monitoring across a sliding execution window. Reject any trajectory candidate whose frequency spectrum or repeated effort exceeds the motor's identified mechanical or thermal envelope. If smoothing filters alter a candidate chunk, re-run the full kinematic, seam continuity, and terminal stop checks on the modified trajectory prior to admission.

Pitfall: *Delaying fallback transition past the hard stopping horizon in the hope that delayed compute finishes.*

An overdue compute cycle never justifies extending a physical commitment deadline. In an alternate schedule operating with an admission cutoff of 278 ms, the active trajectory record supplies nominal setpoints that expire at 400 ms. The record carries a 275 ms matched stopping suffix that must finish deceleration by 575 ms. To guarantee physical braking onset by 300 ms, the MCU must dispatch the fallback trajectory no later than the 278 ms cutoff unless a verified replacement plan has already arrived. If the host application processor reports that neural inference is nearly complete but has not yet delivered a validated plan, delaying the fallback transition consumes the runway reserved for stopping. The MCU must dispatch the resident stopping suffix by the earlier cutoff so its physical onset occurs at commitment. Progress reports cannot extend a mechanical stopping budget; only an admitted, physically verifiable trajectory justifies continued forward motion.

Architect's countermeasure: Bind the physical commitment deadline t_{commit} strictly to a monotonic hardware timer on the MCU. When the timer reaches the admission cutoff, close the admission window and dispatch the resident stopping suffix immediately, disregarding any speculative progress updates from the host processor.

Pitfall: *Relying solely on feedforward dynamic models when physical contact or payload mass can change abruptly.*

Feedforward model inversion without closed-loop disturbance bounds can drive an unloaded arm beyond its admitted trajectory. Consider an arm lifting a heavy workpiece near its 3 kg payload limit. To track the aggressive trajectory, the controller injects feedforward torque computed from an inverse dynamics model of the fully loaded arm. If the workpiece slips from the gripper mid-lift, the drives continue applying the large lifting torque intended for the heavy load to an arm that is now empty. Without a timely feedback correction or torque clamp, the excess torque accelerates the arm above its planned rate. While the admitted trajectory has not changed, the physical mass properties that justified those torque commands have vanished. High-bandwidth feedback monitoring must detect the resulting tracking error and clamp torque commands before the arm strikes a mechanical joint stop or triggers inverter thermal derating. Feedforward dynamic models significantly reduce tracking lag under nominal conditions, but they must never run without closed-loop supervisory bounds.

Architect's countermeasure: Implement real-time torque limiters and tracking-error monitoring ($\|\mathbf{p}_{\text{meas}} - \mathbf{r}\| \leq \epsilon_{\text{track}}$) directly inside the 1 kHz servo loop. If an abrupt payload drop or unexpected contact causes acceleration to spike, clamp motor currents immediately and transition the system to compliance mode or an emergency stop.

Fallacy: *A trajectory can omit an achievable terminal stopping suffix if replacement plans are expected to arrive in time.*

A trajectory without a pre-latched stopping continuation is an unhedged bet on infinite compute availability. Traveling at its drive limit of 1.5 m/s, a mobile manipulator's base requires 1,031.25 ms for even the shortest deceleration profile its kinematic bounds permit. That minimum stop follows an S-curve profile $T = v_c/a_{\max} + a_{\max}/j_{\max}$ evaluated at a credible braking acceleration 2 m/s² and jerk limit 7.11 m/s³. Sizing a proposed stopping suffix using the idealized constant-deceleration formula v_c/a_{brake} yields 750 ms. However, no physical actuator can ramp deceleration instantaneously without infinite jerk. Forcing a stop into that truncated duration inevitably violates the acceleration bound, the jerk limit, or both, exceeding what the chassis and its payload can tolerate. Expecting the next plan to arrive on time does not make an unfeasible fallback executable. The admission gate must verify that the terminal stopping suffix strictly respects $a_{\max}$ and $j_{\max}$ throughout its duration. With an S-curve, this requires validating T_{stop} against equation 11.17 and confirming that the stopping distance satisfies $d_{\text{stop}} \leq D_{\text{clear}}$ within verified clearance. The admission gate must reject any record that fails this test. Every admitted trajectory requires a physically executable termination path to protect the machine when upstream inference stalls.

Architect's countermeasure: Require every candidate trajectory record to incorporate a complete, closed-form C^2 stopping profile along its admitted corridor. Deceleration and jerk along this profile must remain strictly within vehicle and payload stability limits, while the stopping distance must satisfy $d_{\text{stop}} \leq D_{\text{clear}}$ within verified clear space. Reject any record at the admission gate that lacks this independently executable stopping guarantee.

11.10 Summary

A trajectory transforms a high-level goal into timed physical motion. On an active machine, it must resolve three questions that a geometric path leaves unanswered: how long the motion remains valid and executable, how it splices smoothly into the motion already under way, and how the machine stops safely if no replacement arrives. A multi-step task such as the reach for a mug progresses through a continuous sequence of renewed, validated trajectory prefixes without forcing the entire task into a single observation window. Predictive models and planners generate candidate trajectories, but the runtime system grants execution authority only after verifying fresh sensor evidence, admission deadlines, and the machine's true state. When a replacement trajectory arrives late, the controller falls back to its resident stopping maneuver. Tail latency bounds ($Q_{1-\epsilon}(L)$) therefore quantify the expected frequency of service degradation to this safe fallback, while the machine's physical safety rests on the stopping profile itself.

Whether a physical system can track a candidate trajectory is distinct from whether that trajectory avoids obstacles. Kinematic feasibility alone can fail in subtle ways. Near kinematic singularities,

the manipulator Jacobian maps modest Cartesian end-effector velocities into unbounded joint rates. Damped least-squares inversion caps these joint steps, but does so by accepting tracking error that can still push joints against their limits. Dynamic feasibility imposes even stricter constraints. The rigid-body manipulator equations translate planned motions into actuator torques, where reflected rotor inertia amplifies any velocity or acceleration discontinuity across trajectory seams into severe torque spikes. A quintic bridge matches position, velocity, and acceleration across the boundary, eliminating these impulsive torque requests. Similarly, time-optimal path parameterization drives actuators along their torque envelopes, but bang-bang acceleration profiles demand instantaneous torque steps that physical drives cannot achieve. Enforcing an explicit jerk bound rounds these transitions at minimal time cost, turning theoretical path timings into executable motor commands. Whether candidates originate from sampling-based search, trajectory optimization, or learned action chunking, the underlying physical obligations remain unchanged. Each planning method generates a prospective motion proposal, but never a license to execute without validation.

Real-time execution relies on strict timing contracts between the planner and the low-level controller. A 60 ms lease halts a stalled proposal stream using a state-matched stopping response, reserving an illustrative 80.5 mm safety buffer to absorb sensing delay and model uncertainty. In an alternate longer-lease configuration, replacement admission closes strictly by 278 ms so that physical deceleration can initiate no later than 300 ms. Both regimes enforce the identical systems invariant: every active trajectory must reserve sufficient travel to accommodate perception-action latency and the entire stopping maneuver. The base faces the same arithmetic. Its jerk-limited S-curve, the shortest stop under the stipulated load bounds, raises the partial stopping budget at the drive limit to 1,123.84 mm (row 6 of table 12.1). Because this exceeds the available 1.10 m rack-end clearance, the runtime controller must proactively restrict operating speed. Table 11.5 lists the equations behind these admission decisions, detailing the physical limit each bounds and where it is derived in this chapter.

Table 11.5: Key equations of trajectory planning: Each load-bearing equation of the chapter, the limit it bounds or the decision it settles, and the equation where it is derived.

Equation	What it bounds or decides	Derived in
$\Delta\mathbf{q}_\lambda = \mathbf{J}^\top(\mathbf{J}\mathbf{J}^\top + \lambda^2\mathbf{I})^{-1}\Delta\mathbf{p}$	The inverse-kinematics step near a singularity, capped at $v_{\text{TCP}}/(2\lambda)$ at the price of tool error	equation 11.2
$L = t_{\text{age}} + \Delta_{\text{da}}$	Replacement latency from capture to admission, which the renewal schedule must absorb	equation 11.3
$\epsilon \le \epsilon_{\text{mission}}/K$	The per-handoff tail that a mission target implies, far beyond p99	equation 11.4
$T_{\text{record}} \ge T_{\text{request}} + Q_{1-\epsilon}(L) + T_{\text{reserve}} + T_{\text{stop}}$	Conservative capture-latency charge; full reserve includes scheduling slack and response; stop included	equation 11.5
$\tau = \mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{g} - \mathbf{J}^\top\mathbf{F}_{\text{ext}}$	The torque a planned motion demands, evaluated by inverse dynamics at admission	equation 11.8
$\lvert\dot{q}_k\rvert \le v_{\max} - \frac{1}{2}a_{\max}T_s$	A sampled velocity limit that still holds between samples	equation 11.10
$\tau_{\text{request}} = J_{\text{eff}}\,\Delta\dot{q}/T_s$	The torque a seam's velocity step asks of the reflected inertia	equation 11.11
$j_{\text{joint}}(t) = 6a_3 + 24a_4 t + 60a_5 t^2$	The jerk of a quintic bridge, whose extrema the checker evaluates in closed form	equation 11.13
$V_{\text{bus}} \ge L_{\text{phase}}\,di_q/dt + R_{\text{phase}}\,i_q + K_e\omega_e$	Whether the drive has the voltage for the current slew a bridge demands	equation 11.14
$\tau = \mathbf{a}_\tau(s)\ddot{s} + \mathbf{b}_\tau(s)\dot{s}^2 + \mathbf{g}(s)$	The path accelerations the torque limits allow, and so the fastest timing of a path	equation 11.15
$d_{\text{stop}} = v^2/2a_{\max} + v\,a_{\max}/2j_{\max}$	The shortest stop within deceleration and jerk bounds, above the plateau speed $a_{\max}^2/j_{\max}$	equation 11.17
$d_{\text{stop}}(t_{\text{commit}}) \le D_{\text{clear}}(t_{\text{commit}})$	Whether a trajectory may be admitted at all	equation 11.18

DRAFT

Key Takeaways: Timed motion and independent stopping

- **Prediction is not execution authority**: A long predicted path can guide motion, but the controller executes only short, validated prefixes. While renewal cadence dictates how frequently new plans are requested, target evidence retains its own capture-based timestamp, and its evidence horizon bounds how long it stays valid.
- **Reserve a stopping response from the current state**: A stopping suffix is mathematically valid only for its declared entry state. If an execution lease or sensor observation expires, the machine must possess a pre-validated fallback trajectory, sufficient reserve energy, and enough physical clearance to absorb both response latency and full deceleration.
- **Admission precedes physical commitment**: The alternate arm schedule closes replacement admission strictly by 278 ms to ensure a physical stop can initiate at 300 ms. A late planner proposal cannot spend or delay this reserved response window.
- **A collision-free path is not inherently executable**: Near singularities, Cartesian end-effector speeds demand infeasible joint velocities. Damped least squares bounds the inverse-kinematics step only by introducing tracking error. Similarly, time-optimal path timing produces discontinuous torque demands that trigger actuator saturation. Adding quintic seams and jerk bounds smooths transitions, but interior joint limits, inverter voltage headroom, and clearance remain binding constraints.
- **Trajectory smoothness dictates stopping distance**: Finite jerk bounds make smooth stopping profiles significantly longer than ideal constant-deceleration braking. An S-curve profile pays the least, the equivalent of cruising for half of one jerk ramp, yet that overhead still sets operating speed limits near rack ends and obstacles.
- **Candidate rejection does not require immediate stopping**: The running trajectory continues executing normally as long as its state, sensor evidence, lease deadline, and fallback trajectory remain valid. Rejecting an invalid replacement proposal simply leaves those original expiration boundaries unchanged.
- **Admission and runtime enforcement require separate system budgets**: Evaluating a candidate plan requires an asynchronous, bounded scan over the entire trajectory chunk, whereas per-tick enforcement performs strict real-time checks against current state and local sensor data. System designers must isolate their CPU time, memory footprints, and bus interference to prevent high-level planning from disrupting the low-level control loop.

A plan stays valid only while the stop it carries can still be executed. When a timing, seam, or clearance check fails, the remedy is to shorten the lease, slow the motion, or lengthen the bridge until every check passes with the resident stop still inside the clearance, never to wait for a better proposal. The stall runway shows which term to work on. If the travel before stop onset rivals the stop itself, the lease is the term to shorten. If the stop dominates, the deceleration or jerk bound the load tolerates is the term to measure.

For motion, the third law, proposal is not permission (principle 3), reduces to a clearance test. However smooth, collision-free, and timely a candidate is, the MCU admits it only with an independently executable stop that fits the clearance that remains, and that test does not depend on how the candidate was generated. Admission is not a waiver either. The conditions certified at admission remain obligations on every control tick, so the machine must keep checking live state against the clearance it has left.

11.11 Historical Perspective and Further Reading

Motion planning became a concrete computational discipline when Lozano-Pérez (1983) mapped geometric collision avoidance into configuration-space search, shrinking the geometry of a complex moving body to a single point. In the same year, Schwartz and Sharir (1983) formulated the piano movers' problem through exact algebraic decomposition. While theoretically complete, exact algebraic methods scale doubly exponentially with degrees of freedom, rendering them intractable for

multi-joint manipulators. In the 1990s, randomized sampling bypassed this geometric bottleneck by trading exact completeness for probabilistic guarantees. Probabilistic roadmaps (Kavraki et al. 1996) introduced multi-query graph construction across free configuration space, while rapidly-exploring random trees (LaValle 1998) solved single-query kinodynamic problems by incrementally biasing search trees toward unexplored regions. Later, RRT* (Karaman and Frazzoli 2011) proved that standard random trees almost surely fail to find optimal paths, introducing local edge rewiring to guarantee asymptotic convergence toward the optimum. Together, these foundational algorithms resolve where a robot may safely pass, which represents the geometric half of motion planning.

The second half, timing and dynamics, followed an independent line of work. Bobrow et al. (1985) showed that the fastest traversal along a pre-specified path under actuator torque limits follows a bang-bang structure in the phase plane, switching between maximum acceleration and maximum deceleration. Decades later, TOPP-RA (Pham and Pham 2018) reformulated time-optimal path parameterization through reachability analysis, casting the search into a sequence of linear programs that execute in time linear in the number of path waypoints. Pure time-optimal trajectories command discontinuous accelerations, however, and the resulting infinite jerk excites mechanical resonances that degrade physical drives. To produce smoother execution, roboticists drew inspiration from biology: Flash and Hogan (1985) showed that human reaching movements naturally minimize jerk. In robotic manipulation, Kröger and Wahl (2010) demonstrated that complete, jerk-limited trajectory profiles could be synthesized deterministically from an arbitrary initial state within a single millisecond-scale control cycle. Ruckig (Berscheid and Kröger 2021) generalized this formulation to arbitrary target kinematic states and asymmetric limits, establishing the fast, closed-form generator that produces this chapter's stopping profiles. Trajectory optimization reached robotics along a parallel route. Direct collocation (Hargraves and Paris 1987) originated in aerospace trajectory design to transcribe continuous optimal control into sparse nonlinear programs. Receding-horizon control matured in the process industries (Qin and Badgwell 2003), where slow chemical plant dynamics afforded ample time for numerical convergence. Later, algorithms like CHOMP (Ratliff et al. 2009) brought functional gradient optimization directly to robotic arms, optimizing trajectory smoothness and obstacle clearance simultaneously.

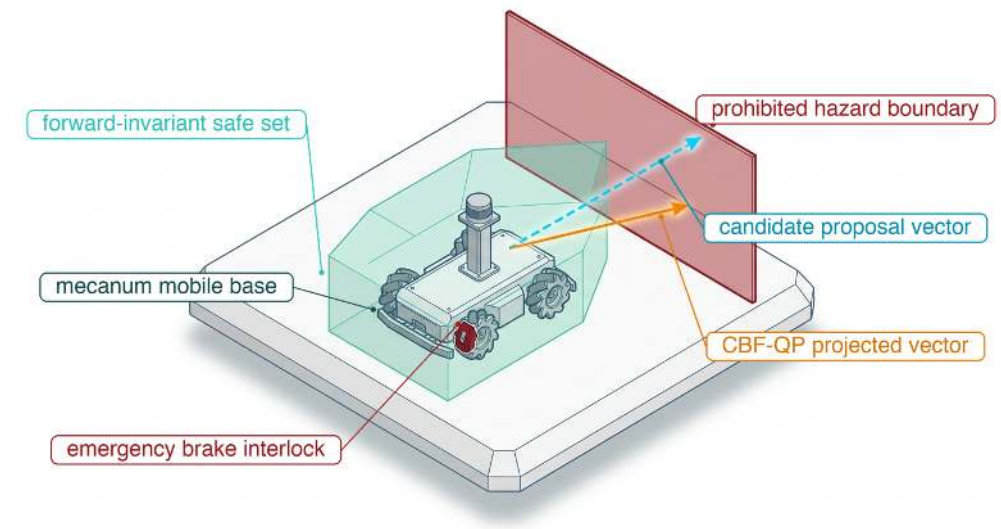
The commitment problem, deciding when a planned motion becomes irrevocable and keeping execution safe after that point, is the most recent to mature. Because physical systems possess inertia, safety cannot be judged solely by examining whether the current state is collision-free. Fraichard and Asama (2004) formalized inevitable collision states, establishing that a planner must verify that a system never enters a state from which every future control trajectory culminates in a crash. This formulation gave a robotic form to the viability kernels that Aubin (1991) had introduced in control theory. Modern learning-based methods have transformed how candidate motions are generated. Action chunking (Zhao et al. 2023) and diffusion policies (Chi et al. 2025) predict multi-step action trajectories directly from visual observations, capturing dexterous behaviors without explicit geometric reconstruction. To bridge the latency gap between neural network inference and high-frequency actuation, real-time chunking (Black, Galliker, et al. 2025) conditions incoming predictions on the action sequence already committed to the hardware controller. Regardless of how candidate motions are generated, the execution runtime must enforce physical safety. The trajectory record binds the admitted trajectory to its initial seam state, enforces hard commitment deadlines, and guarantees a deterministically executable stopping suffix whenever the policy stalls.

For further reading, six works trace the lineage from classical planning to modern learned proposals:

- Qin and Badgwell (2003) provides a comprehensive survey of industrial model predictive control, charting its progression from early petrochemical applications to commercial implementations and illustrating how receding-horizon optimization operates on physical systems whose long time constants tolerate multi-second solve times.
- Fraichard and Asama (2004) formalizes inevitable collision states and defines the dynamic conditions required for provable motion safety under actuator limits, establishing the theoretical foundation for the commitment deadlines analyzed in section 11.5.3.
- Biagiotti and Melchiorri (2008) provides an exhaustive reference on trajectory generation profiles across robotics and industrial automation, detailing the analytical formulation of

polynomial splines, filter-based smoothers, and the double-S profile used for the C^2 stopping suffix in section 11.5.2.

- Kröger and Wahl (2010) develops the mathematical framework for online trajectory generation, deriving algorithms that compute kinematically feasible, jerk-limited motion profiles from arbitrary initial states within single-cycle real-time deadlines.
- Lynch and Park (2017) offers a unified, geometrically rigorous treatment of configuration space, kinematics, rigid-body dynamics, time scaling, and motion planning, serving as a comprehensive companion to section B.6.1.
- Chi et al. (2025) details diffusion policies for robotic manipulation, examining receding-horizon execution of predicted action sequences and presenting the modern learned proposers whose seams, deadlines, and fallback stopping profiles this chapter evaluates.



What's Next: From admitted plans to per-tick permission

Admission judges a trajectory against the state the planner predicted, but the machine executes it against the state it actually reaches. Between the two, the body lags its reference, a person can step into the aisle, and an actuator can run short of torque, and the stopping budget assembled here has not yet charged the first of these. On the base the gap is already decisive, because the jerk-limited stop carries the partial budget to 1,123.84 mm against 1.10 m of rack-end clearance at the drive limit before the body's departure from its reference is priced. Chapter 12 begins with the per-tick gatekeeper, the permission-path check that runs on every control tick against live state. It prices tracking error as an inset on the stopping distance and derives a candidate aisle speed whose timing and braking premises still require qualification. When a check fails, it selects among fallback responses that include the resident stopping suffix latched at admission.

Purpose

Why does an admitted plan still need permission on every control tick?

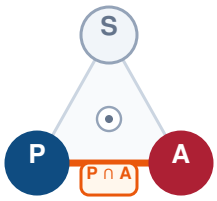
A trajectory can be feasible when it arrives and become unsafe while the machine follows it. The body lags its reference, a payload or a hot motor erodes braking authority, a person steps into the path, or the learned proposer stalls with its last command still in force. A machine that checks only before motion begins discovers these changes after the energy is already moving, and the proposer cannot be trusted to notice them, because nothing in its output bounds stopping distance, actuator effort, or timing. Learned proposals therefore need an independent permission path that re-checks current conditions on every tick, keeps useful motion inside a stopping envelope, corrects a command when a feasible correction exists, and holds a response it can execute without the proposer before the remaining margin is spent. Each of those guarantees depends on bounded sensing error, available actuator force, and a decision delivered on time. Enforcement joins these conditions at the causal boundary, where a permitted command becomes motion that software cannot undo.

Learning Objectives

- Calculate the finished stopping budget and its speed ceiling, treating the tracking bound as a premise the enforcer monitors on every tick
- Derive how momentum and commanded effort change the remaining safety margin, and the contact force at a latch and at a handover that caps approach speed
- Explain how a control barrier function limits motion while its model, sensing, actuator, and timing assumptions hold
- Formulate a quadratic program that minimally adjusts a proposal within feasible actuator and safety constraints
- Select state-matched fallback responses when sensing, computation, or actuator limits invalidate normal enforcement
- Distinguish the permission path's unrated performance checks from the certified drive, scanner, and arm safety functions that carry the protective claim beneath it
- Construct an enforcement record and formulate the admitted command that binds each check to its detector, its fallback response, and the records it consumes

12.1 The Per-Tick Gatekeeper

Every physical AI system ends in the same act. A command leaves software, becomes current in a motor winding, and puts momentum into a world that does not roll back. Safety enforcement is the runtime mechanism that decides, one control tick at a time, whether the next command may cross that causal boundary. Checking a plan once before it runs does not settle the question, because admission judges the plan against the state the planner predicted, and the machine then executes it against the state it actually reaches. Between those two moments the body can lag its reference, an actuator can run short of torque, a person can step into the aisle, and the learned proposer can stall or emit a setpoint the plan never contained. Enforcement exists so that none of these events is discovered only after the energy has been delivered.



The central constraint is that the learned proposer can neither be trusted with that decision nor be discarded. Its competence is what makes the machine useful, yet nothing in its output bounds stopping distance, actuator effort, or timing. Enforcement resolves the tension by separating proposal from permission, the third law (principle 3), and by giving the permission side three jobs. It must hold a stopping reservation, the clearance the machine needs to arrest its motion from the current state; it must correct a proposal minimally when a feasible correction exists; and it must select a response it can execute without the proposer when none does. The chapter builds the three jobs in that order.

On the warehouse mobile manipulator, the safety microcontroller (MCU) admits the run down the aisle only after the matched stop suffix named in its trajectory record is resident in the MCU's memory and feasible from the commitment entry state defined in section 11.5.1. Commitment is the instant after which the machine can no longer abandon the plan's motion without that latched suffix, so the suffix is matched to the state the machine will have at that instant, not to the states it passes through on the way. Before commitment, a different response must cover the motion. Admission requires an independently executable, state-matched fallback from every state reachable up to that instant. It also requires a bounded representation of the S-curve suffix that the MCU can decode, validate, and execute within its declared workload (the polynomial layout of section C.15.3 is an illustrative encoding rather than that S-curve representation). Because that admission step checks the plan only once before motion starts, the machine still executes the plan one millisecond tick at a time, and enforcement is the check made on every one of those ticks together with the response it selects when even the resident stop no longer fits.

The enforcer, the permission path's per-tick gatekeeper, sits on the permission side of the proposal boundary. It is a hard real-time component that evaluates candidate proposals, verifies invariant state bounds, and holds the exclusive hardware authority to permit current flow or command a fallback stop, keeping the task competence of learned policies while denying them authority over geometric clearance, thermal limits, and human-safety invariants.

↩ The trajectory record and the matched stop suffix it names are established in section 11.8.

↩ The per-tick permission cadence on which the enforcer runs is established in section 4.3.1.

Enforcement sits on the Plan-to-Act edge: no proposal reaches a drive unchecked.

In the architecture this chapter follows, the enforcer executes on a dedicated microcontroller wired to the sensing and drive interfaces it needs. It checks each candidate command before the drive can apply it. A packet firewall offers a limited software analogy: a sender may request an operation without having authority to perform it. Unlike a packet filter, the enforcer must also account for momentum already present in the plant and preserve an achievable response when it refuses a request.

The architecture separates a capable proposer, a resident protective controller, and an output selector. This is the **Simplex architecture**[1] (Seto et al. 1998; Sha 2001), the runtime-assurance pattern that section 1.7 first named. The proposer supplies useful candidates, while the permission path retains the exclusive ability to select a physically feasible response without waiting for it.

↪ The silicon placement that keeps the permission path independent of the proposer is developed in section 13.6.

The rest of the chapter follows the running machine through that per-tick check. The starting point is the deficit planning left open, when the jerk-limited stop carried the base's stopping budget past the rack-end clearance at the drive limit while the body's departure from its reference remained unpriced: the first quantity the enforcer needs is how far the body can stray from the reference it is asked to follow, because every clearance the permission path defends must also contain that error. Once the tracking bound supplies that missing spatial term, the finished stopping budget fixes the reservation and a candidate aisle speed that still requires physical qualification. Actuator saturation then reveals how quickly that reservation shrinks once gravity or thermal limits spend braking authority. A control barrier function turns the reservation into a constraint on the next command. A least-change filter can then correct a violating proposal, both in free space and in contact, inside a declared cycle budget on a processor the proposer cannot preempt. When a check fails or a lease expires, the fallback hierarchy supplies the surviving hardware response, and the chapter closes with the infrastructure failures that break these premises and the enforcement record that binds every check to its evidence.

[1] **Simplex Architecture**: The design came from Carnegie Mellon in the 1990s as a way to upgrade the controller of a running plant without stopping it. An untested new controller drove the plant while a simple verified controller and a switching rule stood ready to take it back (Seto et al. 1998). The learned proposer occupies the untested controller's seat, and the design's premise, that the region from which the verified controller can still recover is known in advance, is the stopping envelope this chapter computes.

12.2 The Tracker Handoff and Dynamic Reference Envelopes

Even when communication latency is zero and the permission path admits every reference command without delay, physical robots follow reference trajectories imperfectly. Mechanical compliance, inertia, and non-ideal motor dynamics produce tracking discrepancies. The feedback tracker, the closed-loop controller that turns admitted references into actuator effort, must bound this deviation across the entire maneuver. The bound is a **worst-case tracking error tube** (ϵ_{track}), an upper bound on the spatial departure of the tracked position output from its nominal reference. For Cartesian point tracking, $\mathbf{p}(t)$ and $\mathbf{r}(t)$ denote the actual and reference positions evaluated in the same spatial frame. For whole-body systems such as mobile manipulators, the execution stack defines a declared output map or metric weighting that bounds the maximum physical swept-volume displacement in meters. The safety enforcer depends directly on this bound. Any spatial clearance reserved around a planned reference path must guarantee physical containment of the actual robot body.

Provided that the physical system begins within an initial qualified error region and its operating parameters (reference velocity, command acceleration, payload mass, external disturbances, and actuator temperature) stay within their validated operating envelope, the feedback controller guarantees the transient position-error bound:

↩ The admitted setpoints and feedforward torques that the tracker turns into actuator effort are established in section 11.2.

$$\|\mathbf{p}(t) - \mathbf{r}(t)\| \leq \epsilon_{\text{track}} \quad \forall t \geq 0.$$

This guarantee forms a software contract between the tracking layer and the safety enforcer. Rather than re-analyzing raw plant dynamics or reconstructing low-level controller state on every millisecond control cycle, the enforcer consumes this certified error bound as an invariant. However, this contract confines physical motion to the ϵ_{track} tube only while the operational conditions used to establish the certificate remain valid.

The magnitude of ϵ_{track} is a physical distance dictated by hardware properties: reflected rotor inertia ($N_{\text{gear}}^2 J_{\text{rotor}}$), gearbox backlash, structural compliance, and actuator torque saturation. While a steady-state stiffness calculation balances constant external disturbances against closed-loop restoring force, steady-state metrics fail to capture transient overshoot, phase lag, or settling oscillations excited during aggressive maneuvers. Consequently, engineering teams cannot rely on static linear approximations; they must support the tracking tube bound ϵ_{track} with a bounded plant and controller model, defined operating limits, and full-envelope dynamic qualification tests. Tests can

expose an invalid bound; the tested trajectories alone do not prove containment for every admissible maneuver.

↩ Reflected rotor inertia, $N_{\text{gear}}^2 J_{\text{rotor}}$, is established in section 2.4.3.

For the baseline warehouse mobile manipulator, the illustrative dynamic qualification target is $\epsilon_{\text{track}} = 40$ mm (illustrative; see the Reader Guide). The tracking controller sustains this bound only while three coupled operational constraints remain satisfied. First, reference trajectories must not demand accelerations exceeding drive torque limits. Second, external disturbance forces must remain below d_{max}, the qualified bound on external disturbance force. Last, actuator coils must operate below their continuous thermal derating thresholds and DC bus voltage limits. A reference trajectory demanding acceleration beyond peak torque drives the actuators into saturation, causing the physical chassis to lag behind the command. Without aggressive anti-windup clamping, the integrator state accumulates severe windup, prolonging recovery long after the reference demand subsides. Outside this qualified operating envelope, the tracking certificate is void, and the system loses its guaranteed error bound.

↩ Continuous thermal derating of motor windings is established in section 2.5.

Because the physical robot can deviate from its planned reference by up to ϵ_{track} in any direction, the safety architecture must subtract this uncertainty margin directly from the admissible workspace. Let h measure the spatial clearance remaining around a reference. To guarantee that the physical robot maintains non-negative clearance, the enforcer applies an inset contraction:

$$h_{\text{contracted}}(\mathbf{r}) = h(\mathbf{r}) - \epsilon_{\text{track}} \geq 0.$$

A reference trajectory that maintains nominal clearance c from a warehouse rack upright guarantees the physical chassis only $c - \epsilon_{\text{track}}$ of actual clearance. Consequently, the safety enforcer evaluates reference commands against a contracted boundary that adds 40 mm to the nominal buffer. As detailed in section 12.3, this tracking inset compounds directly with stopping distance budgets, where localization uncertainty and transport delay consume additional clearance. Mechanical wear poses an insidious operational risk here. If worn drive bearings, tire degradation, or altered motor parameters double the true tracking error to 80 mm without updating the enforcer's parameter registry, the physical base consumes an unbudgeted 40 mm of clearance that the enforcer assumes remains available. An unmodeled tracking degradation silently undermines every higher-level safety margin.

↩ Clearance insets that absorb spatial sensing error are established in section 8.6.

To maintain safety guarantees in production, the runtime monitoring stack must treat ϵ_{track} as an actively verified contract rather than a static design assumption. The underlying real-time middleware publishes ϵ_{track} alongside its validity envelope, while hardware monitors estimate the instantaneous tracking error $e(t) = \|\mathbf{p}(t) - \mathbf{r}(t)\|$ on every 1 ms controller tick. Agreement with encoder-reported position is a runtime proxy, not independent evidence of physical localization; the localization allowance must contain drift that these channels cannot expose. If an observable disturbance or actuator thermal throttling causes the monitored $e(t)$ to exceed ϵ_{track}, the tracking contract is broken. Upon detecting this violation, the safety enforcer revokes the admitted command and activates a state-matched emergency fallback maneuver. Maintaining physical containment during this transition requires that the fallback braking trajectory remains dynamically feasible even after the tracking bound is lost.

> **Systems Perspective 12.1: The inset margin invariant**
>
> A spatial stopping boundary must reserve margin for the tracking loop's qualified error bound. The runtime stopping envelope (equation 12.1) incorporates this geometric inset alongside displacement accumulated during transport lag before admitting reference trajectories. When the safety barrier certificates of section 12.5 are formulated in non-spatial coordinates (such as energy or momentum limits), the safety layer must map the tracking tube into a corresponding conservative bound on barrier variation, rather than subtracting a scalar distance. Evaluating barrier certificates against nominal trajectory geometry alone risks admitting references whose physical tracking tubes intersect obstacle boundaries.

Control theory provides rich methodologies for synthesizing tracking controllers, state observers, and disturbance rejection algorithms (Slotine and Li 1991; Åström and Murray 2021). In embedded industrial robotics, systems frequently deploy a **cascaded control hierarchy**, where outer position

DRAFT

loops feed intermediate velocity setpoints down to high-rate current loops. Alternatively, a **tracking Model Predictive Controller (MPC)** solves an online optimization problem over a receding horizon to generate optimal corrective control actions while respecting actuator bounds. From the perspective of the safety enforcer, the specific internal architecture of the tracking controller is abstracted away; the safety filter requires only that the chosen implementation certifies and guarantees a concrete tracking bound ϵ_{track} under specified operational conditions.

A tracking controller may establish convergence to the reference path under its qualified model and operating conditions. That result supplies no collision-avoidance guarantee. A well-tuned tracker will follow an erroneous trajectory directly into a warehouse support column with high precision. Control Lyapunov functions[2] mathematically formalize this asymptotic convergence toward reference targets; section B.3.2 details their theoretical foundation and how optimization pipelines unify stabilizing Lyapunov objectives with the safety barrier certificates this chapter develops in section 12.5.

This division of responsibilities cleanly separates trajectory tracking from safety enforcement. The low-level tracking controller focuses on driving the physical plant toward reference states, while the safety enforcer determines whether those references can be executed without violating invariant boundaries. The tracking error bound ϵ_{track} bridges these subsystems by quantifying the spatial divergence between admitted commands and physical execution. Because environmental disturbances, unmodeled payload shifts, or thermal current derating can rapidly widen this error tube, safety architectures must continuously verify physical performance against contracted assumptions. The downstream stopping envelope accounts for this tracking tube alongside sensor latency, braking distance, and localization drift, ensuring that the physical robot remains safely buffered from surrounding hazards.

[2] **Control Lyapunov Function**: A Lyapunov function certifies that an unforced system settles; a control Lyapunov function asks only that, at each state, some admissible input make it decrease. Artstein (1983) tied the existence of such a function to stabilizability by feedback, and Sontag (1989) gave an explicit formula that builds the stabilizing input from it. The control barrier function, defined later in this chapter, is its mirror image, keeping the state out of a region instead of pulling it toward a point, and when the two conflict the combined optimization relaxes convergence so that the barrier holds.

12.3 Stopping Envelopes

If the warehouse mobile manipulator approaches a rack end at its 1.5 m/s mechanical drive limit when a coworker steps into the aisle, the delay before braking begins and the jerk-limited deceleration curve carry the base past the 1.10 m clearance even before tracking error is counted. That rack-end crossing is the scene in which nearly every chapter since chapter 2 has priced one stopping term: the body supplied braking and its fixed allowances, the Nervous System the lease path, perception the observation age, and planning the jerk-limited stop suffix that exceeded the rack-end clearance at the drive limit (section 11.5.4). The tracking bound of section 12.2 is the last spatial term. Every one of these terms serves the test that the first law, irreversibility (principle 1), sets, $d_{\text{stop}} \leq D_{\text{clear}}$. The enforcer applies that test not as one calculation but as a set of states.

Definition 12.1: Stopping envelope

Stopping envelope is the set of plant states, parameterized by clearance and velocity along each degree of freedom, from which the resident emergency braking response, initiated after accounting for all worst-case delays, halts motion before reaching an obstacle boundary while preserving all localization, protective, and tracking margins.

1. **Significance**: The envelope translates the abstract irreversibility requirement $d_{\text{stop}} \leq D_{\text{clear}}$ into an actionable runtime velocity ceiling. When approaching a rack end, the warehouse mobile manipulator's envelope restricts forward velocity, with the stated dispatch allocation, to at most 1.35 m/s, substantially below its mechanical drive limit of 1.5 m/s.
2. **Distinction**: Unlike a static geometric keep-out zone that depends solely on position, the stopping envelope is a dynamic construct governed by speed, system latencies, and braking authority. A given physical clearance safely admits a slow approach while strictly forbidding a high-speed transit.
3. **Common pitfall**: Treating the stopping envelope as a static, precomputed boundary. In practice, carried payload mass, surface traction coefficients, and motor thermal limits continuously reshape this boundary; calculating safety margins from ideal datasheet

> decelerations severely overestimates stopping authority when the machine is heavily loaded.

The stopping envelope is the machine's recoverable set, the states from which the resident stop still succeeds. Section 11.5.3 fixes the same boundary in time, as the commitment deadline past which momentum can carry the machine into an inevitable collision state. Velocity enters the recoverable set twice. Delay travel grows linearly with speed and braking travel quadratically, so a clearance that admits a slow approach forbids a fast one at the same position, and the enforcer must keep the machine inside the envelope on every tick, before a fault or an unmodeled disturbance can carry it out. The running calculation uses representative engineering limits; deployment requires each term to be qualified on the actual hardware.

The pre-brake delay τ_{delay} of section 2.3.1 already contains the enforcer's permission cycle, budgeted alongside the lease communication path in section 4.4. One interval stays out of the spatial sum: the dispatch-to-admission delay Δ_{da}, which table 4.1 places between proposal dispatch and admission. The budget charges it instead against the timing allowance that the remaining clearance leaves (section 12.3.1). What the spatial sum still lacks is the tracking error between the commanded reference and the actual plant.

The enforcer accounts for that error with the tracking bound ϵ_{track}, offsetting the baseline stopping distance of equation 2.2. It can admit a candidate reference trajectory only if the plant, which may lag that reference by up to ϵ_{track}, can still brake to a standstill within the available free distance D_{clear}. Combining physical clearance, latency, and velocity yields the stopping subtotal before dispatch-to-admission travel is charged:

$$v\,\tau_{\text{delay}} + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} \leq D_{\text{clear}} \tag{12.1}$$

Here, $d_{\text{suffix}}(v)$ represents the physical distance traversed during the braking maneuver from an initial speed v. For idealized constant-deceleration braking, this term simplifies to $v^2/(2a_{\text{brake}})$. Under realistic jerk-limited trajectory profiles, $d_{\text{suffix}}(v)$ is governed by equation 11.17, which incorporates the additional displacement accrued during finite jerk transitions. The term δ_{loc} denotes the localization uncertainty bound, while δ_{margin} provides an explicit protective safety cushion. The left-hand side sums the baseline stopping distance $d_{\text{stop}}(v)$ from equation 2.2 with the tracking inset ϵ_{track}.

↪ The full stopping-distance model, tracking inset included, is developed in section C.13.

For complete static-obstacle admission, the delay term uses $\tau_{\text{delay}} + \Delta_{\text{da}}$ in place of τ_{delay}; the resident stop and fixed allowances are unchanged. This inequality defines a conditional stopping subtotal in state space. Within this set, the accounted reaction latency and braking profile fit within the measured obstacle clearance; complete admission must also charge dispatch-to-admission travel. Operating outside this boundary violates the stopping reservation under the qualified model assumptions, though conservative engineering margins do not imply that an instantaneous collision is certain under all conceivable emergency maneuvers. Per-tick enforcement must maintain this stopping reservation over the entire control epoch until the next validated command can take effect, rather than merely verifying instantaneous feasibility at the sample instant.

Whenever a proposed trajectory requires a stopping distance in equation 12.1 that exceeds the measured clearance along the current heading, the enforcer rejects the command. Because the robot moves directionally, the stopping envelope is anisotropic. Heading dictates which obstacles threaten forward travel and consume braking clearance, while localization uncertainty and the robot's swept geometric volume demand clearance margins around the entire perimeter.

12.3.1 Sizing the composite stopping budget

Omitting any single interval during which the base keeps moving before or during a stop, or evaluating those intervals under mismatched operating conditions, admits transit speeds that overrun the physical boundary when all delays coincide. The composite stopping budget therefore reserves clearance for every interval in the arrest sequence: sensor transduction lag, compute scheduling delays, actuator engagement, the deceleration profile, and tracking divergence, each evaluated under the same worst-case operating conditions.

DRAFT

For the warehouse mobile manipulator, the tracking bound of 40 mm is the final spatial term. At the 1.5 m/s drive limit, the matched stop suffix had already pushed the cumulative requirement to 1,123.84 mm, past the 1.10 m rack-end clearance; that is the deficit section 11.5.4 left open. The tracking inset carries the total to 1,163.84 mm, an overshoot of 63.84 mm beyond the physical boundary.

The C^2 stop suffix replaces idealized constant deceleration ($v^2/2a_{\text{brake}}$) with the jerk-limited S-curve of section 11.5.2, governed by the peak jerk limit $j_{\max} = 7.11$ m/s^3. Planning stipulated that bound from the reference C^2 polynomial rather than measuring it; the S-curve is the stop the MCU actually runs, and the polynomial supplies only its jerk bound. Because both operating velocities reach the peak deceleration threshold, equation 11.17 models this maneuver by adding the displacement of half a jerk ramp:

$$d_{\text{suffix}}(v) = \frac{v^2}{2a_{\text{brake}}} + v\,\frac{a_{\text{brake}}}{2j_{\max}}.$$

Because this smoothly shaped stop consumes more clearance than discontinuous full-torque braking, the admissible transit speed must be read from the finished budget rather than from the constant-deceleration estimate.

Velocity remains the single operational variable the control architecture can dynamically modulate. Above the characteristic velocity threshold $a_{\text{brake}}^2/j_{\max} = 0.56$ m/s, the finite jerk ramps function equivalently to an added delay of $a_{\text{brake}}/(2j_{\max})$ prior to braking at constant deceleration a_{brake}. Under these conditions, the pre-dispatch **speed ceiling** keeps the form of equation 2.3, the positive root of the stopping inequality at equality. The jerk ramps lengthen the pre-brake delay to an effective delay, and the tracking bound comes off the available braking distance:

$$v_{\max} = -a_{\text{brake}}T_{\text{eff}} + \sqrt{(a_{\text{brake}}T_{\text{eff}})^2 + 2a_{\text{brake}}D_{\text{avail}}}, \qquad T_{\text{eff}} = \tau_{\text{delay}} + \frac{a_{\text{brake}}}{2j_{\max}}, \qquad D_{\text{avail}} = D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - \epsilon_{\text{track}} \tag{12.2}$$

Below $a_{\text{brake}}^2/j_{\max}$, the deceleration trajectory never reaches the peak limit a_{brake}, rendering stopping distance non-quadratic in velocity; in this low-speed regime, MLSysIM evaluates equation 12.1 via numerical root-finding. Notebook 12.1 computes this ceiling for the mobile manipulator approaching the aisle rack end.

Napkin Math 12.1: The ceiling the budget sets

Problem: The warehouse mobile manipulator approaches the rack end with rows 1 to 7 of table 12.1 accounted, before dispatch-to-admission travel. What is the highest speed at which the jerk-limited stop still fits the clear distance, and how much clearance does a candidate aisle speed of 1.3 m/s leave?

Variables:

- $D_{\text{clear}} = 1.10$ m (Illustrative; clear distance at the rack end).
- $\delta_{\text{loc}} + \delta_{\text{margin}} = 50$ mm $+ 100$ mm (Illustrative localization bound; chosen protective clearance), and $\epsilon_{\text{track}} = 40$ mm (Illustrative; the qualification target of section 12.2).
- $a_{\text{brake}} = 2$ m/s^2 (Illustrative; credible loaded deceleration on a dry floor) and $j_{\max} = 7.11$ m/s^3 (Derived; the peak jerk of the reference C^2 polynomial).
- $\tau_{\text{delay}} = 133.6$ ms (Derived; observation age plus lease path plus brake onset, excluding Δ_{da}).
- Drive limit 1.5 m/s (Illustrative).

Math: The fixed allowances leave $D_{\text{avail}} = 1{,}100$ mm $- 190$ mm $= 910$ mm. The jerk ramps lengthen the delay to $T_{\text{eff}} = 133.6$ ms $+ 140.6$ ms $= 274.2$ ms, so $a_{\text{brake}}T_{\text{eff}} = 0.5485$ m/s. Under the square root of equation 12.2, $(a_{\text{brake}}T_{\text{eff}})^2 = 0.3008$ and $2a_{\text{brake}}D_{\text{avail}} = 3.64$ (both in m^2/s^2), whose sum has root 1.9851 m/s; subtracting 0.5485 m/s gives the ceiling. At 1.3 m/s the terms of table 12.1 sum to 969.0 mm, and the remainder divided by the speed is the timing allowance.

Result: The pre-dispatch ceiling is $v_{\text{max}} = 1.44$ m/s, below the 1.5 m/s drive limit. The candidate aisle speed leaves 131.0 mm of spare, equivalent to 100.8 ms of unallocated delay.

Systems insight: The irreversibility requirement $d_{\text{stop}} \leq D_{\text{clear}}$, rather than motor electrical capability, dictates the operating speed. Running at the nominal drive limit violates the verified spatial budget, and the speed ceiling shifts strictly through the parameters governing the quadratic root and effective latency T_{eff}: available clearance, qualified braking deceleration, fixed margins, and end-to-end transport lag. Any latency introduced by downstream processing directly consumes the 100.8 ms timing allowance, which cannot be arbitrarily replenished.

The candidate transit speed, 1.3 m/s, sits below that ceiling, and its 131.0 mm margin is the only clearance left to absorb unmodeled pipeline delays or to serve as a reserve. That margin is narrow relative to the failure modes it must absorb. If chunk lease enforcement were entrusted to a non-real-time host operating system, an upstream planning stall lasting 200 ms instead of the nominal 60 ms lease would inject 182 mm of unbraked displacement, causing the base to overrun the rack clearance by 50.99 mm. This hazard shows why lease termination must be autonomously enforced by dedicated microcontroller hardware directly gating motor power (section 12.6).

The observation-age term ends at dispatch, and the chunk lease begins at admission, so the interval between them, Δ_{da}, belongs to neither. The complete operational delay therefore expands to $T_{\text{true}} = \tau_{\text{delay}} + \Delta_{\text{da}}$, requiring an additional spatial reservation of $v\Delta_{\text{da}}$. This phase encompasses any remaining neural inference, safety envelope projection, and inter-process communication; pipelined or overlapping stages must be budgeted carefully to avoid double-counting. A newly arrived sensor observation updates this budget only when the hardware pipeline delivers and validates it prior to actuation. Laid out on one time axis (figure 12.2), the observation age ends at dispatch, the dispatch-to-admission interval follows, and the lease, one tick, one bus cycle, and drive onset bring the base to brake onset. A travel row beneath converts each interval into millimeters at the candidate aisle speed.

At this candidate speed, dividing the 131.0 mm spare distance by the speed yields 100.8 ms of unallocated timing allowance. Added to the 51.6 ms observation age, that allowance places the latest admission after capture at 152.4 ms. Added to the 133.6 ms pre-brake delay, it places the latest brake onset after capture at 234.4 ms. The dispatch-to-admission interval spends part of that allowance and leaves whatever remains as the reserve; because operating right at these boundaries spends all available clearance, the figures are qualification constraints rather than performance claims. The budget carries forward the allocation that the placement chapter makes for this interval (section 13.6.2), $\Delta_{\text{da}} = 63.3$ ms for the partitioned compute pipeline. That allocation consumes 82.3 mm of the spatial margin, leaves a cushion of 37.5 ms (48.7 mm of distance), and puts total latency from capture to brake onset at 196.9 ms. Because that allocation is an engineering budget rather than a measurement, an instrumented campaign with hardware timestamps must confirm it before the vehicle can be certified at this speed. Read row by row (table 12.1, figure 12.1), the terms through observation age fit inside the clear distance at the 1.5 m/s drive limit, whereas the jerk-limited stop (row 6) carries the total past the line and the tracking inset (row 7) widens the breach. At the 1.3 m/s aisle speed, those same terms stop 131.0 mm short of the line and still leave a 48.7 mm reserve once dispatch-to-admission travel is charged.

Table 12.1: The warehouse mobile manipulator's stopping budget: Each numbered row details the distance contributed by a physical subsystem or software stage, modeled for a loaded chassis on a dry industrial floor at the 1.5 m/s drive limit vs. the candidate 1.3 m/s aisle speed; the running total and clearance remainder are evaluated at the drive limit against the 1.10 m obstacle clearance. Row 6 accounts for the additional displacement imposed by jerk-limited C^2 deceleration profiles relative to ideal constant deceleration. Time-only rows contribute latency rather than physical distance. The totals cover rows 1 to 7; row 8, the dispatch-to-admission travel $v\Delta_{\text{da}}$, is charged against the spare at the aisle speed only, and the last line is the reserve it leaves. The second column names the section that prices each term, so every partial total stated in earlier chapters traces to a row of this table.

Row	Added in	Term	At drive limit (mm)	Running total (mm)	Left of D_{clear} (mm)	At aisle speed (mm)

This baseline stopping model evaluates a stationary obstacle situated at distance D_{clear}, such as a dropped warehouse tote or a pedestrian who has stepped out from an aisle rack and stopped. Under this assumption, the hazard remains fixed from the instant braking begins. If, instead, a pedestrian continues walking toward the vehicle throughout the reaction and braking phases, the obstacle actively closes the safety gap from the opposing direction. Before dispatch allocation, an ongoing pedestrian approach restricts the mobile base to a subtotal ceiling of just 0.26 m/s at this rack end.

This drastic velocity reduction occurs because an active hazard penalizes the stopping budget by the *duration* of the stop rather than merely its displacement. Assuming an ISO 13855 approach velocity $v_h = 1.6$ m/s across the entire reaction and stopping interval $\tau_{\text{delay}} + T_{\text{stop}}(v)$, the spatial budget acquires an additional closure penalty $v_h\,[\tau_{\text{delay}} + T_{\text{stop}}(v)]$ absent from static calculations. When operating below the velocity threshold $a_{\text{brake}}^2/j_{\text{max}} = 0.56$ m/s, the jerk-limited braking profile cannot achieve peak deceleration a_{brake}; it ramps deceleration up and immediately down in a triangular profile lasting $2\sqrt{v/j_{\text{max}}}$. This duration diminishes far more slowly than the linear scaling v/a_{brake} as velocity decreases. Initiating a jerk-limited stop from 0.26 m/s requires 382 ms, compared to only 130 ms for idealized step deceleration. While the mobile base travels only 50 mm during braking, the pedestrian advances 612 mm toward the robot over the same window. Achieving peak deceleration from such low speeds would demand a jerk of 41 m/s^3, several times the stipulated bound the load was assumed to tolerate, whereas unconstrained step deceleration would permit 0.64 m/s. That contrast arises because the jerk bound costs differently in the two regimes. Above $a_{\text{brake}}^2/j_{\text{max}}$ it adds a fixed delay of $a_{\text{brake}}/(2j_{\text{max}})$ whose travel grows with speed and forms the row-6 term pushing the drive limit past the clear distance. Below that threshold it stretches the stop's duration. Against a person who keeps walking, duration is what the budget pays for, so reducing operating speed yields diminishing safety returns.

Throttling nominal aisle velocity to the walking-person ceiling would severely degrade warehouse transport throughput for an event that facility layout and procedural crossing rules can prevent. The baseline operational design therefore mandates enforced physical or optical crossing restrictions at aisle ends, while the residual-claims register in section 18.3.3 tracks the governing premise that pedestrian incursions into the stopping zone are procedurally prevented. Operating at the candidate aisle velocity remains contingent on empirical validation of these access restrictions. The derivation

↩ The pedestrian intrusion distance, evaluated for a constant-deceleration stop at the drive limit, is established in section 9.7.

DRAFT

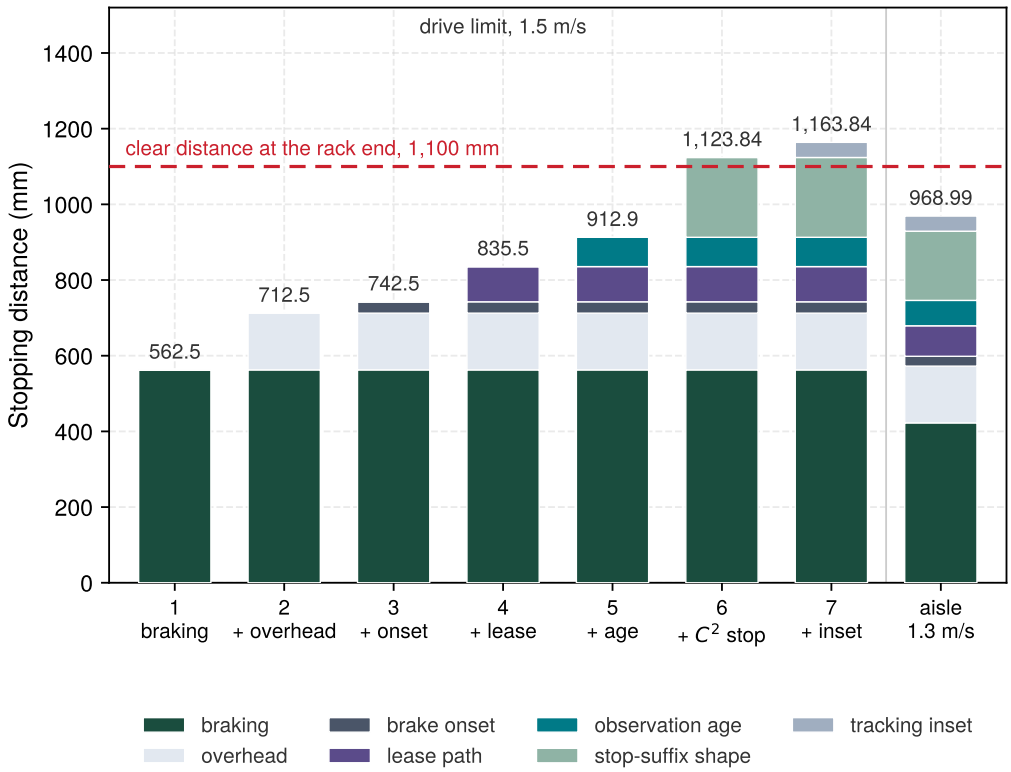

Figure 12.1: The stopping budget, row by row: Each bar illustrates the cumulative distance required as each successive physical and timing term is incorporated into the budget, evaluated at the vehicle drive limit under loaded conditions on dry concrete. While kinematic braking, fixed margins, actuator onset, lease execution, and perception age collectively remain within the available clearance, the jerk-limited deceleration profile causes the total to exceed the boundary, and the closed-loop tracking inset exacerbates this overrun. The final bar displays the accounted subtotal at the candidate aisle speed, where the remaining clearance must absorb the dispatch-to-admission interval before providing a net safety reserve.

bounds stopping against a static obstruction; protecting against an unconstrained approaching pedestrian requires certified physical interlocks or external safety scanners.

Three operating regimes therefore set three ceilings (figure 12.3). On a dry floor, fixed allowances, linear delay travel $v\tau_{\text{delay}}$, quadratic braking travel $v^2/(2a_{\text{brake}})$, and jerk-ramp travel sum to a total that meets the 1.10 m clear distance at 1.44 m/s. Even an optimistic all-weight traction screen requires a floor friction coefficient of at least 0.204, because $a = \min(a_{\text{brake}}, \mu g)$ assumes all weight contributes braking traction. The running machine also requires qualified driven-wheel load share, torque, and stability (section 2.3). On a sealed floor inspected to $\mu = 0.12$, the ceiling falls to 1.23 m/s. A pedestrian walking toward the base at 1.6 m/s charges the stop by its duration and contracts the ceiling to 0.26 m/s. Because these three roots are subtotal ceilings before dispatch allocation, charging the 63.3 ms allocation lowers each of them. The dry-floor root falls to 1.35 m/s by adding the base's travel through dispatch. The optimistic inspected-floor root falls to 1.17 m/s in the same way. The walking-person root falls to 0.19 m/s by adding both the base's travel and the person's closure across that interval. Because operating at any maximum root spends all clearance and leaves zero reserve, the remaining reserve must be recomputed for the selected speed, floor, and hazard motion. The 37.5 ms timing reserve belongs specifically to the dry, static-obstacle 1.3 m/s candidate, and an authority transition cannot claim its original 100.8 ms margin a second time.

An independent protective safety scanner operates under its own hardware-to-actuation timing budget. When an obstacle breaches a safety-rated zone, the scanner's internal optical sampling, fail-safe output switching, safety controller logic, and drive disconnect delays entirely bypass the perception dispatch and software lease infrastructure. However, the physical response must

↪ The authority transitions that must fit inside this remaining reserve are developed in section 14.3.

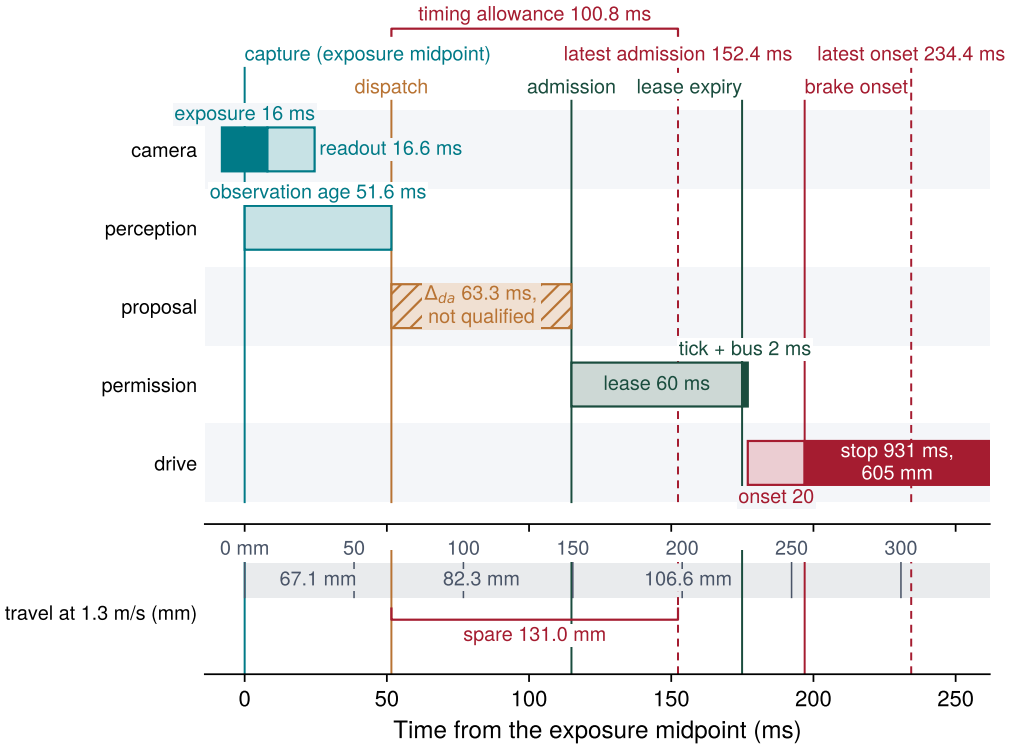

Figure 12.2: From capture to brake onset, in time and in travel: The warehouse mobile manipulator's permission path at the 1.3 m/s aisle speed, drawn to scale from the exposure midpoint of the frame that first shows the hazard. The observation age of 51.6 ms ends at dispatch; the hatched dispatch-to-admission interval is the 63.3 ms allocation that placement makes, a budget that loaded measurement must still confirm; the lease, one tick, one bus cycle, and drive onset follow admission. The row beneath reads the same axis as travel, so the 100.8 ms timing allowance and the 131.0 mm spare are one interval. Admission later than 152.4 ms, or onset later than 234.4 ms, spends clearance the budget does not have. The jerk-limited stop that follows onset runs past the right edge.

still reserve the same underlying deceleration distance, mechanical tracking error, localization tolerance, and protective safety cushion; only computational delays bypassed by the safety bus are eliminated from the sum. Industrial mobile bases deploy such protective fields under ISO 3691-4 (International Organization for Standardization 2023b) for driverless industrial trucks and ISO 13849-1 (International Organization for Standardization 2023a) for safety-related control circuits, using a safety-rated planar scanner of the kind in figure 12.4, which evaluates programmable warning and protective fields. The physical dimensions of this protective field must be calculated from the dedicated scanner path's verified hardware timing budget, rather than inheriting the software lease and vision latencies of the neural planner. The safety-rated optical scanner is a component of a separately qualified protective function, distinct from the primary perception LiDAR that generates non-safety-rated point clouds for neural proposal generation. Its component rating does not certify the complete sensor-to-stop path. In the running architecture, that path must establish the detection coverage, response time, and physical stopping performance required for protection at rack intersections. Section 12.9.3 maps the software stopping budget onto this certified hardware baseline and shows that industrial vehicle testing standards validate pedestrian detection against the same static-obstacle assumption derived here.

12.3.2 Phase portraits and speed ceilings

Checking velocity against a fixed scalar limit fails as soon as obstacle distance shrinks: a speed that is recoverable two meters from the rack end becomes an inevitable collision eighty centimeters closer. Drawn in the distance–velocity (D_{clear}, v) phase plane (figure 12.5), the plotted pre-dispatch

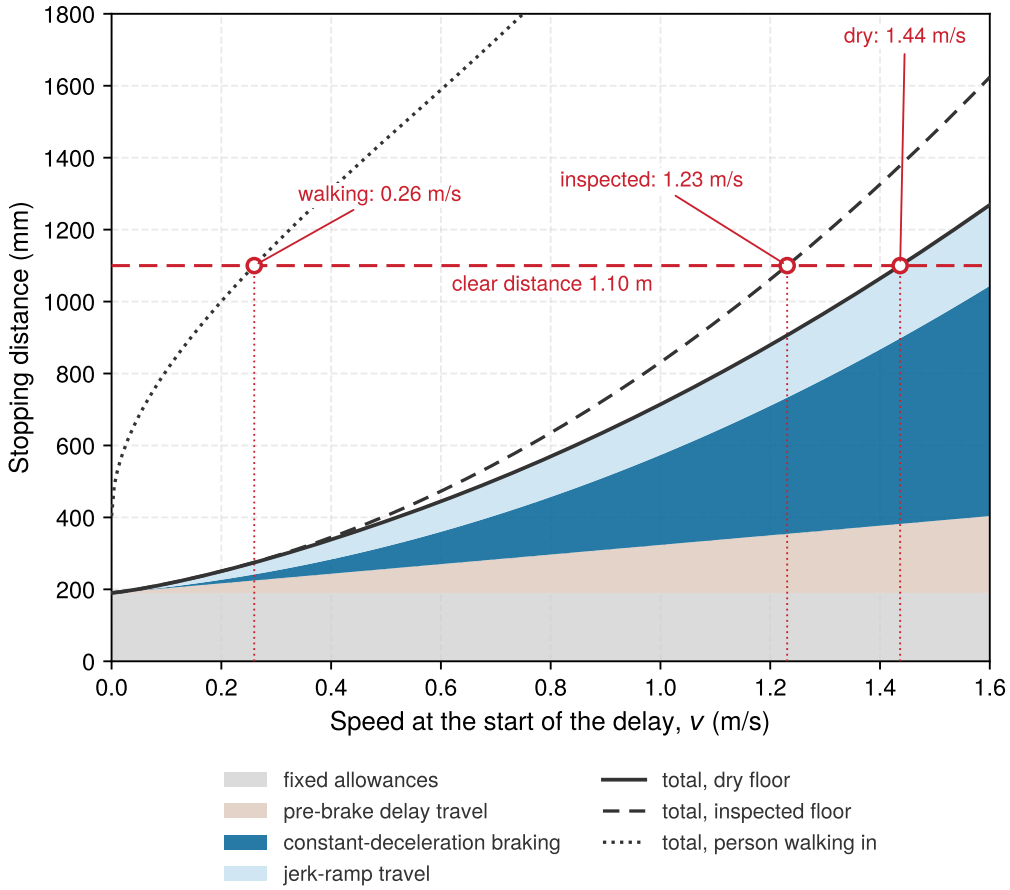

Figure 12.3: Stopping subtotals against speed, and the three pre-dispatch ceilings: The stacked bands build the dry-floor stop from the fixed allowances, the travel during the 133.6 ms pre-brake delay, constant-deceleration braking, and the extra travel of the jerk ramps. Delay travel grows linearly with speed and braking travel quadratically, so the total meets the 1.10 m clear distance at 1.44 m/s. The dashed curve applies the optimistic all-weight traction screen for a floor inspected to $\mu = 0.12$, moving the ceiling to 1.23 m/s. The dotted curve adds the closure of a person walking toward the base through the delay and the stop, which charges the stop by its duration and gives a pre-dispatch ceiling of 0.26 m/s. All three curves omit dispatch-to-admission travel; complete scenario ceilings are lower.

envelope separates states whose accounted subtotal fits from states whose subtotal already exceeds clearance. Complete admission contracts that boundary further by charging dispatch travel. Braking alone traces the outer parabola. The inset boundary pulls the viable set, the recoverable set drawn in this plane, inward by the pre-brake travel $v\tau_{\text{delay}}$, the jerk ramps of the matched stop, and the fixed localization, protective, and tracking allowances. At the rack-end clear distance the height of that plotted boundary is the subtotal speed ceiling, with the candidate aisle speed beneath it. The complete dry-floor ceiling is 1.35 m/s; the governor must use the fully charged boundary. Under the verified delay and deceleration bounds, the envelope is therefore a velocity ceiling that varies with clearance, and a state outside it violates the stopping reservation even if an emergency maneuver might avoid a collision in an edge case.

Evaluated on every enforcer tick, the envelope becomes a speed governor that runs in two stages, and their order matters:

1. **Current-state feasibility check**: The enforcer first verifies whether the robot's current operational state (D_{clear}, v) remains strictly inside the envelope. It tests whether a full braking response from the current velocity v, with all transport lags, jerk transitions, and margin allowances, fits within the currently measured clearance D_{clear}. If this condition fails, no newly

Figure 12.4: Planar laser scanner: A rotating mirror sweeps a time-of-flight beam across a horizontal fan, so the device reports range over one plane around the base. A safety-rated scanner of this form adds an early warning field and a protective field. The warning field requests earlier deceleration; the protective field's safety output feeds a controller that selects a risk-assessed stop. Protective-field length must include scanner response, controller and drive delay, braking travel, and uncertainty; a moving base does not become safe merely because motor torque is removed. (Credit: Björn Heller, Wikimedia Commons, CC BY-SA 3.0 DE.)

proposed command setpoint can restore the lost stopping reservation, because reducing the target acceleration cannot retroactively erase the kinetic energy or displacement accrued from the existing physical velocity. A violation at this step immediately selects `STOP`, the resident controlled stop that section 12.9 defines among the enforcer's fallback responses.

2. **Candidate command projection**: If and only if the current state passes validation, the enforcer samples the speed ceiling $v_{\max}(D_{\text{clear}})$ from the fully charged counterpart of the pre-dispatch boundary shown in figure 12.5. It then clamps the candidate velocity proposal v_{cand} to the admissible ceiling, admitting $v^* = \min(v_{\text{cand}}, \max(0, v_{\max}))$. Rather than discarding an overspeed proposal entirely, this governor projects the command onto the boundary of the safe set.

If obstacle clearance shrinks, computational jitter expands end-to-end latency, or floor friction degrades, the envelope boundary shifts inward, throttling admissible velocity on the subsequent control cycle when qualified sensing or configuration evidence exposes the change. A reference clamp alone does not establish that actual velocity remains inside the envelope between checks. This one-dimensional velocity governor is the scalar prototype for multi-dimensional safety filters; in section 12.5, control barrier functions extend this exact principle to enforce forward invariance over full state spaces.

The stopping envelope is the kinematic roofline of section 1.4.3 carried through the finished budget. Physical clearance (D_{clear}) sets a ceiling on transit speed for the qualified braking, margin, and timing bounds. A faster inference frame rate raises that ceiling only if it reduces a delay charged to the stopping budget. Model size and inference optimizations affect the ceiling through their share of the sensor-to-actuator delay τ_{delay}. On the warehouse mobile manipulator, every 1 ms of added pipeline delay consumes 1.3 mm of spatial clearance at nominal aisle velocity, and an unbudgeted 10 ms latency increase depresses the allowable speed ceiling by approximately 14 mm/s. Consequently, deploying an oversized vision-language model that increases latency directly lowers maximum transit speed, whereas an inference improvement that does not change the scheduled delivery tick may leave the charged delay unchanged. The speed ceiling shifts materially only when altering the physical parameters of the plant: verified deceleration authority a_{brake}, end-to-end transport lag τ_{delay}, tracking error bound ϵ_{track}, and localization uncertainty δ_{loc}.

↩ The clearance-parameterized velocity ceiling is established as a kinematic constraint in section 2.3.2.

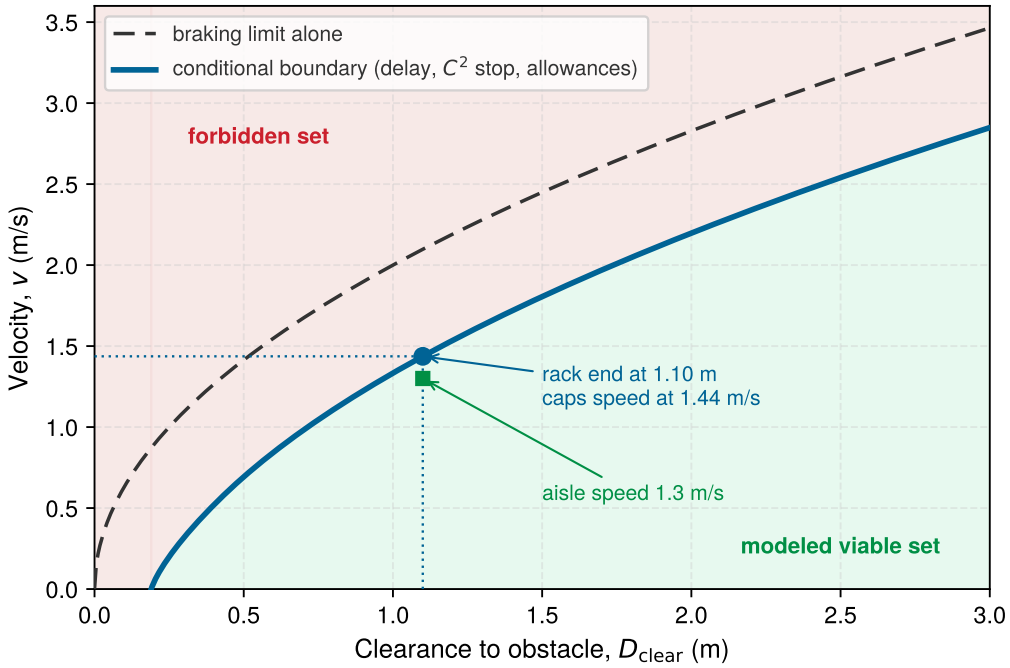

Figure 12.5: Conditional stopping subtotal before dispatch: For the warehouse mobile manipulator's base, a boundary separates states with modeled braking clearance from states that have already exhausted it. The inset includes the pre-brake delay, the matched stop suffix's jerk ramps, and the localization, protective, and tracking allowances. Clearance below the fixed allowances admits no approach speed, including zero. The curves use the accounted delay and stated braking envelope; unaccounted dispatch-to-admission time lowers the ceiling further.

None of these governing parameters remain stationary during real-world operation. Manipulating a heavy payload in the end-effector increases arm inertia, diminishing joint deceleration limits within peak motor torque bounds. Industrial floor contaminants such as oil or water severely degrade tire traction beneath the assumed braking limit a_{brake}, while aggressive operational cycles heat motor windings and drive inverters into thermal derating. A safety enforcer that treats a_{brake} as an immutable datasheet constant will dangerously underestimate stopping distance under heavy workloads. Runtime safety monitors must update braking bounds as observable, qualified payload and thermal states evolve. Instantaneous wheel-floor friction is not measured on this machine; an unobserved floor change invalidates the inspection premise and requires an operating restriction rather than automatic adaptation. In either case, relying on unvalidated, optimistic estimates invalidates the formal safety contract.

Dynamic adaptation remains effective only as long as state estimators remain uncorrupted and physical actuators retain control authority. If severe surface contamination reduces friction toward zero, or if sustained high-torque demands push drive inverters beyond their thermal trip thresholds, physical braking authority collapses. When required stopping torque exceeds what the physical hardware can exert against the environment, software can still detect the boundary violation, but it can no longer prevent an impact.

12.4 Authority Exhaustion and Emergency Fallback

A loaded arm descending toward the packing station must counter gravity before any torque remains to slow its motion. **Actuator saturation** occurs when requested effort reaches the electrical, mechanical, or thermal limits of the physical body, which can cause downstream integral controllers to accumulate windup.[3] The actuator cannot deliver the corrective control action $\mathbf{u}^*$ at its commanded magnitude in any of several cases. Motor phase currents may hit inverter current-chopping limits ($I_{\max}$). The DC bus may sag under inductive switching transients ($L_{\text{bus}}\, dI/dt$). Back-EMF at high

[3] **Integrator Windup**: A proportional-integral controller's integral term continues summing tracking error while an actuator sits at its saturation limit, as standard feedback loops do not inherently know that command outputs are clipped. When tracking error reverses, this accumulated state must unwind before the actuator command can leave the saturation rail. That unwinding delay directly consumes safety clearance. While modern anti-windup schemes clamp or back-calculate integrator state during saturation (Åström and Murray 2021), the safety enforcer must still budget whatever residual unwinding delay remains in the low-level hardware controller.

rotor speeds may collapse voltage headroom ($V_{\text{rail}} - K_e\omega_m \to 0$). Winding temperatures may approach thermal derating thresholds ($T_{\text{winding}} \to T_{\text{limit}}$). No mathematical safety boundary can be defended with control effort the physical body cannot generate.

When required braking effort exceeds physical actuator limits, no safety filter can enforce the promised stopping horizon. An emergency fallback invoked after control authority is lost can mitigate damage, but it cannot restore an invariant guarantee that physical dynamics have already broken. The runtime enforcer must therefore contract its forward reservation *before* actuator effort saturates, preserving a feasible braking margin under worst-case loading.

↩ The electrical and transmission limits that bound delivered actuator effort are established in section 2.4.

A stopping envelope based on peak torque alone overstates braking authority when gravity drives the moving load toward a hazard. Under a steady-state bias torque τ_{bias}, the effective deceleration available to arrest angular motion collapses:

$$\alpha_{\text{net}} = \frac{\tau_{\text{max}} - \tau_{\text{bias}}}{J_{\text{eff}}} \tag{12.3}$$

where J_{eff} is mechanism inertia and τ_{max} is the peak dynamic torque limit. In linear translational systems with mass m and bias force u_{bias}, equation 12.3 takes the equivalent form $a_{\text{net}} = (u_{\text{max}} - |u_{\text{bias}}|)/m$. For motion aligned with the bias, a payload consuming 75 percent of peak opposing torque leaves only the remaining quarter for active braking, quadrupling the constant-deceleration stopping distance at that speed.

Gravitational and dynamic biases are directionally asymmetric. When motion opposes gravity (such as during an upward arm swing), gravity assists motor braking, yielding $\alpha_{\text{net}} = (\tau_{\text{max}} + \tau_{\text{bias}})/J_{\text{eff}}$. Conversely, when motion aligns with the bias (such as a loaded arm descending toward a workstation), gravity directly opposes deceleration, collapsing braking headroom to $\alpha_{\text{net}} = (\tau_{\text{max}} - \tau_{\text{bias}})/J_{\text{eff}}$. Because safety certificates must guarantee forward invariance in the worst-case physical direction, the runtime enforcer must evaluate α_{net} with directional sign awareness rather than treating braking authority as an isotropic scalar. Suppose the warehouse mobile manipulator carries a mug from the takeaway conveyor down toward a coworker at the packing station. Its tool center point (TCP) moves at 0.96 m/s, within its 1 m/s free-space limit (only the final approach to the coworker's hand runs at the reduced handover speed derived in section 12.7.2). Gravitational bias during this descent quadruples the tool's stopping distance (notebook 12.2).

Napkin Math 12.2: The gravity braking tax

Problem: The loaded joint descends toward the packing station at ω_0. How far does the tool point travel before the joint stops when the whole peak torque brakes, and how far when gravity on the arm and mug holds part of it?

Variables:

- $\omega_0 = 1.2$ rad/s and $r_{\text{arm}} = 0.80$ m (Illustrative; the joint speed and effective link lever arm of the scenario, see the Reader Guide).
- $J_{\text{eff}} = 3$ kg·m² (Illustrative; joint inertia with the mug).
- $\tau_{\text{max}} = 87$ N·m (Datasheet; peak torque of the registered arm's axes 1 to 4).
- $\tau_{\text{bias}} = 65.25$ N·m, 75 percent of peak torque (Illustrative; gravity on the arm and mug in the direction of motion).

Math: With no bias, $\alpha_{\text{nom}} = \tau_{\text{max}}/J_{\text{eff}} = 29$ rad/s², the stopping angle is $\omega_0^2/(2\alpha_{\text{nom}}) = 0.0248$ rad (1.42°), and the tool point travels $r_{\text{arm}}\,\Delta\theta_{\text{joint}} = 19.86$ mm. On the descent, equation 12.3 leaves $\tau_{\text{max}} - \tau_{\text{bias}} = 21.75$ N·m for braking, so $\alpha_{\text{net}} = 7.25$ rad/s², the stopping angle is 0.0993 rad (5.69°), and the tool travels 79.45 mm.

Result: The descending stop is four times the unbiased one, an unbudgeted overrun of 59.59 mm for an enforcer that assumes the datasheet torque.

Systems insight: Stopping distance scales as $1/\alpha_{\text{net}}$, so a bias that takes 75 percent of the torque quadruples the braking term of d_{stop} at the same speed. The certificate must use the net authority in the worst direction, not the actuator's rating.

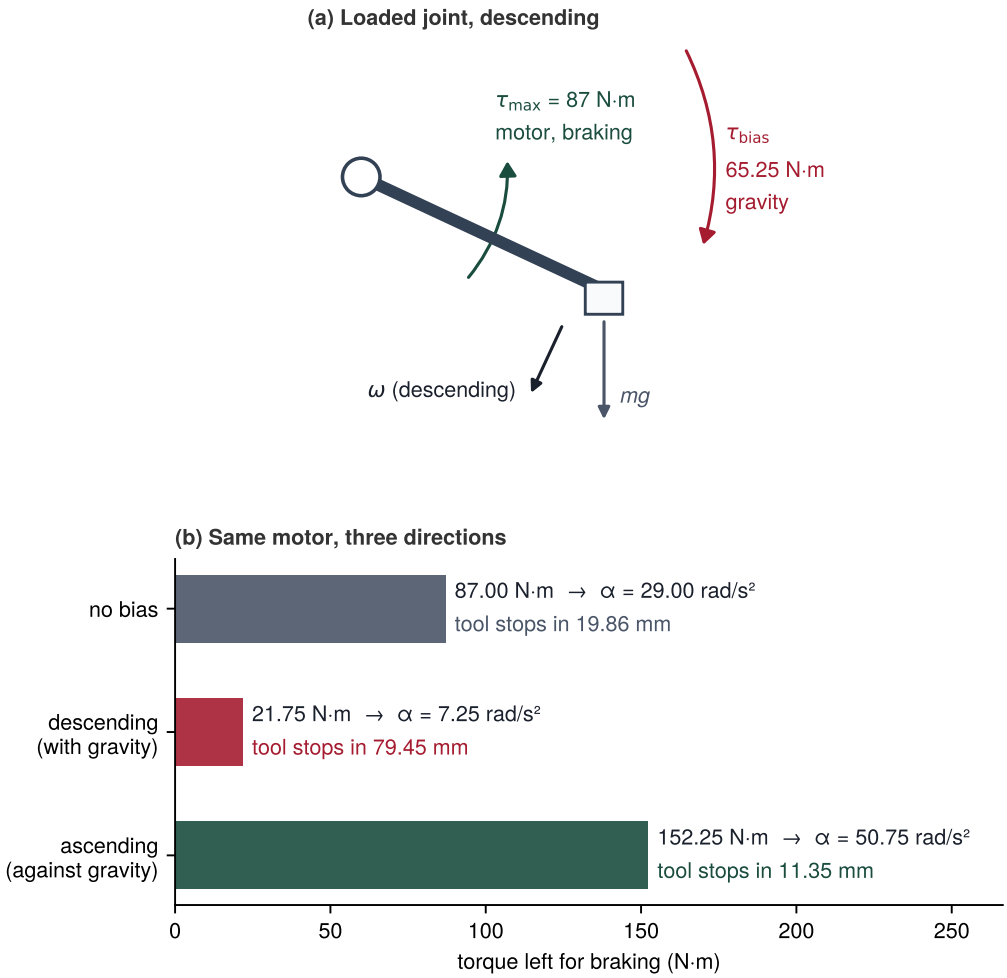

Figure 12.6: Gravity decides how much braking is left: (a) On the way down, gravity on the arm and mug loads the joint with 65.25 N·m in the direction of motion, against the motor's 87 N·m peak. (b) The same motor leaves 21.75 N·m for braking on the descent, a quarter of the unbiased case, so the tool stops in 79.45 mm instead of 19.86 mm; moving up, gravity adds to the braking torque. The certificate must use the descending case.

The asymmetry is direction, not magnitude (figure 12.6). On the descent, gravity torque acts with the motion and leaves only 21.75 N·m of the motor's peak for braking, while the same joint moving up recruits gravity and stops in less distance than the unbiased case. Whether the descending overrun reaches the workstation depends on the clearance left when braking begins, the margin the barrier certificate of section 12.5 evaluates. The coworker's hand must never fall within the arm's biased stopping distance of 79.45 mm plus its blind travel during sensing and communication delay before the handover channel engages.

An unprotected integrator downstream of the safety enforcer can introduce severe latency during actuator saturation. If clipping does not halt integration, tracking error continues to accumulate in the controller state. When the safety system subsequently requests maximum braking, the command must pass through this wound-up state rather than bypassing it. The actuator command consequently remains pinned at its forward saturation limit while the integrator unwinds. Take an illustrative case in which tracking error accumulates for 200 ms and the unwinding phase then delays net braking deceleration by $T_{\text{unwind}} = 150$ ms. The two durations are independent assumptions rather than one derived from the other; the unwind time depends on the integrator gain and on how sharply the error reverses, and only a test of the actual drive fixes it. At an aisle speed of 1.3 m/s,

this latency adds $vT_{\text{unwind}} = 195$ mm of unbraked travel. That overrun exceeds the system's entire 131.0 mm unallocated clearance buffer by 63.99 mm, even before dispatch-to-admission latency is charged. Classical techniques such as integrator clamping, back-calculation, and conditional integration prevent windup in the feedback loop (Åström and Hägglund 2006; Franklin et al. 1998). The enforcement architecture, however, must explicitly quantify any residual unwinding delay and budget the corresponding unbraked distance into the stopping horizon.

Actuator saturation is one of the few hardware limitations with an immediate, deterministic detector inside the permission path. On each 1 ms tick, the permission path compares the commanded effort u_{cmd} against the realizable actuator envelope: $u_{\text{act}} = \text{clip}(u_{\text{cmd}}, u_{\min}, u_{\max})$. A nonzero residual $u_{\text{cmd}} - u_{\text{act}} \neq 0$ or an active drive-stage current-limit flag directly reveals that the requested effort has been clipped. This comparison detects saturation at the command interface, however, rather than measuring delivered shaft torque or tire-ground traction. Qualified physical evidence (phase currents, DC bus voltage, thermal derating thresholds, and kinematic state telemetry) must support a conservative lower bound on available directional braking deceleration. An upper actuator-effort ceiling limits possible braking; it does not establish the braking that a stop may credit, and a clipping detector does not measure tire-floor traction.

Because degraded authority immediately lengthens stopping distance, the enforcer updates its braking envelope in real time. Before admitting the next trajectory segment, the filter recomputes the effective deceleration $a_{\text{net}} = (u_{\max} - |u_{\text{bias}}|)/m$. Allowable vehicle velocity scales down as authority contracts; if the recalculated stopping distance no longer fits within the confirmed clear distance, the enforcer must command immediate deceleration while sufficient braking headroom remains.

Authority exhaustion must also be communicated upstream to the planner. If a 20 Hz trajectory generator continues commanding aggressive accelerations while the low-level 1 kHz loop reports saturation, the policy is planning trajectories for a virtual body that the physical robot cannot realize. The permission path treats saturation as an active constraint violation. It revokes the active trajectory lease and forces a replan initialized from the machine's actual, authority-constrained dynamic state.

Systems Perspective 12.2: The actuator authority invariant

A control barrier function, as formulated in section B.4, remains mathematically valid only while physical actuators retain sufficient current, voltage, and thermal headroom to deliver the computed corrective effort: $u^* \in [u_{\min}, u_{\max}]$. When steady-state gravity, friction, or payload inertia encroaches on this operating envelope, the runtime enforcer must dynamically contract the safe set before marginal control authority vanishes.

Checkpoint 12.1: Stopping envelope and actuator headroom

Consider how the stopping envelope, and the actuator authority beneath it, bound permissible motion:

- ☐ **Quadratic envelope scaling**: Why does the stopping budget grow faster than speed, so that the finished budget, rather than the drive limit, sets the aisle speed, and why can no planning policy bypass this kinematic floor?
- ☐ **Transport lag vs. braking estimate**: At the 1.3 m/s aisle speed, what clearance is spent during τ_{delay} ($v\tau_{\text{delay}}$) and during constant-deceleration braking ($v^2/2a_{\text{brake}}$), and what is the speed below which the delay term dominates?
- ☐ **Effective deceleration collapse**: What is the physical mechanism that causes stopping distance to quadruple when steady-state gravity consumes 75 percent of peak actuator torque?
- ☐ **Dynamic safe set contraction**: Why must the permission path actively shrink the admissible state space when an actuator approaches thermal or electrical saturation, rather than waiting for tracking error to breach a hard limit?

12.5 Safe Sets as Conditional Permission

Once gravitational bias torque is counted, the descending arm analyzed in section 12.4 requires 79.45 mm of tool travel to brake to a complete stop, and this stopping distance scales quadratically with approach speed. A clearance margin that guarantees safety at one velocity fails completely at a higher velocity. The runtime safety enforcer therefore requires a joint predicate over position and velocity that it can evaluate synchronously on every tick of the control clock.

While a stopping budget establishes a static physical margin, a control barrier function[4] transforms that spatial margin into an instantaneous constraint on the next actuator command (Ames et al. 2014; Ames et al. 2019). This formulation belongs to the broader family of **safety filters** that monitor candidate action proposals against certified fallbacks, intervening only when necessary (Hsu et al. 2024) so that the machine can execute aggressive tasks while guaranteeing sufficient braking authority to halt.

A **safe set** $\mathcal{C}$ collects all system states for which a scalar certificate $h(\mathbf{x})$ remains nonnegative. Its boundary represents zero margin, whereas its interior provides positive margin. For the manipulator arm, both position and velocity must enter this certificate because a physical clearance that safely accommodates a slow approach must reject a high-speed approach at the identical position:

$$\mathcal{C} = \{\mathbf{x} \in \mathcal{X} \mid h(\mathbf{x}) \geq 0\}, \quad \partial\mathcal{C} = \{\mathbf{x} \in \mathcal{X} \mid h(\mathbf{x}) = 0\}, \quad \text{Int}(\mathcal{C}) = \{\mathbf{x} \in \mathcal{X} \mid h(\mathbf{x}) > 0\}.$$

Ensuring that trajectories remain inside $\mathcal{C}$ is known as forward invariance, the physical counterpart to an **inductive loop invariant** in formal software verification:

$$h(\mathbf{x}_0) \geq 0 \quad \wedge \quad \dot{h}(\mathbf{x}, \mathbf{u}) \geq -\kappa(h(\mathbf{x})) \quad \Longrightarrow \quad h(\mathbf{x}_t) \geq 0 \quad \forall t \geq 0. \tag{12.4}$$

This implication holds in continuous time under valid plant models and actuator feasibility. Nagumo's theorem[5] (Blanchini 1999) provides the geometric boundary interpretation: the closed-loop vector field at the boundary $\partial\mathcal{C}$ must point tangent to or back into the set. The comparison function $\kappa(\cdot)$, chosen as an extended class-$\mathcal{K}$ function, strictly increases with safety margin and vanishes at zero. This allows rapid approach motions deep inside the interior of $\mathcal{C}$ while enforcing a nondecreasing safety margin along the perimeter. In an embedded implementation, discrete-time sampling, state estimation noise, and torque delivery latency demand additional safety buffers before continuous-time invariance translates into physical reliability.

Definition 12.2: Control barrier function

A ***control barrier function*** is a continuously differentiable scalar function $h(\mathbf{x})$ of the plant state whose 0-superlevel set defines the safe set $\mathcal{C}$, and whose directional derivative can be directly influenced by the control input. Restricting actuation to control inputs that satisfy $\dot{h}(\mathbf{x}, \mathbf{u}) \geq -\kappa(h(\mathbf{x}))$ guarantees that any trajectory initialized within $\mathcal{C}$ remains inside $\mathcal{C}$ for all time (forward invariance, equation 12.4), provided the plant model, actuator limits, and timing assumptions remain valid.

1. **Significance**: The function translates an empirical stopping margin into an admissible half-space constraint on the next control cycle. For the descending arm of section 12.4, its zero level set sits exactly where remaining tool clearance equals the biased stopping distance of 79.45 mm; closer than this boundary, no admissible torque command can keep the system within $\mathcal{C}$.
2. **Distinction**: Whereas a Lyapunov function certifies asymptotic convergence toward an equilibrium state, a control barrier function certifies set invariance, proving that system trajectories never exit an admissible operating region. The barrier function provides the mathematical certificate; the least-change quadratic program filter of section 12.7 provides the runtime mechanism to enforce it.
3. **Common pitfall**: Formulating h strictly as raw geometric distance. Because distance has relative degree two with respect to torque (commanded torque produces acceleration, which integrates to velocity, which in turn integrates to position), the control input has zero direct authority over $\dot{h}$ at the boundary. A filter monitoring position alone reacts

[4] **Barrier Function**: In constrained optimization, an interior barrier term such as $-\log(-g(x))$ grows without bound near constraint boundaries, preventing numerical iterates from escaping the feasible set. Barrier certificates extended this mathematical principle to dynamical systems, proving that no trajectory starting in a safe set can ever reach an unsafe state (Prajna and Jadbabaie 2004). Control barrier functions subsequently formulated this certificate as an explicit, affine condition on the instantaneous control input (Wieland and Allgöwer 2007). While an optimization algorithm's safety guarantee holds because its numerical iterates are evaluated exactly in software, a physical plant's safety guarantee holds only as long as actuator limits, dynamics, and real-time execution match the model assumed by the certificate.

[5] **Nagumo's Theorem**: Nagumo (1942) established that, under conditions ensuring unique solutions, a closed set is forward-invariant if and only if the system vector field points into the set or remains tangent to its boundary at every boundary point; viability theory subsequently formalized and generalized this principle. Because Nagumo's condition applies to continuous-time flows, a digital controller executing at periodic control ticks requires an inter-sample buffer, sized among the conditions forward invariance rests on (section 12.7.3), to guarantee physical safety between discrete updates.

only after physical momentum has made collision unavoidable. An effective barrier must incorporate approach velocity and net braking deceleration, as shown in section 12.5.1.

12.5.1 Kinetic barrier certificates and relative degree

On the descending arm, a barrier function written purely in terms of remaining spatial distance θ_{clear} leaves commanded motor torque out of its first time derivative, so the safety filter remains blind to closing velocity until the arm reaches the boundary with momentum it can no longer arrest. Across the causal boundary, high-level software proposals meet continuous physical plant dynamics governed by a control-affine differential equation:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$$

where $\mathbf{f}(\mathbf{x})$ captures unforced physical drift (including inertia, Coriolis forces, gravitational bias, and passive friction), $\mathbf{g}(\mathbf{x})$ maps control inputs to generalized accelerations, and $\mathbf{u}$ represents delivered joint torques. On this robot, embedded motor drives close the internal current and velocity loops, meaning the MCU does not write raw voltages to the coils; the per-tick cycle described in section 12.7.4 converts a torque-space decision into the setpoint and torque limit the drive accepts under the qualified delivered-effort realization contract developed there.

Evaluating how a scalar barrier certificate $h(\mathbf{x})$ evolves along state trajectories requires computing its directional time derivative. By the multivariable chain rule, the total time derivative $\dot{h}$ expands across the state velocity $\dot{\mathbf{x}}$:

$$\dot{h}(\mathbf{x}, \mathbf{u}) = \frac{dh}{dt} = \frac{\partial h}{\partial \mathbf{x}}\dot{\mathbf{x}} = \nabla h(\mathbf{x}) \cdot \dot{\mathbf{x}} = \underbrace{\nabla h(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x})}_{L_{\mathbf{f}}h(\mathbf{x})} + \underbrace{(\nabla h(\mathbf{x}) \cdot \mathbf{g}(\mathbf{x}))}_{L_{\mathbf{g}}h(\mathbf{x})}\mathbf{u}$$

Nonlinear control theory designates $L_{\mathbf{f}}h$ and $L_{\mathbf{g}}h$ as Lie derivatives.[6] In modern computational systems, these directional derivatives are standard **Jacobian-vector products (JVPs)** supported natively by autodiff frameworks such as JAX and PyTorch:

$$L_{\mathbf{f}}h(\mathbf{x}) = \nabla h(\mathbf{x})^\top \mathbf{f}(\mathbf{x}) = \text{JVP}(h, \mathbf{x}, \mathbf{f}(\mathbf{x})), \qquad L_{\mathbf{g}}h(\mathbf{x}) = \nabla h(\mathbf{x})^\top \mathbf{g}(\mathbf{x}) = \text{JVP}(h, \mathbf{x}, \mathbf{g}(\mathbf{x})).$$

In forward-mode automatic differentiation, a JVP evaluates the derivative along a single tangent vector. When the control matrix $\mathbf{g}(\mathbf{x})$ contains multiple input columns $\mathbf{g}_j(\mathbf{x})$, the notation $\text{JVP}(h, \mathbf{x}, \mathbf{g})$ denotes the row vector of individual channel products $\text{JVP}(h, \mathbf{x}, \mathbf{g}_j)$. The drift term and the control-channel terms capture distinct physical dynamics:

1. $L_{\mathbf{f}}h(\mathbf{x}) = \text{JVP}(h, \mathbf{x}, \mathbf{f}(\mathbf{x}))$ is the **system drift JVP**, measuring the rate at which safety margin changes due solely to momentum, gravitational load, and passive dynamics.
2. $L_{\mathbf{g}}h(\mathbf{x}) = \text{JVP}(h, \mathbf{x}, \mathbf{g}(\mathbf{x}))$ is the **control authority JVP**, measuring the instantaneous sensitivity of the barrier rate of change to commanded actuator torque across the causal boundary.

Formulating an effective barrier certificate requires avoiding the **relative degree trap**. In computational graph terms, relative degree is the graph distance, counted in time-integrator nodes, between the commanded control input $\mathbf{u}$ and the barrier certificate $h(\mathbf{x})$. If an engineer defines a safety certificate purely as geometric clearance, $h(\mathbf{x}) = x_{\text{obstacle}} - x_{\text{robot}} \geq 0$, the commanded actuation is separated from position by two successive integrations:

$$\text{Actuation } u \xrightarrow{\int \frac{1}{m} dt} \text{Velocity } v_{\text{robot}} \xrightarrow{\int dt} \text{Position } x_{\text{robot}}$$

This two-stage integration cascade establishes relative degree $r = 2$. Taking the first time derivative of clearance yields the closing velocity, $\dot{h} = -v_{\text{robot}}$, which contains no control input whatsoever ($L_{\mathbf{g}}h(\mathbf{x}) = \text{JVP}(h, \mathbf{x}, \mathbf{g}(\mathbf{x})) = \mathbf{0}$). Because the control authority JVP evaluates to zero, motor torque has zero instantaneous authority over the rate of barrier decay. At the boundary of the safe set ($h = 0$), enforcing forward invariance $\dot{h} \geq -\kappa(0) = 0$ requires $-v_{\text{robot}} \geq 0 \implies v_{\text{robot}} \leq 0$. Halting a moving system instantaneously would require infinite deceleration and unbounded torque ($u = -\infty$). Applying this first-derivative condition to position alone provides no torque constraint before

[6] **Lie Derivative** (the derivative along a flow): Named after Sophus Lie, whose continuous transformation groups generate the flows along which the derivative is taken, the Lie derivative in control theory is identical to the Jacobian-vector product in modern scientific computing. Because both describe the same directional derivative, the automatic differentiation frameworks used during neural policy training can directly evaluate drift and control authority for learned or tabulated barrier functions, whereas the embedded safety enforcer executes the analytical closed form.

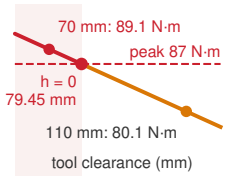
DRAFT

the geometric boundary. Higher-order barrier formulations can retain a position constraint and differentiate until the input appears; this chapter instead incorporates the stopping distance explicitly.

To restore nonzero control authority ($L_{\mathbf{g}}h \neq \mathbf{0}$), the barrier certificate must explicitly incorporate kinetic energy and braking limits. For an approaching arm joint, let $\theta_{\text{clear}} = d_{\text{tool}}/r_{\text{arm}}$ represent the remaining angular clearance, $\omega > 0$ the approach speed, $J_{\text{eff}}\dot{\omega} = \tau + \tau_{\text{bias}}$ the joint dynamics, and α_{net} a validated lower bound on net available angular braking deceleration. Adopting the linear class-$\mathcal{K}$ function $\kappa(h) = \gamma_{\text{cbf}}h$, where $\gamma_{\text{cbf}} > 0$ is a constant approach-rate gain, the **kinetic barrier certificate** is:

$$h(\theta_{\text{clear}}, \omega) = \theta_{\text{clear}} - \frac{\omega^2}{2\alpha_{\text{net}}}. \tag{12.5}$$

Differentiating $h(\theta_{\text{clear}}, \omega)$ along the joint dynamics yields $\dot{h} = L_{\mathbf{f}}h + L_{\mathbf{g}}h\,\tau$, where $L_{\mathbf{g}}h = -\frac{\omega}{J_{\text{eff}}\alpha_{\text{net}}} \neq 0$ for any nonzero approach speed $\omega > 0$. Because commanded torque τ appears directly in this first time derivative with a nonzero coefficient, the kinetic barrier achieves **relative degree one** ($r = 1$). Actuator commands now exert immediate control authority across the causal boundary. Enforcing the forward-invariance condition $\dot{h} + \gamma_{\text{cbf}}h \geq 0$ isolates the admissible torque into an explicit affine half-space constraint:[7]



$$\tau \leq -\tau_{\text{bias}} + J_{\text{eff}}\alpha_{\text{net}}\left(\frac{\gamma_{\text{cbf}}h}{\omega} - 1\right), \qquad -\tau_{\max} \leq \tau \leq \tau_{\max}. \tag{12.6}$$

In this sign convention, positive angular velocity ω, positive gravitational bias τ_{bias}, and positive motor torque τ all act downward toward the workstation so that clearance shrinks at rate $\dot{\theta}_{\text{clear}} = -\omega$, and a negative upper bound on τ in equation 12.6 therefore sets a minimum magnitude on the upward braking torque $-\tau$ that the motor must apply against gravity. This condition defines the linear half-space $\mathbf{a}_{\text{cbf}}(\mathbf{x})^{\top}\mathbf{u} \leq b_{\text{cbf}}(\mathbf{x})$ solved by the control barrier function quadratic program (CBF-QP) filter developed next, with the half-space normal and scalar threshold determined directly by the Jacobian-vector products: $\mathbf{a}_{\text{cbf}}(\mathbf{x})^{\top} = -L_{\mathbf{g}}h(\mathbf{x})$ and $b_{\text{cbf}}(\mathbf{x}) = L_{\mathbf{f}}h(\mathbf{x}) + \gamma_{\text{cbf}}h(\mathbf{x})$. At standstill ($\omega = 0$), the microcontroller firmware applies a separate static acceleration and position-hold check to prevent division by zero.[8]

Applying this kinetic barrier to the descending-arm parameters from section 12.4 sets concrete torque ceilings across the approach. The moment of inertia is $J_{\text{eff}} = 3$ kg·m². The gravitational bias torque is $\tau_{\text{bias}} = 65.25$ N·m, directed toward the workstation. The actuator saturation limit is $|\tau| \leq 87$ N·m, so the net angular braking deceleration is $\alpha_{\text{net}} = (\tau_{\max} - \tau_{\text{bias}})/J_{\text{eff}} = 7.25$ rad/s². The link lever arm is $r_{\text{arm}} = 0.80$ m, the approach speed is $\omega = 1.2$ rad/s, and the barrier gain is $\gamma_{\text{cbf}} = 10\ \text{s}^{-1}$. These are stipulated joint-level dynamics that deployment must calibrate on the actual arm. At 110 mm of tool clearance from the workstation surface, the angular clearance is $\theta_{\text{clear}} = 0.1375$ rad and the barrier certificate evaluates to $h = 0.0382$ rad, so substituting into equation 12.6 requires the joint to deliver at least 80.1 N·m of counteracting braking torque. Most of that demand is not deceleration at all, because the first 65.25 N·m merely cancels gravity to keep the joint from speeding up and only the remainder slows it, which is why a joint still outside its zero set already asks for most of its peak torque. At 79.45 mm, the system reaches the zero set ($h = 0$) where the barrier demands 87 N·m, the motor's full peak torque capacity. If clearance degrades further to 70 mm, the inequality demands 89.1 N·m, which exceeds peak actuator limits and places the state outside the control-admissible viable set. There, under these scalar dynamics, fixed bias, and instantaneous maximum-braking assumptions, no controller initiated at that point can prevent contact.

Physical robotic hardware provides neither perfectly continuous state feedback nor instantaneous torque response. Stator current rise times, fieldbus jitter, and drivetrain mechanical compliance delay and soften corrective torque delivery. To guarantee safety under these real-world non-idealities, the runtime enforcer evaluates the barrier certificate against an inset boundary that explicitly accounts for the worst-case stopping deficit induced by hardware latency and compliant dynamics. This initiates corrective filtering earlier along the trajectory.

This kinetic barrier construction follows directly from rigid-body braking mechanics. For the stipulated scalar approach with exact dynamics, fixed bias, instantaneous effort, and no omitted margins, its zero level set represents the exact boundary of states from which maximum allowable braking stops the joint before collision: the **viability kernel** (Aubin 1991) of a double integrator

Inside 79.45 mm of clearance the barrier asks for more braking than the joint has.

[7] **Kinetic barrier directional derivative chain rule**: Evaluating $\dot{h}(\theta_{\text{clear}}, \omega) = \frac{\partial h}{\partial \theta_{\text{clear}}}\dot{\theta}_{\text{clear}} + \frac{\partial h}{\partial \omega}\dot{\omega}$ with $\dot{\theta}_{\text{clear}} = -\omega$ and $\dot{\omega} = (\tau + \tau_{\text{bias}})/J_{\text{eff}}$ yields $\dot{h} = (-\omega - \frac{\omega\tau_{\text{bias}}}{J_{\text{eff}}\alpha_{\text{net}}}) - \frac{\omega}{J_{\text{eff}}\alpha_{\text{net}}}\tau = L_{\mathbf{f}}h(\theta_{\text{clear}}, \omega) + L_{\mathbf{g}}h(\theta_{\text{clear}}, \omega)\tau$. Substituting into $\dot{h} + \gamma_{\text{cbf}}h \geq 0$ and rearranging produces $\frac{\omega(\tau + \tau_{\text{bias}})}{J_{\text{eff}}\alpha_{\text{net}}} \leq \gamma_{\text{cbf}}h - \omega$. Multiplying by the positive factor $\frac{J_{\text{eff}}\alpha_{\text{net}}}{\omega}$ and subtracting the bias yields equation 12.6.

[8] **Standstill velocity thresholding**: In microcontroller firmware, floating-point evaluation of $\frac{\gamma_{\text{cbf}}h}{\omega}$ is explicitly guarded by a velocity threshold ϵ_{vel}: when $|\omega| \leq \epsilon_{\text{vel}}$, the kinetic barrier is bypassed in favor of a static acceleration or position-hold bound, preventing floating-point division by zero and NaN exceptions in the sub-millisecond loop.

subject to actuator saturation. Among collision-free states, the kernel's complement is the set of inevitable collision states defined in section 11.5.3. With a conservative available lower bound instead of exact maximum braking, the same construction supplies a sufficient stopping set rather than the exact kernel. The resulting torque requirement remains compatible with the stipulated actuator limits. At $h = 0$, the inequality in equation 12.6 demands exactly $-\tau_{\max}$, and for all $h > 0$ the demand is strictly less restrictive, ensuring that at least one admissible control command exists everywhere within the safe set. Actuator feasibility across the entire set, not merely the calculus of the derivative, is what qualifies $h(\theta_{\text{clear}}, \omega)$ as a valid barrier certificate under input constraints.

This identical principle governs autonomous base navigation. The mobile base certificate $h_{\text{base}}(D_{\text{clear}}, v) = D_{\text{clear}} - [v\,\tau_{\text{delay}} + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}}]$ is nonnegative precisely when the stopping subtotal in equation 12.1 fits the clearance. The operational certificate must additionally subtract the dispatch-to-admission travel before granting permission. Both constructions reserve the motion needed to stop. A nonnegative stopping reservation alone does not establish forward invariance; the sampled implementation must also preserve that reservation under its qualified state, effort, and timing bounds. The single-joint arm derivation omits latency and localization margins temporarily only to isolate the mechanics of relative degree.

When complex nonlinear dynamics prevent closed-form analytical solutions for the viability kernel, **Hamilton-Jacobi (HJ) reachability**[9] computes the boundary numerically as the zero level set of an optimal control value function (Mitchell et al. 2005; Bansal et al. 2017). The resulting tabulated lookup surface serves as the runtime barrier certificate, with its spatial gradient defining the half-space normal for real-time filtering. Because state-space grid discretization scales exponentially with dimensionality, HJ reachability lookup tables are best suited for decoupled, low-dimensional subsystems such as a single revolute joint or the longitudinal tracking channel of a mobile base.

A barrier certificate specifies which actuator commands preserve forward invariance, but it does not specify how the runtime safety path should handle an uncertified proposal. When a candidate command violates the half-space constraint, the enforcer must choose whether to project the command onto the boundary of admissible inputs, reject it in favor of a precomputed emergency braking trajectory, or maintain the previously certified setpoint. This intervention policy determines how mathematical barrier constraints translate into real-time authority over the motor drives.

12.6 Refusing Proposals and Enforcing State Invariants

A trajectory chunk arrives from the application processor on schedule, properly framed, and bearing a fresh evidence timestamp, yet one of its constituent joint setpoints would accelerate the arm directly into a steel rack upright. Nothing in the incoming packet payload marks that setpoint as erroneous. The permission path therefore grants zero executive authority to an incoming learned command until that proposal passes the configured state, input, freshness, and stopping-clearance checks. This is the third law, **proposal is not permission** (principle 3), executed deterministically one 1 ms tick at a time. Rather than assuming that a learned proposal satisfies stability criteria, actuator limits, or stopping guarantees, the permission path treats every incoming vector strictly as an advisory candidate.

The resident controller and output selector translate this principle of refusal into deterministic execution. The resident controller maintains a fallback response qualified for the current machine state, while the selector determines whether to admit an incoming candidate, apply a feasible correction, or transfer authority directly to that resident response. Rejecting an incoming candidate does not instantaneously abort the command currently driving the plant. Instead, the active command continues running so long as its own evidence timestamp, lease deadline, tracking error bound, and stopping reservation remain valid.

Under this architecture, the upstream neural policy never commands the physical plant directly. Its proposals reach the safety MCU through the board link and seqlock mailbox, with no addressable memory shared between the two compute domains. Each admitted chunk drives the plant only under a chunk lease, a hardware-enforced dead-man permission[10] that lapses unless a fresh, validated proposal renews it. A trajectory chunk arrives as a horizon of H waypoints, and the admission filter inspects all H points against reach, velocity, and stopping-reservation constraints before permitting the first waypoint to execute. On each subsequent control tick, the enforcer re-evaluates the specific setpoint scheduled for execution against live sensor telemetry. If the enforcer projects a setpoint

9 **Hamilton-Jacobi Reachability**: Originating in the zero-sum differential game formulations of Isaacs (1965), reachability analysis frames safety as a game between a control policy and a worst-case adversarial disturbance. The resulting safe set contains precisely those states from which the controller can guarantee safety against any bounded disturbance trajectory. Consequently, an HJ reachability table is inherently robust but conservative, and its safety guarantee holds only within the assumed disturbance envelope.

↪ The Hamilton-Jacobi value function and its differential-game formulation are developed in section B.6.3.

10 **Dead-Man Control**: Early electric locomotives incorporated a spring-loaded dead-man handle that the operator had to depress continuously; releasing the handle (if the driver lost consciousness, for example) interrupted tractive power and engaged the mechanical brakes. System safety arose from the cessation of action rather than the transmission of an explicit fault message. The chunk lease applies the same principle in software. The host must actively renew its permission, ensuring that an upstream processor too damaged to command a stop is inherently incapable of renewing execution authority.

on a single tick, it does not rewrite the chunk's downstream waypoints. Instead, the safety MCU reports the intervention upstream, requiring the policy to replan from the actual, corrected state rather than resuming execution along a trajectory computed for a state the machine never reached.

↩ The seqlock mailbox that hands proposals to the permission path is established in section 4.3.2.

If the proposal remains fresh, the physical machine state resides within the qualified stopping region, and the tracking error satisfies $\|e(t)\| \leq \epsilon_{\text{track}}$, the output selector permits the proposal (or its minimally projected variant $\mathbf{u}^*$) to drive the actuators. Conversely, if the chunk lease expires without renewal, tracking error breaches the tolerance bound, no admissible command satisfies instantaneous physical constraints, or the active command endangers physical boundaries beyond the corrective capacity of projection, the output selector revokes permission and unilaterally engages the baseline safety controller. The upstream neural policy is not consulted, cannot negotiate, and possesses no hardware mechanism to override the selector's decision.

When a proposal conflicts with physical constraints, the enforcer chooses between filtering and vetoing the command. Filtering applies when the proposal is structurally sound and a nearby admissible control action preserves the policy's underlying intent. Consider the manipulator arm approaching a spring-latched cage door when the chunk policy proposes approaching the strike plate at 0.10 m/s. The door zone admits only the guarded approach speed of 0.03 m/s defined by the target operational design domain (ODD), the velocity envelope validated across empirical trials and demonstration datasets. The faster proposal therefore fails on both evidential and physical grounds. It fails on evidence, because no trial or demonstration sampled that speed. It also fails on physics, because the contact analysis of section 12.7.2 shows that at that speed the force on the plate at brake onset nearly reaches the latch limit, leaving a stop that demands far harder arm deceleration than the guarded approach needs. Consequently, the enforcer preserves the approach trajectory's target and spatial direction, projecting only its scalar speed down to the 0.03 m/s limit. The least-change quadratic program formulated in section 12.7 solves this projection in real time alongside the half-space constraints derived by a control barrier function.

↩ The evaluation record's target ODD boundary, sampled at the guarded approach speed, is established in section 7.8.

Filtering must account for momentum alongside position, ensuring that the actuators retain sufficient control authority to bring the machine to a complete stop before available clearance vanishes (section 12.5). In the latch example, scalar speed projection preserves both the goal and the approach direction. In a coupled joint-torque filter, however, a correction can alter the end-effector trajectory through task space; such modification remains permissible only when the revised motion satisfies dynamic continuity constraints and remains task-admissible. Conversely, a structurally invalid proposal (a discontinuous jump in commanded position, an acceleration profile beyond peak motor torque, or a trajectory pointed directly into an immovable obstacle) indicates that perception or inference has entered an unmodeled failure mode. Projecting an ungrounded candidate onto the nearest admissible boundary would execute arbitrary motion unrelated to any coherent task intent. Under these conditions, the enforcer exercises an outright veto. The selector permits the active command to finish only if that command continues to satisfy its own validity checks; otherwise, it immediately transfers authority to a prequalified local fallback.

Both filtering and veto operate strictly at runtime; offline training cannot substitute for either mechanism. Penalty terms, barrier losses, and reward shaping bias the policy distribution during training, but they cannot mathematically bound what the deployed neural network will emit in edge cases. The **statistical safety fallacy** conflates a bound on expected violation cost with an absolute guarantee across every execution trace. A constrained reinforcement learning objective such as $\mathbb{E}[\text{cost}] \leq \delta$ constrains only the ensemble mean, leaving open the possibility of catastrophic tail events during individual rollouts. Formal neural-network verification can establish provable output bounds over bounded input sets (Katz et al. 2017), and closed-loop verification can combine those bounds with plant models. Formal proofs nevertheless remain vulnerable to reality gaps: unmodeled friction, sensor latency, non-deterministic scheduling, or actuator saturation outside the proof's operational assumptions will invalidate the guarantee. The permission path therefore verifies every candidate control vector at the hardware actuation boundary, regardless of the optimization objective used during training. When an incoming proposal is safe, the verification check is transparent, allowing learned sensorimotor competence to pass directly to the motor drives without alteration.

↩ Why training-time penalties cannot bound the actions a deployed policy emits is established in section 1.12.

The chunk lease, 60 ms on this machine, bounds upstream execution authority during a host stall or scheduling delay, provided the local timer, selector, sensing, and actuation paths survive. In addition to the lease, a dedicated 100 Hz host heartbeat monitors basic link viability with a 30 ms

DRAFT

silence timeout. The safety MCU executes its deterministic 1 kHz control loop, servicing a local 5 ms hardware watchdog timer only after successfully completing an entire cycle; an independent hardware trip circuit supervises MCU power and clock integrity. If either the host heartbeat or the chunk lease expires, the safety MCU revokes proposal permissions and engages a deterministic, state-matched fallback from the responses that section 12.9 defines, assuming reserved clearance and actuator braking capacities remain sufficient. On the warehouse mobile manipulator, if a proposer renews its lease and subsequently stalls, mechanical braking begins within 82 ms of the last valid renewal. This lease-expiry scenario assumes the underlying heartbeat remains active even as valid proposals cease; a total host operating-system freeze trips the 30 ms heartbeat timeout even earlier. If a worker steps out from behind a warehouse rack, the sensor capture latency of the camera frame that first revealed the obstacle adds directly to this renewal-to-onset delay, and section 12.3 carries this cumulative latency directly into the admission check.

↩ The lease, heartbeat, and self-watchdog timers, and why a heartbeat cannot renew a lease, are established in section 4.4.1.

Severing upstream authority requires an unambiguously defined physical response at the lowest hardware interface. The zero-command floor defines the default physical state enforced when active software control terminates, but commanding 'zero' produces drastically different dynamics depending on the actuator topology. Injecting zero current into a low-friction, direct-drive actuator allows a gravity-loaded manipulator arm to drop freely unless a mechanical brake or counterweight holds the link. Conversely, commanding zero velocity to a stiff position-controlled servo can demand infinite acceleration and trigger violent inertial transients. As detailed in section 2.6.2, an unpowered drive drops into one of three hardware states: unconstrained coasting, phase-short dynamic braking, or mechanical locking via spring-applied brakes. The system architect must ensure that the commanded fallback matches both the instantaneous kinetic state and the physical capabilities of the surviving hardware.

Proposal rejection is a continuous, steady-state operating decision rather than an exceptional emergency trip. The enforcer must evaluate every invariant and execute its selected fallback deterministically even if the upstream proposer crashes completely, provided local sensing, braking authority, and stopping clearance remain intact. When those physical invariants hold, runtime filtering smoothly reconciles learned proposals with safety boundaries, preserving admissible task progress within the qualified physical envelope.

12.7 The Minimal Intervention Principle and Optimization Filters

When the arm approaches the cage-door latch too quickly while still proposing a useful target and direction, rejecting every such proposal would discard useful learned behavior, whereas accepting it unchecked would exceed the permitted approach speed. The **minimal intervention principle** resolves this trade-off by passing an admissible proposal untouched and choosing the smallest feasible correction, one that satisfies physical constraints and finishes before the permission deadline, whenever a proposal crosses a boundary. The resulting **safety shield**[11] preserves useful task progress within the physical limits. For the torque forbidden by equation 12.6, the correction should remove only the constraint violation; replacing every near-boundary command with a stop would discard admissible learned behavior.

[11] **Shielding**: In safe reinforcement learning, a shield sits between the learning agent and its environment and overrides only those actions that would violate a temporal-logic safety specification (Alshiekh et al. 2018). The CBF-QP is a continuous-control shield. Its override is the smallest torque change rather than a substituted discrete action, and its specification is a stopping margin rather than a logic formula, which lets it keep the learned action's direction instead of replacing it.

For the already-derived torque half-space, the enforcer solves a constrained least-change problem, the **CBF-QP safety filter** (Ames et al. 2017). The tracker supplies the nominal effort; the barrier and actuator limits constrain the result. The combined program of section B.3.2, which optimizes convergence and safety together and relaxes convergence when they conflict, is not needed here. The tracker of section 12.2 already supplies the nominal effort, and the filter has only to keep it inside the barrier:

$$\min_{\mathbf{u}\in\mathbb{R}^m} \frac{1}{2}\|\mathbf{u}-\mathbf{u}_{\text{nom}}\|^2 \quad \text{s.t.} \quad \mathbf{a}_{\text{cbf}}(\mathbf{x})^\top \mathbf{u} \le b_{\text{cbf}}(\mathbf{x}), \quad \mathbf{u}_{\min} \le \mathbf{u} \le \mathbf{u}_{\max} \tag{12.7}$$

where the half-space normal and threshold are defined by the directional derivatives $\mathbf{a}_{\text{cbf}}(\mathbf{x})^\top = -L_{\mathbf{g}}h(\mathbf{x})$ and $b_{\text{cbf}}(\mathbf{x}) = L_{\mathbf{f}}h(\mathbf{x}) + \kappa(h(\mathbf{x}))$ derived in section 12.5.1, matching the single-axis torque constraint of equation 12.6, and $[\mathbf{u}_{\min}, \mathbf{u}_{\max}]$ represents the verified actuator torque envelope. The selected implementation allocates 150 µs to this solve. Dedicated memory and a fixed iteration cap support that target; qualification must establish completion or a timely fallback under the admitted constraint set.

12.7.1 Closed-form quadratic programming and torque projection

Clamping each joint axis independently, or projecting a command onto a barrier and then clipping it to motor torque limits afterward, can leave the coupled stopping constraint violated while skewing the direction of motion across task space. A single active barrier admits a closed-form projection when the projected command also lies inside the actuator bounds; if a bound becomes active, the enforcer must solve for the intersection rather than project onto the barrier and clamp afterward.

For a nonzero constraint normal and inactive actuator bounds, the single barrier constraint $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u} \leq b_{\text{cbf}}$ in equation 12.7 admits the closed-form projection derived in section B.4.4:

$$\mathbf{u}^{*} = \mathbf{u}_{\text{nom}} - \lambda^{*}\mathbf{a}_{\text{cbf}}, \qquad \lambda^{*} = \max\left(0, \frac{\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u}_{\text{nom}} - b_{\text{cbf}}}{\|\mathbf{a}_{\text{cbf}}\|^{2}}\right) \tag{12.8}$$

where the optimal dual multiplier $\lambda^{*} \geq 0$ is zero whenever the nominal proposal is safe ($\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u}_{\text{nom}} \leq b_{\text{cbf}}$), leaving $\mathbf{u}^{*} = \mathbf{u}_{\text{nom}}$. It is strictly positive when the proposal breaches the boundary ($\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u}_{\text{nom}} > b_{\text{cbf}}$). In that case it scales the minimal intervention vector $\Delta\mathbf{u} = -\lambda^{*}\mathbf{a}_{\text{cbf}}$, which projects $\mathbf{u}^{*}$ orthogonally onto the safe half-space boundary $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u} = b_{\text{cbf}}$.

On a two-axis manipulator with illustrative values, suppose the tracker following setpoints from an unconstrained neural policy computes nominal joint torques $\mathbf{u}_{\text{nom}} = [\,3.5,\, 3\,]^{\top}\ \text{N}\cdot\text{m}$ against a validated safety half-space $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u} \leq b_{\text{cbf}}$. Its parameters are $\mathbf{a}_{\text{cbf}} = [\,2,\, 1\,]^{\top}$ and $b_{\text{cbf}} = 5\ \text{N}\cdot\text{m}$. The per-joint actuator limits are $\pm 5\ \text{N}\cdot\text{m}$. Because the candidate gives $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u}_{\text{nom}} = 10\ \text{N}\cdot\text{m}$ and breaches the boundary by $5\ \text{N}\cdot\text{m}$, equation 12.8 yields $\lambda^{*} = 1$ and projects the command to $\mathbf{u}^{*} = [\,1.5,\, 2\,]^{\top}\ \text{N}\cdot\text{m}$. This meets the half-space exactly while keeping both joints within their limits at an intervention norm of $2.236\ \text{N}\cdot\text{m}$. By contrast, an independent per-axis clamp that ignores the coupling and cuts only the joint with the larger normal component holds Joint 1 to $2\ \text{N}\cdot\text{m}$ while passing Joint 2 at $3\ \text{N}\cdot\text{m}$. That clamp gives $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u}_{\text{clip}} = 7\ \text{N}\cdot\text{m}$, still $2\ \text{N}\cdot\text{m}$ outside the constraint, while skewing the torque vector from 40.6° to 56.3°. The per-axis clamp both violates the coupled constraint and distorts the command. Orthogonal projection satisfies the constraint with the smallest possible torque change, though it too rotates the torque vector, so the resulting end-effector path still requires checking against the coupled plant model.

This geometric behavior exposes the distinction between **torque-space and task-space minimal intervention**: an orthogonal projection $\mathbf{u}^{*} = \mathbf{u}_{\text{nom}} + \Delta\mathbf{u}$ minimizes joint effort deviation $\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^{2}$, which redistributes multi-axis joint torques and rotates the net Cartesian wrench. While a feasible projection can preserve the safe set $\mathcal{C}$ under the stated model and timing assumptions, it deflects the end-effector trajectory and may arrest task progress. If the upstream neural policy continues emitting unprojected nominal setpoints without awareness of the intervention, the robot can chatter or stall at the boundary. The downstream enforcer must therefore stream the intervention vector $\Delta\mathbf{u}$ back to the application processor as a telemetry signal, notifying the high-level planner to re-plan around the newly active physical constraint.

The same correction has a picture in state space and one in torque space (figure 12.7). In state space, a trajectory that would breach the velocity-dependent boundary $\partial\mathcal{C}$ is turned along it; in the torque plane, the projection places $\mathbf{u}^{*}$ on the half-space boundary $\mathbf{a}_{\text{cbf}}^{\top}\mathbf{u} = b_{\text{cbf}}$, while the per-axis clamp leaves $\mathbf{u}_{\text{clip}}$ outside it and skews its direction.

Filter choice joins a mathematical condition to a measured execution budget and the machine's available braking authority. As summarized in table 12.2, architectural choices differ in their handling of relative degree, solver worst-case execution time (WCET), forward invariance guarantees, and directional fidelity. Independent clamping can miss coupled constraints; a CBF-QP can enforce a derived half-space if it is feasible and finishes within the verified cycle. Predictive filters (Wabersich and Zeilinger 2021) trade a longer horizon for configuration-dependent compute cost.

The rows of table 12.2 belong to one unified family rather than rival techniques (Hsu et al. 2024): each filter monitors a candidate against a **fallback policy** known to keep the machine safe and intervenes whenever the candidate would leave the set from which that fallback still works, differing only in how the intervention occurs. Whereas a **least-restrictive** filter passes the proposal untouched up to the boundary and then switches abruptly to the fallback (which is simple to implement but chatters along the boundary), a smooth filter such as the CBF-QP blends in a correction before the boundary is reached. This chapter's enforcer combines both mechanisms: admitting a trajectory only with a matched stop suffix and holding a state-matched fallback for every reachable state forms

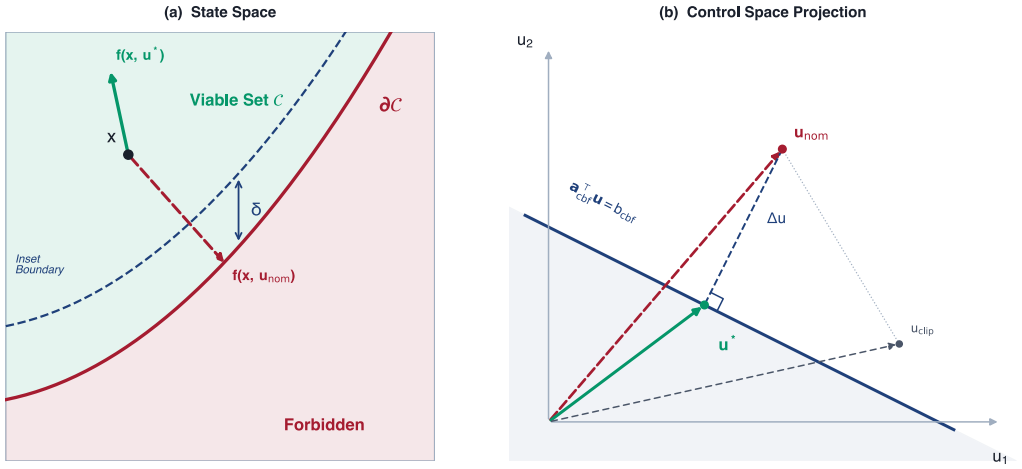


Figure 12.7: Kinetic barrier and torque projection: Panel (a) schematically shows a velocity-dependent viable boundary inset from geometric clearance; the raw distance alone has relative degree two for torque. Panel (b) illustrates Euclidean projection onto a supplied torque half-space. Panel (b) is schematic and not drawn to the worked example's values; that example's $[2, 1]$ normal and $5\ \mathrm{N \cdot m}$ threshold are abstract arithmetic inputs, not coefficients derived from the arm example.

a **backup-set filter** that checks safety by rolling the fallback forward from the proposed state (Gurriet et al. 2018; Chen et al. 2021). The per-tick CBF-QP acts as the smooth local filter layered on top of it, and HJ reachability (Fisac et al. 2019) supplies the value function when a precomputed surface replaces a closed-form barrier.

Table 12.2: Safety-filter decisions: A filter's physical claim depends on the chosen barrier and validated plant, not on the algorithm name. Nominal solve measurements are not worst-case deadlines. The energy-tank row is developed for intentional contact in section 12.7.2.

Filter	Input and condition	What it can establish	Main validation task
Independent torque clamp	Each axis checked separately	Hardware amplitude limit, not coupled stopping clearance	Test coupled wrench and stopping behavior
First-order CBF-QP	Barrier whose first derivative contains the input	Conditional invariance from a viable initial state	Validate model, feasible torque set, and cycle bound
Kinetic / higher-order barrier	Position constraint with speed and braking authority included	Conditional stopping margin before geometric contact	Bound bias torque, delay, estimate error, and discretization
Energy tank / passivity filter	State E_{tank}, power balance $\dot{E}_{\mathrm{tank}}$, force F_{limit}	Conditional energy bound; force requires a separately qualified channel	Bound force-sensor bias, calibrate virtual damping matrix $\mathbf{D}_{\mathrm{virt}}$, and set reserve floor E_{min}
HJ value-function filter	Precomputed value function over a gridded state space	Containment for the modeled region	Verify grid coverage, interpolation error, and disturbance bounds
Predictive safety filter	Finite-horizon trajectory and terminal set	Recursive feasibility only under terminal and timing assumptions	Bound full solve time and fallback on timeout

Operating near an active safe-set boundary can produce chattering. If a learned policy repeatedly proposes an unsafe command, sampled enforcement may switch the active constraint across successive 1 ms ticks. Depending on the plant and controller, rapid torque changes can excite a structural mode or increase motor heating and transmission wear. A tested boundary layer or hysteresis can reduce switching, but its added tracking error must fit inside the validated stopping margin.

The intervention vector $\Delta\mathbf{u} = \mathbf{u}^* - \mathbf{u}_{\mathrm{nom}}$ also measures upstream policy health. A rising intervention frequency or magnitude can indicate proposal drift, a changed task, or a changed plant.

Normal filtering can also preserve successful whole-machine service while reducing unassisted proposer autonomy; the log must distinguish these outcomes rather than count every correction as a task failure. Summed over an illustrative rolling window of $W = 500$ ms as $\sum_k \|\mathbf{u}_k^* - \mathbf{u}_{\text{nom}_k}\| \Delta t$, the metric lets the permission path flag divergence for logging or operator notification while the per-tick limits still protect the plant.

12.7.2 Intentional contact and in-contact energy barriers

Once the manipulator arm reaches the cage-door strike plate ($\theta_{\text{clear}} = 0$), the spatial kinetic barrier (equation 12.5) reduces to $h(0, \omega) = -\omega^2/(2\alpha_{\text{net}}) \geq 0$, which admits only zero speed ($\omega = 0$) and freezes the gripper before it can depress the latch. A spatial kinetic barrier operates under the premise that the robot's objective is to avoid collision ($\theta_{\text{clear}} > 0$), whereas manipulation, grasping, and assembly require intentional physical contact ($\theta_{\text{clear}} = 0$). While the spatial barrier can admit arrival at contact with zero approach speed, it does not govern the subsequent force-controlled interaction where geometric separation no longer supplies the relevant margin. Once the warehouse mobile manipulator's gripper meets the strike plate at the guarded approach, the arm must push against the latch spring, and the margin that matters is the energy and force it delivers there.

Enforcing safety during intentional contact requires transitioning from a **spatial clearance barrier** to an **energetic passivity barrier**. When physical clearance is zero ($D_{\text{clear}} = 0$), safety cannot mean zero velocity; it means bounding mechanical energy exchange and normal contact force $f_{k,\perp}$. A controller in physical contact interacts with an unmodeled, potentially stiff environment. If tracking errors or neural policy oscillations pump unmeasured energy into the interface, the closed-loop system undergoes contact chattering, limit cycles, or high-force impact spikes that damage both the workpiece and the robot's transmission.

To bound active energy exchange, the enforcer augments the controller state with an **energy tank** $E_{\text{tank}}(t)$[12] (Ferraguti et al. 2013; Hogan 1985) grounded in passivity. A passive system can return no more energy than its initial stored energy plus the energy it absorbs, so a power-preserving interconnection with a passive environment retains a passive energy balance (while a stability claim additionally requires the appropriate dissipation and state-observability conditions). The tank enforces that property by bookkeeping, acting as a software tally of work rather than a physical store of energy. Every joule that virtual damping removes from the arm's motion is credited to the tank, and the controller may spend actively only what the tank holds, namely its accumulated credits plus a fixed initial reserve. In this contact formulation, $\mathbf{u}_{\text{active}}$ denotes the active torque component excluding damping, so the total controller torque is $\mathbf{u}_{\text{active}} - \mathbf{D}_{\text{virt}}\dot{\mathbf{q}}$. The damping term can credit the tank only to the extent that the actuator actually realizes the corresponding dissipative work, and using total torque in the debit while also crediting damping would count the same dissipation twice. With those components separated, the modeled balance is:

$$\dot{E}_{\text{tank}} = \dot{\mathbf{q}}^\top \mathbf{D}_{\text{virt}}\, \dot{\mathbf{q}} - \mathbf{u}_{\text{active}}^\top \dot{\mathbf{q}} \tag{12.9}$$

where $\dot{\mathbf{q}}^\top \mathbf{D}_{\text{virt}}\, \dot{\mathbf{q}} \geq 0$ is the dissipative power credited under qualified torque tracking and $\mathbf{u}_{\text{active}}^\top \dot{\mathbf{q}}$ is active mechanical power. Saturation, delay, or tracking error requires conservative bounds on realized work rather than credit for an unrealized damping request. The enforcer then defines the energy-tank barrier certificate of equation 12.10:

$$h_{\text{energy}}(\mathbf{x}, E_{\text{tank}}) = E_{\text{tank}} - E_{\min} \geq 0 \tag{12.10}$$

where $E_{\min} > 0$ is a reserved baseline. Combined with a hard contact-force limit $h_{\text{force}}(\mathbf{F}_{\text{contact}}) = F_{\text{limit}} - \|\mathbf{F}_{\text{contact}}\| \geq 0$, the enforcer establishes the in-contact viable set $\mathcal{C}_{\text{contact}}$. While $E_{\text{tank}} > E_{\min}$ and $\|\mathbf{F}_{\text{contact}}\| < F_{\text{limit}}$, candidate neural actions are admitted to perform manipulation. If the task consumes the allocated energy budget ($E_{\text{tank}} \to E_{\min}$) or contact force approaches F_{limit}, the barrier filter clamps active energy injection ($\mathbf{u}_{\text{active}}^\top \dot{\mathbf{q}} \leq 0$), restricting active work under the modeled power balance. This energy constraint does not by itself bound contact force, because a passive interaction with a stiff surface can still produce a large force. The force channel needs its own sensing-error, response-delay, and actuator bounds before the combined constraints can justify continued contact.

For a contact command, integrating the work balance in equation 12.9 over one control interval Δt supplies the energy allowance for the same least-change decision. Suppose the current tank

[12] **Dissipativity**: Willems (1972) generalized circuit passivity to any dynamical system with a storage function, an energy-like quantity that can grow no faster than the power supplied to the system. Interconnected passive systems inherit that bound, which is why contact with an unknown but passive environment can be kept stable without a model of the environment. The energy tank is a storage function that the controller keeps explicitly in software, so the bound holds only as far as the tank's bookkeeping matches the work the actuators actually do.

level is $E_{\text{tank}_0} \geq E_{\text{min}}$, a conservative lower bound on damping power actually realized is P_d, and a bounded contact-direction speed $v_c > 0$ is held over this simplified interval. The spendable work is then $E_{\text{tank}_0} - E_{\text{min}} + P_d \Delta t$. Because a proposed constant force $F_{\text{nom}} \geq 0$ debits $F_{\text{nom}} v_c \Delta t$, the energy allowance caps force at $F_E = (E_{\text{tank}_0} - E_{\text{min}} + P_d \Delta t)/(v_c \Delta t)$. Letting F_{cap} denote the smaller of the deliverable force and the contact-force ceiling after sensing and delay allowances, the admitted command under these stipulated scalar conditions is $F^* = \min(F_{\text{nom}}, F_E, F_{\text{cap}})$, whose debit leaves $E_{\text{tank}_1} = E_{\text{tank}_0} + P_d \Delta t - F^* v_c \Delta t \geq E_{\text{min}}$ while keeping force below the independent cap. The controller can therefore continue useful contact with a reduced force instead of abandoning the task. At the reserve with no credited damping, however, no positive active work is admitted. Zero speed requires a separate force check rather than division by speed, and delayed or uncertain power requires conservative work bounds over the interval.

The force channel's own bounds can be computed for the running machine's two contacts: the cage door, which the arm pushes on purpose, and the coworker's hand, which it must never press too hard. Each calculation turns a force limit into a speed that the enforcement record carries as a channel ceiling, and each rests on premises that only a measurement can settle. They are derived here, where the channel is enforced; the release decision consumes the results as premises.

↪ Contact force and speed ceilings are enforced as release premises in section 16.2.

At the door the quantity that matters is how fast force rises. Against a strike plate of stiffness k_{latch}, an arm approaching at v_{latch} raises the contact force at $df_{k,\perp}/dt = k_{\text{latch}} v_{\text{latch}}$, which at the guarded 0.03 m/s against the 4.0 × 10^5 N/m plate is 12 N/ms. The contact tripwire fires at $F_{\text{trip}} = 15$ N, but the contact loop needs $T_c = 2$ ms for detection, command delivery, and torque rise, and the plate keeps compressing by $v_{\text{latch}} T_c$ before deceleration begins. The force at physical braking onset is therefore

$$F_{\text{cmd}} = F_{\text{trip}} + k_{\text{latch}} v_{\text{latch}} T_c \tag{12.11}$$

which evaluates to 39 N, well inside the 100 N latch limit. The limit still binds the stop that follows, because the plate goes on compressing while the arm sheds its remaining kinetic energy:

$$x_{\text{max}} = \frac{F_{\text{cmd}}}{k_{\text{latch}}} + \frac{v_{\text{latch}}^2}{2a_{\text{arm}}} \leq \frac{F_{\text{lim}}}{k_{\text{latch}}} \tag{12.12}$$

Against time since first contact (figure 12.8), force climbs through the tripwire and across the loop-response window to 39 N at brake onset; the commanded stop then bends the curve over to finish at the 100 N latch limit, while an unbraked run crosses the limit within a few milliseconds. The braking term ignores the plate's spring work, which would help decelerate the arm, so the bound is conservative. Below the limit the plate can compress only 0.15 mm further, and stopping within that distance requires about 3 m/s², an illustrative stop of about 10 ms.

The same two equations show why the approach speed is an enforced channel rather than a preference. At the chunk policy's proposed 0.10 m/s (section 12.6), equation 12.11 already gives 95 N at braking onset, and equation 12.12 then demands an arm deceleration of 400 m/s². The faster approach spends the response interval on force that the stop can no longer absorb. This is the physical half of the refusal in section 12.6; the evidential half is that no trial sampled this speed. Both results treat the arm as rigid and the plate as the whole contact stiffness. Gripper, wrist-sensor, and joint compliance in series lower the effective stiffness and slow the rise, while a geared joint reflects rotor inertia into the moving mass. Whether this arm achieves the required deceleration within a fraction of a millimeter depends on joint torque, drive rise time, and structural stiffness that only arm stopping trials establish. A compliant element placed in series on purpose turns that softening into passive protection. Springs in series add their compliances, so the combined stiffness falls below that of the softer element and the force rises more slowly, a protection that holds even when the enforcer cannot stop in time. The stiffness of that element is therefore part of the contact margin, and section 18.3.4.2 sizes it for this latch.

The coworker's hand is the opposite case, a contact the task tolerates only up to a bounded peak force. The force depends first on which contact occurs. In a *transient* contact the hand is free and recoils, so both bodies move and the collision acts through their reduced mass m_{red}. In a *clamped* (quasi-static) contact the hand is trapped against a rack upright or the robot's own body, cannot recoil, and receives the full robot-side effective mass at the tool center point, $m_{\text{eff}} = 12$ kg. The biomechanical body model of ISO/TS 15066:2016, whose collaborative-application requirements ISO 10218-2:2025 now incorporates (section 12.9.3), assigns the hand and fingers an effective mass

DRAFT

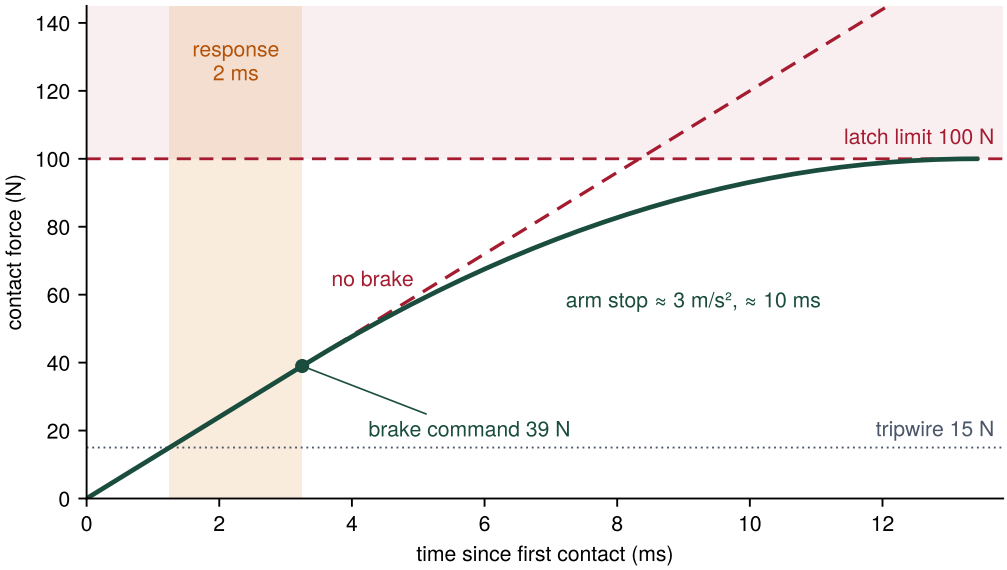

Figure 12.8: Latch contact force against time: Force on the strike plate rises at 12 N/ms from first contact. It crosses the 15 N tripwire, but the 2 ms contact-loop response lets it reach 39 N before the brake command. A stop at about 3 m/s², lasting about 10 ms, brings the arm to rest exactly at the 100 N limit; without the brake, force crosses the limit within a few milliseconds. The plate is modeled as a linear spring and the arm as rigid.

m_H of 0.6 kg and an effective spring constant k_H of 75 N/mm (International Organization for Standardization 2016, 2025b; Kirschner et al. 2022). This worked example estimates the robot-side mass as half the arm's moving mass plus its payload capacity; it does not compute the configuration- and direction-dependent mass reflected through the contact Jacobian. In an unbraked elastic contact the peak force is

$$F_{\text{unbraked}} = v_{\text{approach}} \sqrt{k_H \, m_{\text{red}}}, \qquad m_{\text{red}} = \left(\frac{1}{m_H} + \frac{1}{m_{\text{eff}}} \right)^{-1} \tag{12.13}$$

This is the spring-mass bound of equation 6.7, which equated a moving mass's kinetic energy to the peak elastic energy of the contact, with one change: two bodies move. Momentum conservation keeps the pair's common (center-of-mass) motion unchanged through the contact, so only the kinetic energy of their relative motion, $\frac{1}{2} m_{\text{red}} v_{\text{approach}}^2$ for a closing speed v_{approach}, can compress the hand, and the reduced mass takes the place of the single moving mass. For this hand and arm, m_{red} is 0.57 kg, because the light hand dominates the sum; a clamped hand is the limit $m_H \to \infty$, in which m_{red} becomes m_{eff}. Solved for speed at a force criterion F_h, the equation gives the channel ceiling $v_{\text{approach}} = F_h / \sqrt{k_H \, m_{\text{red}}}$. The peak follows the assumed masses and stiffness; the model establishes neither an impact duration nor a pressure or injury limit.

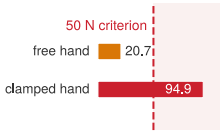
↩ The single-mass spring-impact bound that this reduced-mass form extends is established in section 6.4.2.

At the arm's 1 m/s free-space limit even the transient model predicts 207 N, or 4.1× the 50 N criterion, so the arm cannot enter an unseparated contact at that speed. At the handover speed the two contact cases bound the approach very differently (notebook 12.3).

Napkin Math 12.3: The clamped-hand penalty

Problem: The arm approaches the coworker's hand at the handover speed. What peak force does equation 12.13 predict for a free hand that recoils and for a hand clamped against a rack upright, and what approach speed does the force criterion allow in each case?

Variables:



- $m_{\text{eff}} = 12$ kg (Derived; the simplified half-arm-mass plus payload-capacity estimate used above).
- $m_H = 0.6$ kg and $k_H = 75$ N/mm (Datasheet; the ISO/TS 15066 hand body model).
- $v_{\text{approach}} = 0.10$ m/s (Chosen; the handover approach while the coworker holds the `accept_item` grant that section 14.2 defines).
- $F_h = 50$ N (Chosen; the handover force criterion).

Math: For a free hand, $m_{\text{red}} = (1/0.6 + 1/12)^{-1} = 0.571$ kg, and with $k_H = 75{,}000$ N/m the stiffness term is $\sqrt{k_H m_{\text{red}}} = 207$ N per m/s. The peak force is $v_{\text{approach}}\sqrt{k_H m_{\text{red}}} = 0.10 \times 207 = 20.7$ N, and the criterion admits $F_h/\sqrt{k_H m_{\text{red}}} = 50 \,/\, 207$, or 0.24 m/s. A clamped hand cannot recoil, so m_{red} becomes m_{eff} and $\sqrt{k_H m_{\text{eff}}} = 949$ N per m/s. The same approach then delivers $0.10 \times 949 = 94.9$ N, and the criterion admits only $50 \,/\, 949$, or 0.053 m/s.

Result: The free hand sees 20.7 N, inside the criterion; the clamped hand sees 94.9 N, which fails it.

Systems insight: Clamping multiplies the force at any speed by $\sqrt{m_{\text{eff}}/m_{\text{red}}} = 4.6$, because the whole arm-side mass, not the light hand, sets the collision. A speed ceiling derived for a free hand is therefore a geometric premise as much as a kinematic one.

The handover channel is therefore a transient-contact ceiling. It holds only while the handover geometry excludes clamping, with the handover point in free space and no rack upright, tote edge, or link of the arm within reach of the hand along the approach. Both contacts end the same way. The arithmetic is exact; what it cannot supply is the premise it rests on, whether an achievable arm deceleration, a contact stiffness, or a clamp-free geometry. The enforcement record keeps each ceiling beside that premise, and the same discipline governs every barrier in this chapter.

At one handover speed a free hand passes the force criterion and a clamped hand fails it.

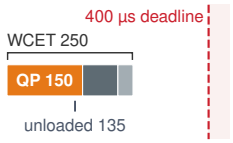
12.7.3 The conditions forward invariance rests on

Unmodeled friction loss, actuator saturation, solver overruns, or inter-sample drift under a held torque command can each push a physical plant across a barrier boundary even when the continuous-time inequality is satisfied at the sample instant. The containment claim provided by both spatial and energetic barrier calculations is therefore strictly conditional. A forward-invariance claim requires a feasible barrier and the following bounded conditions; the list is necessary for this design, not an exhaustive if-and-only-if test:

1. **Model Fidelity:** The nominal plant dynamics $\mathbf{f}(\mathbf{x})$ and $\mathbf{g}(\mathbf{x})$ must capture the true system dynamics within a validated parameter error bound.
2. **Disturbance Bounds:** External forces and unmodeled friction acting on the mass must remain strictly within the modeled disturbance envelope $|d(t)| \leq d_{\max}$.
3. **Actuation Authority:** Physical actuators must possess sufficient voltage, current, and thermal headroom to realize the commanded corrective force within a qualified delivered-effort error and response-delay envelope, as well as without saturation ($u^* \in [u_{\min}, u_{\max}]$).
4. **Solver Determinism:** The optimization solver or projection algorithm must terminate strictly within its allocated execution budget ($T_{\text{solve}} \leq T_{\text{budget}} < T_{\text{tick}}$).
5. **Discretization Invariance:** The discrete sampling interval T_{tick} must be sufficiently small that inter-sample state drift does not breach the continuous-time invariance boundary.

The approach-acceleration upper bound is a separate premise from the lower bound on available braking, and equality of their illustrative magnitudes does not identify their roles. Each of the five conditions maps to a dedicated engineering budget: model fidelity and disturbance bounds come from system identification and bench load testing, actuation authority from dynamometer curves and thermal limits, solver determinism from static worst-case execution time analysis on the MCU, and discretization from the loop period itself. Because the drive holds the last admitted command between samples (a zero-order hold[13]), the plant drifts for one full period before the next check can act on it. The drift covers at most $\Delta d_{\text{ZOH}} = vT_{\text{tick}} + \frac{1}{2}a_{\max}T_{\text{tick}}^2$ at speed v, where the worst case is the highest speed the base can reach rather than the ceiling $v_{\max}$ that admission enforces. At the 1.5 m/s

13 **Zero-Order Hold**: The order counts the derivatives the hold carries forward. A zero-order hold keeps the command's value constant until the next sample, while a first-order hold would also extrapolate its slope. For one control tick the plant therefore integrates a torque the controller can no longer change, which is the source of the drift buffer $vT_{\text{tick}} + \frac{1}{2}a_{\max}T_{\text{tick}}^2$; section B.5.5 develops the hold's delay.



drive limit, an independently stipulated 2 m/s² upper bound on approach acceleration, and $T_{\text{tick}} = 1$ ms, that drift is 1.501 mm, a small fraction of δ_{margin}. Tightening a raw-clearance check by this displacement preserves geometric separation over the hold interval under the stated motion bounds, whereas a kinetic or energy barrier requires a bound on its own evolution throughout the interval.

A condition that no detector watches is an assumption, so the permission path attaches one to each. A **disturbance observer** compares predicted with measured acceleration on every cycle. Inverter status registers and current shunts report actuator saturation. A hardware watchdog and cycle counter time the solver against its deadline. Timestamp counters on the sensor bus catch jitter and missed samples. When a detector invalidates a premise, the enforcer cannot restore permission by substituting optimistic parameters. It selects a response whose sensing, effort, and clearance premises survive, as developed in section 12.9. Both the free-space projection and contact decision must finish before the physical margin reserved for computation is spent.

12.7.4 Execution timing in the sub-millisecond loop

A correct barrier calculation delivered after the permission deadline cannot protect the margin reserved for that deadline. The whole cycle must therefore have a bounded execution time (Wilhelm et al. 2008), including state acquisition and the final drive transfer. A real-time operating system can reduce scheduling delays, but its name does not establish a bound on shared-memory or peripheral interference. The permission path's implementation must be qualified under the competing workloads that can delay it, so the declared cycle allocation below is a timing requirement carried into loaded placement tests rather than a measured trace or a platform-independent solver guarantee.

In this heterogeneous design, the shield executes inside a 1 kHz timer interrupt routine on the MCU. An unloaded cycle of acquisition, validation, and a typical active-set solve completes in about 135 µs, an illustrative estimate rather than a bound. The candidate path instead declares a worst-case execution-time requirement of 250 µs for the whole cycle, divided among the stages below, and the whole sequence must finish inside the 400 µs deadline:

The QP solve takes 150 of the 250 µs declared cycle, inside a 400 µs deadline.

1. **Interrupt Entry & State Acquisition (30 µs):** The hardware timer triggers the interrupt service routine (ISR), and firmware latches the wheel and joint encoder registers and the latest inertial measurement unit (IMU) sample.
2. **Proposal & Lease Verification (15 µs):** The MCU makes one bounded read of its local mailbox, which the link receiver fills outside this routine, validates the checksum, and confirms sequence order before checking evidence age, the active chunk lease, and the host heartbeat timer. In the evidence-age check, the evidence's age at dispatch is the difference between the source frame's evidence timestamp and the host dispatch timestamp in the proposal header (section 4.4.1). That age may not exceed 51.8 ms, which combines the 51.6 ms observation age charged in row 5 of table 12.1 with 0.2 ms of clock uncertainty (section 8.8). Passing that test qualifies the evidence only at dispatch, so the MCU also reconstructs the evidence's current age from its source epoch and elapsed time and checks it against the evidence's own validity deadline and the remaining physical margin. Inference, admission, waiting, and transfer after dispatch must already be reserved once in that margin through the dispatch-to-admission allocation inside the timing allowance. Otherwise fresh evidence is required before activation, because a new proposal timestamp cannot renew old evidence. The MCU then verifies that elapsed time since valid admission or renewal has not exceeded the 60 ms active chunk lease and reads the host heartbeat timer, which marks the host silent once no heartbeat has arrived within the 30 ms timeout.
3. **Tracking Contract Verification (10 µs):** Firmware evaluates instantaneous tracking error norm $\|e(t)\| = \|\mathbf{p}(t) - \mathbf{r}(t)\|$ against the qualified bound ϵ_{track}.
4. **CBF-QP Safety Shield Solve (150 µs):** An active-set QP solver[14] running in pre-allocated static SRAM, the MCU's tightly coupled data memory, evaluates active barrier inequalities and computes $\mathbf{u}^* = \arg\min_{\mathbf{u}\in\mathbb{R}^m} \frac{1}{2}\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2$. A fixed iteration cap limits the work count; meeting the allocation also requires bounded per-iteration arithmetic, memory access, interrupt interference, and output service, including ill-conditioned constraint geometry. Dynamic memory allocation is forbidden on this path so that heap service is excluded from that timing obligation. In this two-processor design no memory is shared with the host, so camera direct memory access (DMA) streams cannot reach the memory this cycle uses. The couplings that

[14] **Active-Set QP**: An active-set solver guesses which constraints hold with equality, solves the resulting linear system, and adds or drops one constraint per iteration. Dual variants such as that of Goldfarb and Idnani (1983) start from the unconstrained optimum, here the nominal command itself, and add only violated constraints, so a proposal that already satisfies every barrier costs almost nothing. The iteration count is bounded by the combinations of the constraint set rather than by a clock, so a fixed iteration cap bounds steps while the time per step must still be measured under interference.

remain are the link receiver, whose DMA writes into the MCU's own memory, and any shared supply rail or clock; section 13.8 measures that residual interference and tests whether the isolation holds under load.

5. **Output Selection & Admitted Command Staging (15 µs):** If the QP is feasible and constraints hold, the enforcer emits the **admitted command**. The drives close the velocity and current loops. Because industrial servo drives running in position mode choose torque direction internally from position tracking error while an unsigned torque limit clips only the magnitude of each joint's effort symmetrically, a position setpoint plus an unsigned torque limit does not by itself realize the signed braking effort or coupled multi-axis half-space the QP requires. This interface needs a qualified mapping from the staged command to delivered effort, with bounded realization error and response delay. The filter tightens each commanded half-space by the largest possible projection of that effort error along its normal, so every effort the drive may realize still satisfies the delivered-effort constraint. Near full braking, that allowance may remove feasibility and require earlier intervention. The drive configuration and qualification evidence must establish these bounds; this example supplies no measured error or delay. During the response interval, a previously held command must remain valid and the intersample/response allowance must cover its effect, charging each delay once. If the position/limit interface cannot satisfy this contract, the design needs a qualified effort interface or a stricter qualified operating envelope and fallback. The next position setpoint and per-axis torque limit travel in the next EtherCAT frame only under that realization contract. Drive-reported torque on the following tick can detect a breach but cannot retroactively certify the preceding interval; an invalid replacement leaves previously admitted setpoints in force only while their own evidence, lease, state, and stopping reservation remain valid.
6. **Completion & Reserve (30 µs):** The MCU checks the register write and services its own watchdog only after the cycle succeeds. The reserve absorbs variation in the stages above; a cycle that has not completed by the deadline requires a qualified preempting timer or an independent mechanism to select the resident fallback before the next tick. The overrunning ISR cannot be assumed to detect and recover from its own stall. Only with that bounded transfer does a missed tick cost the base 1.3 mm of travel at the aisle speed. Section 13.7 tests whether the declared WCET holds under load, so that ticks are not missed.

Stage 5 is also where refusal takes effect. Any of several conditions triggers it. The chunk lease may have expired, the host heartbeat may have fallen silent, the shared drive bus may report undervoltage, tracking error $\|e(t)\|$ may exceed ϵ_{track}, actuator saturation may render the feasible control set empty ($\mathcal{U}_{\text{safe}} = \emptyset$), or an operating-contract detector such as the disturbance observer or the solver deadline may trip. In any of these cases, the output selector withholds the admitted command, revokes policy authority, and selects the state-matched stop. At standstill, lease or heartbeat expiry selects HOLD, the powered standstill hold that section 12.9 defines, only while powered support remains available. Undervoltage instead requires a qualified transition to mechanical restraint before that support expires. In motion, STOP under undervoltage remains conditional on drive survival.

↪ The schedulability analysis that a declared WCET and deadline feed is developed in section C.3.

Checkpoint 12.2: Barrier, projection, and cycle budget

The barrier fixes which commands preserve the stop; the filter and its cycle decide whether the chosen command arrives in time.

- ☐ **Relative degree**: Why does a barrier on raw distance give torque no control authority at the boundary, and what does the kinetic barrier of equation 12.5 add to restore it?
- ☐ **Projection vs. clamp**: Why can clamping each joint separately leave a coupled half-space violated, while equation 12.8 satisfies it with the smallest torque change?
- ☐ **Projection estimate**: Treat the latch approach as a one-dimensional speed command whose half-space is the 0.03 m/s target-ODD ceiling. What are λ^* and the admitted speed when the chunk policy proposes 0.10 m/s?

- ☐ **Timing premise**: Which of the five forward-invariance conditions do the declared 250 µs WCET and the 400 µs deadline defend, and what must select the fallback when a cycle overruns?

Every stage of this cycle assumes that the solve returns a feasible command. When saturation empties the admissible torque set, the lease lapses, or the cycle overruns its deadline, projection has nothing to return, and the permission path must already hold a response it can execute without the proposer. Executing that check deterministically while surviving proposer faults requires placing the enforcer where the host processor cannot preempt or bypass it.

12.8 Admission, Cyclic Checking, and Monitor Independence

A planned waypoint can clear a warehouse rack upright in the planner's geometric check while the physical manipulator overshoots into the steel during execution, and an instantaneous motor torque well within electrical limits can accelerate the arm past the point where its remaining stopping reservation can arrest motion. Relying on trajectory admission alone misses in-flight tracking overshoot and saturation, whereas checking only single-step torque commands without a verified stopping continuation lets the arm enter an inevitable collision state before the local filter reacts. Robust safety enforcement therefore demands both layers (the per-tick cycle of section 12.7.4 on a dedicated MCU and full-plan admission before motion begins). That raises three structural questions: why neither layer can replace the other, where the cyclic checker sits relative to the command stream, and how independent of the proposer the MCU must actually be.

Full-plan admission judges the candidate trajectory, its seams, its swept clearance, and its verified stopping continuation before the machine commits to motion. The expensive geometry behind that judgment (queries of global occupancy octrees, signed distance fields, or mesh collision models) cannot run inside a 1 ms control interrupt merely because the MCU owns final actuation privilege. It therefore runs on the host as a separately scheduled, bounded job, and its result reaches the MCU as the trajectory record. The MCU's own admission check then verifies that record against bounded, qualified local evidence (the resident stop suffix, its entry state, and the commitment deadline) without traversing the global map. The hard real-time cyclic path evaluates current joint state, remaining lease validity, and available actuator effort on every tick before selecting and dispatching the next physical command.

An in-line checker places its worst-case execution time directly inside the control-loop deadline, consuming a portion of the available compute tick. A parallel monitor instead operates asynchronously alongside the proposal pipeline, avoiding added forward latency during nominal execution but contributing detection latency and trip delay to the physical response budget. Either architectural placement must ensure privilege isolation. The untrusted proposer must never be able to bypass the selected output, and the system must preserve the dedicated sensing and actuation channels required by the fallback controller. As section 13.2 will show from the resources each candidate placement shares, isolating these execution domains across memory spaces or heterogeneous processing cores is what allows the safety monitor and its fallback mechanisms to survive the very proposer faults that trigger an intervention. The physical stopping budget supplies the non-negotiable temporal and spatial boundaries that this hardware split must satisfy.

> Systems Perspective 12.3: The monitor independence rule
>
> Any valid safety claim must explicitly define which proposer failure modes its sensing, compute, and actuation pathways survive. Placing a monitor on a separate physical core or processor does not establish true independence if that monitor shares a power rail, a memory bus, a sensor link, or an unisolated clock domain with the untrusted proposer. Shared hardware resources require provably bounded interference or a qualified, survivable fallback state. Any environmental condition that the monitor cannot observe directly must remain an explicit, documented operating premise rather than an unstated assumption.

The running example assumes qualified drive, scanner, and arm safety functions and a rated lease/heartbeat watchdog; the release case must name the scoped evidence supporting those functions. Independence, however, is not certification. The runtime permission path is not the machine's certified functional safety layer, and beneath it sit the certified safety functions embedded within motor drives, safety laser scanners, and the dedicated safety controller. These hardware-interlocked mechanisms carry the formal integrity claims that certification bodies audit against industrial standards. The primary operational duty of the software permission path is to regulate the learned proposer proactively so that the robot never trips those certified hardware interlocks during normal operation. Section 12.9.3 maps each dynamic response developed throughout this chapter onto that underlying certified safety floor once the complete response hierarchy is established, and names the one narrow MCU function that does carry a rating.

12.8.1 Where the thesis bends

When a learned locomotion or manipulation policy emits raw joint targets or motor torques at the control rate instead of handing the permission path a multi-step trajectory, the enforcer loses the ability to verify a collision-free stopping continuation before motion begins. It must then either run an active fallback model on every tick or watch its projections induce distributional shift and boundary chattering. Admission and the cyclic check in this chapter both assume that the proposer hands the permission path a plan it can judge before motion: kinematic intent lives in the learned policy, and deterministic motor drives close the torque loops. Much of contemporary robot learning practice abandons this classical division, outputting joint targets at the control rate above stiff proportional-derivative loops (J. Lee et al. 2020) or emitting motor torques end-to-end. The third law, proposal is not permission (principle 3), does not disappear in such direct control designs. Instead, the range of physical guarantees that the runtime permission path can uphold narrows in precise, quantifiable ways.

Four guarantees survive because each acts directly on raw commands at the causal boundary, without requiring a forward plan. A per-tick limit on rate and amplitude bounds torque slew and joint velocity at the hardware register interface. The kinetic barrier of equation 12.6 operates directly in effort space, so a CBF-QP can filter the policy's output without converting it to an intermediate kinematic setpoint. The passivity-based energy tank of section 12.7.2 monitors power exchange and bounds the physical work the policy can inject into the environment during contact. Beneath all of these, low-level geofencing, safely-limited speed monitoring, and torque removal backed by mechanical spring brakes remain permanently active under the software stack. Communication timing improves along one dimension. If a qualified freshness deadline is selected at one tick and an independent watchdog enforces it, policy silence is detected within that tick plus bus transport delay, which reduces the lease-expiration travel row of table 12.1 from 80.6 mm to 2.6 mm at the aisle speed.

What is lost is admission. Without an explicit multi-step trajectory, the system cannot verify the collision-free stopping suffix before the robot commits to motion. The enforcer must instead evaluate the machine's dynamic stopping reservation on every tick against an active fallback controller that maintains its own internal braking model. On a wheeled mobile base, that fallback is straightforward to formulate. The controller executes a qualified service-braking response along the current heading, followed by wheel restraint after confirmed standstill. On an underactuated balancing machine, such as a bipedal humanoid, the fallback is itself an active balance controller; cutting motor torque produces an immediate uncontrolled fall rather than a safe state.

Runtime projection also alters the closed sensorimotor loop under which the policy was trained. Every time the enforcer projects a proposed action onto the admissible set, it delivers a state to the environment that the policy never intended, precipitating distributional shift in subsequent observations. This penalty surfaces directly in task performance, as quantified by the intervention metrics of section 12.7. Frequent overrides cause the machine to chatter erratically along safety boundaries or freeze conservatively short of its goal. To reconcile this tension, modern architectures adopt filter-aware policy training, incorporating the safety filter directly into the training objective so that the neural network learns to avoid the boundary rather than encountering the enforcer for the first time on physical hardware (Hsu et al. 2024). The core thesis still holds at the causal boundary, where untrusted proposals never bypass runtime enforcement. What bends is how much of the

safety argument can be settled mathematically before motion begins vs. how much performance the machine must sacrifice to settle the remainder while moving.

12.9 The Fallback Ladder

A safety filter must select its fallback before the admissible control set becomes empty. Once the chosen filter has an empty feasible intersection, it cannot maintain its modeled invariant. A qualified alternate response may mitigate damage or support its own narrower containment claim, but selecting it does not restore the lost guarantee. Furthermore, physical systems cannot rely on a single, binary kill switch. Abruptly severing DC bus power whenever a control proposal approaches a barrier boundary induces uncontrolled deceleration, mechanical shock, and incessant false-positive mission aborts. Conversely, complex software optimization is futile during a hardware fault such as an inverter shoot-through, because the fault destroys gate-driver field-effect transistors (FETs) milliseconds before an interrupt handler can even dispatch.

To resolve these competing physical realities, the permission path maintains a deterministic ladder of resident protective responses. The runtime arbiter evaluates plant kinematics, remaining sensor validity, and hardware integrity on every control cycle, selecting deterministically among minimally invasive projection, closed-loop position holding, controlled deceleration, or complete torque removal. The name records an ordering by how much control authority each response retains, from a corrected proposal down to unpowered restraint, not a sequence to descend. The arbiter never climbs down the rungs one at a time; it jumps directly to the one whose prerequisites still hold.

Definition 12.3: Dynamic fallback ladder

Dynamic fallback ladder is the set of resident protective responses ($\mathbf{u} \in \{\mathcal{P}_{\mathcal{C}}(\mathbf{u}_{\text{nom}}), \mathbf{u}_{\text{hold}}, \mathbf{u}_{\text{stop}}, \mathbf{u}_{\text{cutoff}}\}$). A deterministic arbiter selects one of them on every tick according to the check that failed (an invariant violation, a timing overrun, or a hardware fault) and the measured state of the plant. One trigger can therefore select different rungs in motion and at standstill.

1. **Significance**: Physical AI systems cannot treat all faults identically. Cutting actuator power on dynamic, underactuated, or high-momentum plants (for example, legged robots mid-stride or multirotors in flight) precipitates immediate catastrophic falls or tumbling. These platforms require state-matched active deceleration before executing terminal torque removal.
2. **Distinction**: Unlike software exception handlers that unwind the call stack or terminate a user-space thread, a dynamic fallback ladder operates against physical momentum. The arbiter matches each rung to the remaining valid sensor channels, surviving control authority, and available stopping clearance.
3. **Common pitfall**: Treating the rungs as an escalation sequence where lower rungs, such as safe torque off (STO), inherently provide faster or safer arrest. Each rung possesses distinct entry prerequisites; invoking an unpowered torque inhibit on an airborne drone or an unbraked mobile base allows the machine to coast freely without arresting motion.

12.9.1 The four rungs of the fallback ladder

Walking down protective responses one step at a time like a software exception cascade fails on physical hardware: commanding a standstill position hold while the base is rolling at 1.3 m/s saturates the drives, while cutting drive torque before active braking completes lets the vehicle coast into the obstacle. The dynamic fallback architecture therefore organizes protection across four resident responses (`PROJECT`, `HOLD`, `STOP`, and `INHIBIT`). The deterministic arbiter samples measured plant state (velocity, position, payload loading) and fault severity on every millisecond tick to dispatch the response whose compute, sensing, and actuation prerequisites still hold:

1. `PROJECT`, minimal-intervention projection in MCU firmware. The primary safety filter executes on every control cycle while the feasible control set is nonempty ($\mathcal{U}_{\text{safe}} \neq \emptyset$), the proposal

lease is fresh, and tracking error remains within bounds ($\|e(t)\| \leq \epsilon_{\text{track}}$). It computes the minimal-intervention torque $\mathbf{u}^* = \arg\min_{\mathbf{u}} \|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2$ subject to active barrier half-spaces within its 150 µs cycle allocation. It makes the smallest feasible effort correction under the stated invariance assumptions; the planner must still account for any changed task-space path.

2. `HOLD`, powered hold at standstill in MCU firmware. When the machine is stationary, the arbiter selects an energized position hold, analogous to an IEC 60204-1 Category 2 stop: safe stop 2 (SS2) followed by safe operating stop (SOS), the drive function that monitors standstill.[15] Its protective validity stems from that certified standstill monitor rather than the position loop gain. Because IEC 60204-1 permits only Category 0 or Category 1 for an emergency stop, HOLD can never serve as an E-stop response (International Electrotechnical Commission 2016a). The drives maintain coordinate $\mathbf{x}_{\text{hold}}$ under closed-loop position control, modulating inverter phase currents against gravity and static loads. While this rung incurs continuous Joule heating in motor windings, it eliminates friction brake wear and preserves kinematic calibration, enabling instantaneous task resumption when a valid trajectory proposal arrives. On the warehouse mobile manipulator, this rung handles lapsed leases or lost host heartbeats specifically when the platform is already at standstill.
3. `STOP`, controlled dynamic stop in MCU firmware. When a machine in active transit loses proposal authority, tracking error diverges, or an obstacle breaches the stopping envelope, the response is a resident, state-matched controlled stop, analogous to an IEC 60204-1 Category 1 stop (safe stop 1, SS1). Its certified counterpart is the ramp-monitored variant (SS1-r), which checks deceleration against a bounded profile throughout the arrest; the unmonitored, time-controlled variant (SS1-t) merely removes torque after a fixed delay without verifying that the planned ramp actually decelerated the load (International Electrotechnical Commission 2016b). The resident jerk-limited S-curve stop suffix of section 12.3 serves this role provided the entry state falls within its validated domain. Executed autonomously by bare-metal MCU firmware directly from local SRAM, this stop peaks at the credible deceleration a_{brake}, returning kinetic energy through motor inverters to the DC bus for absorption by the qualified regeneration path. Power removal and mechanical brake clamping occur only after confirmed zero velocity.
4. `INHIBIT`, torque inhibit and spring-brake clamping by hardware interlocks. When the safety microcontroller suffers a brownout, clock loss, or watchdog timeout, all software decision logic ceases. Dedicated, out-of-band hardware interlocks trigger STO to de-energize gate drive power supplies and drop hold current to electromechanical spring-applied brakes. This terminal rung removes motor torque without software intervention; the mechanical brakes provide only their independently qualified holding or dynamic stopping capacity.

[15] **Machine Stop Categories**: IEC 60204-1 distinguishes uncontrolled power removal (Category 0), controlled stopping followed by power removal (Category 1), and controlled stopping with power retained (Category 2). A category defines electrical power status rather than stopping distance; every rung therefore requires its own empirically validated stopping measurement.

When a machine in motion loses proposal authority or violates a tracking bound, the arbiter engages a controlled dynamic stop, operating analogously to an IEC 60204-1 Category 1 stop. On the warehouse mobile manipulator base, this rung executes the resident stop suffix pre-admitted alongside the motion trajectory, rather than attempting to synthesize a stopping trajectory on the fly during a fault. In steady-state cruising with zero acceleration, this pre-computed profile matches the operating state at fault onset directly; nonzero acceleration states require their own qualified state-matched suffixes. From an aisle cruise velocity of 1.3 m/s, the jerk-limited S-curve suffix sustains a credible peak deceleration of 2 m/s² between its jerk transitions. The entire maneuver spans 931.25 ms and traverses 605.31 mm, the stop-suffix travel the stopping budget of section 12.3 reserves at this speed. Because the deceleration phase channels kinetic energy back through the inverter into the DC bus, bus capacitance and braking choppers must absorb this regenerative surge without triggering a bus overvoltage fault. Complete electrical power removal, if mandated by protocol, occurs only after sensors verify standstill.

Beyond firmware-driven stops, a separate out-of-band circuit can inhibit motor torque generation entirely. Drive STO cuts gate-drive bias to isolate inverter FETs, but it does not disconnect the DC bus, energize mechanical friction brakes, or actively decelerate a moving rotor; an unbraked motor will simply coast under its existing momentum. In robust architectures, an external safety controller simultaneously drives a separately rated contactor and spring-applied mechanical brakes. Engineers must evaluate the dynamic stopping distance of this combined pathway as an integrated system, because dropping drive torque while an arm is under gravitational load or while a vehicle is at speed

DRAFT

can exacerbate the hazard. For the warehouse mobile manipulator, this pathway, STO combined with nine spring brakes that engage between 30 ms and 80 ms after coil flux decay, constitutes the unbudgeted INHIBIT rung. It serves exclusively as a hardware backstop for MCU cycle failure, and the primary stopping envelope claims do not rely on it.

An undervoltage fault on the shared drive bus can invoke the STOP rung only while inverter gate drives, angular encoders, and control logic retain adequate voltage for closed-loop deceleration. The isolated permission rail maintains power to logic circuits, transceivers, and brake coils for 2 s, but it does not supply the motor currents required for braking torque. Consequently, timing guarantees for powered stopping assume a surviving drive bus. Under this condition, dynamic braking begins within 22 ms of the fault flag; the hold-up hypothetical uses the pre-dispatch inspected-floor ceiling of 1.23 m/s, rather than an admitted operating configuration, and its stop requires 1211.4 ms. Mechanical brake engagement at standstill adds at most 80 ms. This entire sequence completes within 1313.43 ms, preserving a 686.57 ms buffer of control logic hold-up.

↩ The isolated permission rail and its capacitive hold-up are established in section 2.8.2.

This analysis confirms the control-supply duration budget, whereas the electrical drive-energy budget requires separate qualification. Systems engineers must prove through empirical testing that the DC bus capacitance, inverter power stages, and regenerative dump resistors sustain controlled deceleration under worst-case electrical fault conditions. If the drive stage cannot guarantee this power integrity, the system must either adopt an unpowered dynamic braking configuration or restrict its operational safety envelope; INHIBIT cannot be credited with standard Category 1 stopping performance. Similarly, at standstill, an undervoltage fault must trigger verified mechanical brake engagement before the logic supply decays, rather than attempting to maintain an active HOLD indefinitely on finite capacitance.

Physical AI systems engineers must distinguish between **fail-safe** and **fail-operational** plants when configuring terminal fallbacks. In a machine already at a mechanically restrained standstill, removing drive torque is safe once mechanical engagement is verified. On underactuated, open-loop unstable, or high-momentum platforms, however, abruptly removing actuator torque directly initiates a catastrophic failure mode:

1. **Aerial platforms (multirotors and eVTOLs)**: Cutting motor torque drops aerodynamic thrust to zero instantly, transforming an airborne vehicle into an uncontrolled ballistic projectile.
2. **Dynamic legged systems (bipedal humanoids)**: During dynamic locomotion, the robot's center of mass frequently falls outside the support polygon; stability depends on active ground-reaction forces and momentum exchange. Suddenly removing joint torques causes an unrecoverable fall, with impact severity governed by gait phase and available compliance.
3. **High-speed autonomous vehicles**: De-energizing steering actuators or electric traction motors at highway speeds strips away the control authority required to execute a coordinated deceleration, leaving the vehicle at the mercy of passive road friction.

The physical channel that dispatches a hardware torque-removal request is the out-of-band interlock that section 4.6 traced (figure 4.8). In it, dual linked emergency-stop contacts, two force-guided relays whose external device monitoring (EDM) contacts block a restart after a weld, and two STO inputs on the drive leave no single fault able to defeat the trip. What the INHIBIT rung needs from that circuit is its third stage, drawn again here with the brake in its own loop (figure 12.9), because removing drive torque ($\tau = 0$) and arresting physical momentum are distinct functions that need separate validation:

1. **Torque removal (Stage 3, drive side):** De-energizing the safety relays drops the drive's STO inputs, which de-energize the gate drive power supply for the three-phase inverter bridge, rendering the power MOSFETs or insulated-gate bipolar transistors (IGBTs) high-impedance, so the motor can no longer produce electromagnetic torque. STO alone does not apply mechanical braking. An unbraked motor carries momentum and may coast freely.
2. **Mechanical restraint (Stage 3, brake side):** A separate coil circuit powers the spring-applied electromechanical friction brake. When power is removed, coil magnetic flux decays, allowing internal springs to physically clamp friction pads against the motor shaft, applying the brake without electrical power. A holding-brake rating does not establish the ability to arrest a moving load; dynamic stopping requires separate energy, torque, and response qualification.

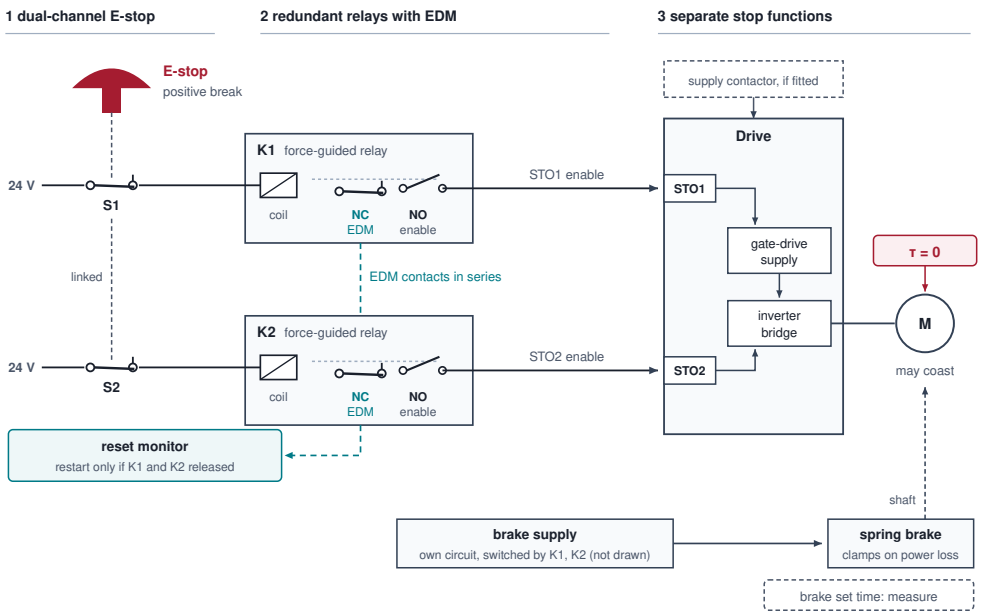


Figure 12.9: Illustrative emergency-stop circuit: Stages 1 and 2 are the out-of-band interlock circuit (Chapter 4); Stage 3 maps to the numbered list above. Two linked contacts each hold a force-guided relay, the relays' enable contacts hold the drive's two Safe Torque Off (STO) inputs, and their EDM contacts in series block a restart after a weld. The spring-applied brake runs on its own supply, and a supply contactor, if fitted, provides galvanic disconnection. A moving motor can coast after STO, so the brake's set time and the physical stopping distance must be measured for the load and state.

That separation between software control and hardwired, out-of-band trip circuits is not a stylistic preference. When the processor running the control loop stalls or corrupts its own state, only a physically independent path can still remove drive enable and clamp the brakes. The precedent that the lineage table of section 1.10 attaches to the third law shows the cost of removing that hardware path and trusting software logic to gate a high-energy actuator on its own (war story 12.1).

War Story 12.1: Therac-25 software interlock elimination

Context: Between 1985 and 1987, the Therac-25 medical linear accelerator administered massive radiation overdoses to six cancer patients after system designers eliminated the electromechanical interlocks used in previous models, assigning safety-critical beam containment entirely to software (Leveson and Turner 1993).

Mechanism: Software race conditions and shared memory corruption in the operator interface allowed the machine to fire its high-current electron beam (25 MeV) without rotating the tungsten target and beam-flattening filter into position. Because the physical microswitches that previously interlocked beam activation had been removed, the underlying hardware possessed no independent means to detect that the operational mode conflicted with the turntable state.

Impact: Six patients received radiation doses estimated between 4,000 and 20,000 rads (up to 100 times the therapeutic level), causing severe tissue necrosis and three direct fatalities (Leveson and Turner 1993).

Response: Investigators mandated the restoration of independent hardware interlocks, requiring positive electromechanical verification of turntable configuration prior to beam generation, alongside formal software safety lifecycle standards.

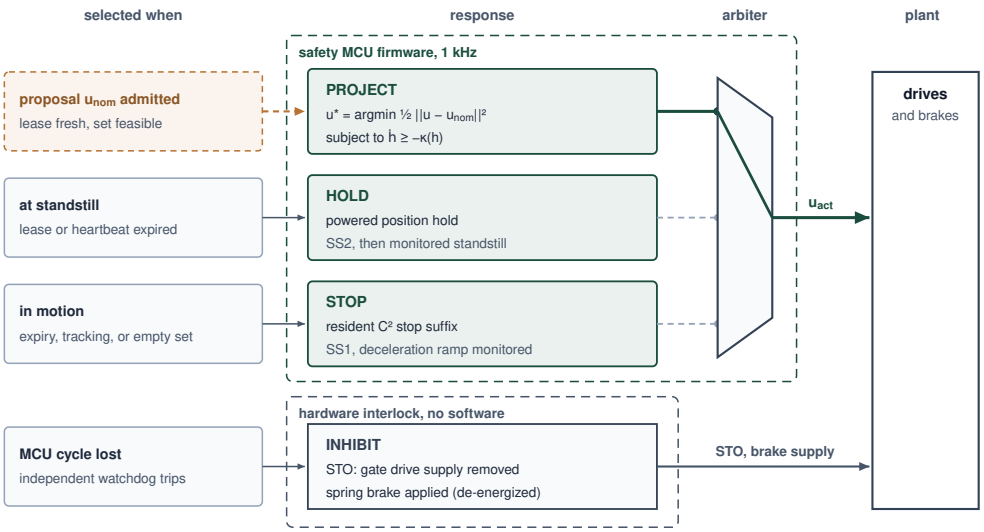

Figure 12.10: Fallback responses and the paths that run them: The plant state and the failed check select one response directly; the four are alternatives, not steps of an escalation. PROJECT, HOLD, and STOP run in the safety MCU's firmware and reach the drives through its arbiter, which here passes the projected command. INHIBIT is the one response that survives loss of the MCU itself, so it bypasses the arbiter on a hardware path that removes gate-drive supply and lets the spring brakes set. On a moving machine that path also removes motor braking, and the machine coasts until the separately qualified brakes take hold.

Systems lesson: A software-based protection layer cannot serve as its own independent backstop. A runtime barrier filter may exercise binding authority over nominal control proposals, but the architecture still requires an out-of-band, physically independent trip mechanism to survive processor lockups, memory corruption, and firmware bugs. Moreover, because torque removal alone does not guarantee deceleration, the surviving physical response must match the plant's dynamic envelope.

The four rungs run on two paths (figure 12.10). `PROJECT`, `HOLD`, and `STOP` run in safety MCU firmware at the 1 kHz tick and reach the drives through one arbiter, which selects a single actuation command $\mathbf{u}_{act}$; `INHIBIT` bypasses the firmware on a hardware path that removes gate-drive supply (STO) and drops spring-brake holding current when the processor itself fails. The rungs trade response latency, control authority, and recovery cost, and the arbiter selects directly among those whose entry prerequisites still hold. A controlled stop demands verified drive electronics and sufficient stopping clearance; losing drive integrity forces unpowered mitigation with strictly weaker physical guarantees. Selection is also only as sound as the state evidence behind it. The 2023 Cruise pullover, which section 1.8 set beside Tempe as a failure after impact, selected a motion fallback on the strength of a missing track (war story 12.2).

War Story 12.2: Cruise post-impact fallback (2023)

Context: In October 2023, an autonomous Cruise robotaxi in San Francisco encountered a pedestrian who had been struck by an adjacent human-driven vehicle and propelled into the robotaxi's travel lane (Exponent, Inc. 2024).

Mechanism: The autonomous vehicle initiated an immediate emergency stop upon detecting the impact. However, the collision-classification subsystem erroneously localized the pedestrian to the side of the vehicle rather than under the chassis, categorizing the event as a side collision. The operational design domain for side collisions specified a secondary pullover maneuver to clear traffic. Because the perception pipeline had tracked the pedestrian only intermittently

before the collision, the tracker marked the lane ahead as clear, prompting the vehicle to accelerate from standstill into the pullover (Exponent, Inc. 2024).

Impact: Executing the pullover dragged the pedestrian, who remained pinned beneath the vehicle's floorpan, approximately 20 ft (6.1 m) at speeds reaching 7.7 mph (3.4 m/s), causing severe trauma (Quinn Emanuel Urquhart and Sullivan, LLP 2024). The California DMV subsequently suspended Cruise's autonomous testing and deployment permits, prompting Cruise to halt fleet operations nationwide and recall software across 950 vehicles (California Department of Motor Vehicles 2023; Exponent, Inc. 2024).

Response: A post-collision fallback must prohibit renewed motion whenever state uncertainty persists. In this scenario, retaining a locked standstill and mandating physical inspection prevents the system from treating missing perceptual tracks as free space. Teleoperation feeds cannot substitute for verified local sensor coverage.

Systems lesson: An embodied fallback cannot infer free space from the absence of sensor tracks. Every transition across fallback states requires positive evidence verifying that assumed physical invariants hold, paired with failsafe physical restraints while state ambiguity remains unresolved.

12.9.2 Industrial stop categories and the safe torque off trap

On a moving mobile base or a gravity-loaded arm, Safe Torque Off (STO) is not an active brake: removing drive torque immediately leaves the base coasting on wheel momentum and lets the arm drop during the milliseconds before its mechanical friction brakes clamp. Decelerating the mobile manipulator safely instead uses closed-loop motor torque during the active braking phase and engages mechanical holding brakes only once the plant reaches confirmed standstill. Industrial standards distinguish machine-level stop categories from drive-level safety functions across this sequence. IEC 60204-1 classifies whether electrical power remains connected during and after deceleration. Functional safety standards such as IEC 61800-5-2 define the drive functions, including STO, SS1, and SS2, that execute individual stages of a response, and the `HOLD` and `STOP` rungs borrowed their names from them. Table 12.3 maps these formal classifications to their concrete physical obligations.

Table 12.3: Stop functions and physical response: Machine stop categories, related drive functions, and the plant response each leaves to be tested. No stop category alone supplies a safety integrity rating, a brake, galvanic isolation, or a guaranteed stopping distance.

Response	Motor torque and power	Physical stop obligation	Appropriate use
Admitted filtering	Drive remains active	Recheck the feasible kinetic barrier and tracking bound every tick	Nominal operation inside the validated envelope
Controlled hold (Category 2 / SS2-like)	Power remains for braking and hold	Verify stopping distance, thermal headroom, and static load support	Hold when feedback and torque authority remain available
Controlled stop then torque removal (Category 1 / SS1-like)	Power remains through deceleration; torque is removed afterward	Verify the full braking and transition time under load	Moving machine with enough reserved clearance
Torque removal (Category 0 / STO-like)	Drive cannot produce commanded torque; DC bus isolation is a separate function	A moving motor may coast; a separate brake or mechanical restraint needs its own timing and rating	State for which loss of torque has been shown safe

12.9.3 Certified safety functions beneath the permission path

Citing an unrated numerical QP solver or software evidence-age check as the primary hazard control in a safety case fails certification audit immediately, because complex solver code without formal tool qualification and hardware diagnostic coverage cannot carry a safety integrity claim. In an embodied deployment, not all firmware executing the fallback ladder carries formal functional safety certification, so a certification engineer partitions software claims by the integrity of the

underlying hardware substrate. On a production machine, formal guarantees rest primarily on a second, lower layer: dedicated safety functions in the motor drives, the optical safety scanner, and the arm's safety controller, each architected and validated to a Performance Level (PL) under ISO 13849-1 (International Organization for Standardization 2023a). A Performance Level grades a safety function rather than a component, by the architecture category of its channels, their mean time to dangerous failure, their diagnostic coverage, and their defenses against common-cause failure (section 4.2); IEC 61508 grades the same functions by Safety Integrity Level (SIL) (International Electrotechnical Commission 2010a). These hardened functions substantiate the certified protective envelope. Above them, the MCU permission path operates primarily as an unrated performance layer designed to keep the learned policy inside the admissible set, preventing unnecessary trips of the hard safety floor. Only one narrow component of this MCU layer carries a safety rating, the watchdog that revokes authority when the chunk lease expires or the host heartbeat falls silent.

Table 12.4 maps each response and speed channel onto its certified industrial counterpart. The core drive functions derive from IEC 61800-5-2 (International Electrotechnical Commission 2016b): **safe torque off (STO)**, **safe stop 1 (SS1)**, **safe stop 2 (SS2)**, **safe operating stop (SOS)** (which monitors standstill), **safely limited speed (SLS)**, and **safe brake control (SBC)** (which drives the mechanical brake coil through a monitored output). For the mobile base, ISO 3691-4 assigns required performance level (PLr) d to braking system control and personnel detection within the travel path, while assigning PLr b to the electromechanical parking brake (International Organization for Standardization 2023b; TÜV Rheinland 2021). For robotic manipulators, ISO 10218-1:2025 classifies systems into Class I (manipulator mass under 10 kg with strictly limited force and velocity) and Class II, mandating PL d (or SIL 2) across all safety functions on Class II arms (International Organization for Standardization 2025a; Hartmann et al. 2026). Because the warehouse arm weighs 18 kg, it is governed by Class II mandates.

Table 12.4: The permission path above its certified floor: Each response and speed channel of this chapter beside the safety-rated function that carries the certified claim on a production machine, the requirement that governs it, and the performance level that requirement sets for this machine. Only the first row has no certified counterpart; its checks are the performance layer. The second row is the one rated function on the MCU.

Response or channel	Certified counterpart	Governing requirement	Required level on this machine
`PROJECT`, feasibility, evidence-age	None; the admission checks are not claimed as safety rated	None	None claimed; recorded as a premise
Lease expiry and heartbeat loss	MCU watchdog that commands STO or SS1 on the drives	ISO 13849-1; IEC 61508 for the MCU firmware	Set by the risk assessment for the stop it triggers
Base aisle-speed ceiling	SLS on the drive wheels, switched by the scanner's field set	IEC 61800-5-2; speed control under ISO 3691-4	Set by ISO 3691-4 and the risk assessment
Person at the rack end	Scanner protective field that selects `STOP`	ISO 3691-4 person detection; ISO 13855 field sizing	PL d
`STOP` on the base	Ramp-monitored SS1 (SS1-r), then parking brake	IEC 61800-5-2; ISO 3691-4 braking control	PL d for braking control; PL b for parking brake
`HOLD`	SS2 into SOS	IEC 61800-5-2	PL d on the arm; base set by the risk assessment
`INHIBIT`	STO with SBC	IEC 61800-5-2; IEC 60204-1 Category 0	PL d on the arm; base as for braking control
Arm TCP, latch, and handover limits	Safety-rated monitored speed in the arm's safety controller	ISO 10218-1:2025	PL d (Class II)
Handover to the coworker's hand	Speed and separation monitoring or power and force limiting	ISO 10218-2:2025	Set by the application risk assessment

As the first row of table 12.4 indicates, the online CBF-QP, feasibility tests, and sensor evidence-age checks operate without formal safety ratings. Consequently, safety cases cannot cite these complex numerical filters as certified protective measures; instead, the enforcement record treats their correct execution as an operational premise. System architects face two choices when structuring this

boundary. An engineering team can treat all MCU-level admission checks strictly as an unrated performance layer, relying entirely on the certified hardware floor to prevent harm. Alternatively, the team can certify the entire MCU firmware stack to functional safety standards (such as IEC 61508 or ISO 26262), subjecting matrix solvers and barrier algorithms to exhaustive formal methods, tool qualification, and deterministic execution bounds.

The running machine assumes the hybrid path. Its qualified watchdog, the table's second row, independently commands STO or SS1 at the drive level when the chunk lease expires or the host heartbeat falls silent. Its bounded scope reduces the qualification burden, while isolation, failure behavior, timing, and lifecycle evidence remain necessary. Meanwhile, the complex admission checks remain unrated, leaving the certified optical scanner and drive-integrated safety functions to handle primary hazard mitigation. This split architecture demands strict physical and temporal isolation between the rated watchdog and unrated solver routines to eliminate common-cause faults.

↪ How the release case treats the certified watchdog as a rated safety function and the unrated admission checks as empirical premises is developed in section 16.3.4.

The robotic arm introduces collaborative operational modes beyond those required by the mobile base. **Speed and separation monitoring (SSM)** continuously modulates or halts arm velocity to maintain a protective clearance envelope around human workers, while **power and force limiting (PFL)** caps transient and quasi-static contact forces during intentional physical collaboration. Standard ISO 10218-2:2025 incorporates the collaborative requirements previously defined in ISO/TS 15066 (International Organization for Standardization 2025b, 2016). The 2025 standard formalizes SSM within section 5.14.5 and normative Annex L, and specifies PFL limits across anatomical regions in section 5.14.6 and informative Annex M (Hartmann et al. 2026). The protective separation distance is governed by:

$$S_p = S_h + S_r + S_s + C + Z_d + Z_r,$$

where $S_h = v_h(T_r + T_{\text{stop}})$ represents worker displacement during robot reaction latency T_r and stopping duration T_{stop}. Next, $S_r = v_r T_r$ is robot displacement prior to brake onset, and S_s is the physical braking distance. The term C is the penetration distance permitted by sensor resolution. Finally, Z_d and Z_r denote positional uncertainties for the human and robot, respectively (Marvel and Norcross 2017).

Evaluating this expression for the descending arm highlights the relative weight of human vs. robot motion. The ISO 13855 human approach speed is $v_h = 1.6$ m/s (International Organization for Standardization 2024a). The vision-path latency is $T_r = 133.6$ ms, and the tool-center-point velocity is $v_r = 0.96$ m/s. The gravity-biased joint deceleration from section 12.4 completes in $T_{\text{stop}} = 166$ ms across $S_s = 79$ mm. With these values, the human displacement term is $S_h = 479$ mm and the robot reaction displacement is $S_r = 128$ mm. Together, these preliminary dynamic components total 686 mm before accounting for sensor intrusion margin C and spatial uncertainties Z_d and Z_r.

Human movement accounts for 70 percent of this cumulative margin. Just as in the walking-person stopping budget of section 12.3.1, human velocity during the combined reaction and deceleration phases dominates the required clearance. Against an approaching human, total stopping duration imposes a far heavier spatial tax than the robot's physical braking distance alone. Because standard vision pipelines lack functional safety ratings, a certified SSM implementation must use dedicated, safety-qualified sensors to measure separation and bound T_r.

The standards distinguish how they treat obstacle velocity. Standard ISO 3691-4 specifies detection assuming a stationary person standing in the travel path (TÜV Rheinland 2021); consequently, vehicle testing protocols evaluate protective envelopes against the static-obstacle formulation of equation 12.1. If a worker continues walking toward the vehicle throughout the braking sequence, the relative closing velocity exceeds the standard's baseline assumptions. In contrast, SSM explicitly models dynamic human approach velocity (v_h), explaining why mobile base navigation requires an explicit aisle-crossing protocol whereas robotic manipulation requires an active separation or contact-limiting channel. For collaborative handoffs, the enforcement record adopts the standardized biomechanical model of the human hand, distinguishing between unconstrained (transient) and clamped (quasi-static) contact scenarios. While simplified models often approximate PFL as a single lumped elastic collision with a fixed force threshold, ISO 10218-2 specifies distinct permissible force and pressure ceilings across individual anatomical regions. A complete architectural map correlating each subsystem, governing regulatory standard, and validation artifact is synthesized in the release decision framework (table 16.3).

DRAFT

Checkpoint 12.3: Choosing the physical fallback

Before selecting a defensive fallback strategy, review the requirements governing state-dependent stopping modes, safety functions, and timing reserves:

- ☐ **State-dependent stop**: Why can powered braking be safer than STO for a moving autonomous mobile robot (AMR), while drive torque inhibit may be appropriate after a separately verified restraint holds a stationary arm?
- ☐ **Independent functions**: What does STO inhibit, and which separate functions would remove bus power or apply a spring brake?
- ☐ **Timing and clearance**: Which measured detection, dispatch, drive, and brake delays belong in the stop reservation?
- ☐ **Lost viability**: What can a fallback still accomplish when the admissible torque set is empty?

12.10 Runtime Enforcement Failure Modes

Every guarantee in this chapter has rested on premises about the computer that runs the filter and the plant it models: a held-up logic rail, a bounded cycle, a credible deceleration, and a bus that delivers the admitted command on time. On the warehouse mobile manipulator each of those premises already carries a concrete spatial price. A missed tick costs 1.3 mm of travel at the aisle speed. A lease honored by the host instead of the MCU turns a 200 ms planning stall into 182 mm of unbraked travel and a 50.99 mm overrun. An unprotected integrator spends 195 mm against a 131.0 mm spare. Gravity on the arm and mug takes 75 percent of the joint's peak torque and quadruples the descending stop. Runtime enforcement failures trace back to four classes, one for each premise:

1. **Common-cause infrastructure failures**: When the learned policy and the safety filter share power rails, clock sources, reset lines, or thermal paths, one fault can disable both. A current surge during hard acceleration can sag a shared supply until it resets both the neural accelerator and the microcontroller that monitors it, and a shared reset or clock fault can silence the monitor at the instant the policy issues an errant command. The running machine therefore holds its permission logic on an isolated, held-up rail (section 12.9.1).
2. **Timing overruns and execution jitter**: A quadratic program that stalls on an ill-conditioned active set, or a filter scheduled on a non-deterministic operating system, spends braking clearance while it computes. An overrunning routine cannot be trusted to detect its own stall, which is why the declared 250 µs cycle comes with a qualified preempting timer or independent mechanism that selects the resident fallback when a deadline expires (section 12.7.4).
3. **Plant mismatch and unobservable state drift**: The filter evaluates safety against a model. A floor film that lowers friction, a payload that shifts the center of mass, or winding heat that lowers peak torque removes control authority the model still credits, so the solver can admit a deceleration the hardware cannot deliver. Where onboard sensors cannot observe the shift, the safe set must carry qualified uncertainty margins or the operating domain must restrict speed, as the complete optimistic inspected-floor screen falls to 1.17 m/s, before driven-wheel load share and available braking are qualified (section 12.3).
4. **Interconnect contention and transport delays**: State reads and command writes must cross physical buses. Unprioritized telemetry or logging can queue a joint reading until it is stale, or hold a filtered command in a transmit queue while the drive keeps executing the previous high-speed setpoint. The running machine carries its admitted command in a cyclic EtherCAT frame (stage 5 of the cycle budget) and charges the board link to the dispatch-to-admission budget.

None of the four yields to a better solver or an automotive-grade microcontroller. Each is answered by evidence. Common causes and contention need isolation and bounded interference, which chapter 13 tests on silicon. Overruns need a verified execution bound with an independent fallback. Plant mismatch needs worst-case rather than nominal parameter margins. All four need a record of

every enforcement decision, with its solver latency, active constraints, and sensor timestamps, so that an incident can be traced to the policy, the plant, or the infrastructure.

12.11 The Enforcement Record

When a warehouse mobile manipulator halts at a rack end because runtime safety logic rejected a motion proposal, forensic analysis requires unambiguous provenance: which threshold failed, which physical detector measured the violation, and which fallback rung took control of the actuators. The **enforcement record** is the tenth record in the record chain, the point where offline characterization meets online execution. It formalizes runtime safety across three cooperating artifacts:

1. **Enforcement contract**: The signed, immutable specification compiled into microcontroller firmware that fixes qualified tracking bounds ϵ_{track}, barrier coefficients, timer deadlines, delivered-effort error and response-delay bounds, and fallback routing tables before deployment.
2. **Admitted command**: The record's per-tick output. On each millisecond control cycle, the microcontroller gatekeeper generates an admitted command for transmission across the causal boundary. This payload contains the admitted or projected control $\mathbf{u}^*$, the verified barrier margin $h(\mathbf{x})$, tracking error validation $e(t) \leq \epsilon_{\text{track}}$, and the remaining hardware lease. The gatekeeper forwards only the bare setpoint and protective envelope to the motor drives, committing the complete supervisory state to the audit log.
3. **Enforcement audit log**: The high-rate forensic stream that captures per-tick proposal evaluations, intervention vectors $\Delta\mathbf{u} = \mathbf{u}^* - \mathbf{u}_{\text{nom}}$, quadratic programming (QP) solve latencies, and veto events in non-volatile storage.

Together, these artifacts render safety decisions fully auditable without burdening the actuator bus. The contract predefines the admissible operating envelope, the admitted command tags the immediate actuator setpoint, and the audit log preserves the causal chain of evidence. Real-time enforcement depends entirely on the protected command path, deterministic loop timing, and verified physical braking capabilities.

12.11.1 The admitted command schema

If the gatekeeper emits a bare torque vector without a monotonic sequence counter, a digest of the admitted parent trajectory, or the remaining lease duration, a replayed frame or a stalled microcontroller cannot be distinguished from a live command, and a post-incident audit cannot reconstruct which safety margins were checked on that millisecond tick. At each control cycle, the gatekeeper therefore produces an admitted command that establishes runtime authority at the drive interface (table 12.5). Its fields explicitly bind the actuator setpoint to its parent trajectory, verified safety margins, and active fallback state. Because each entry records a decision made under assumed physical conditions, runtime containment still relies on those assumptions matching physical reality.

Table 12.5: Admitted command schema: The per-tick output of the enforcement record, the tenth record in the record chain. Formed on every 1 ms tick by the microcontroller and written to the audit log, identifying the selected command, checked assumptions, and state-matched response. The drives receive only the setpoint, torque limit, and active rung inside a black-channel safety message; drive hardware containment relies on the local safety watchdog rather than the record itself.

Field Name	Type & Units	Physical System Invariant & Validation Rule	Mobile Manipulator Parameter / Value
`token_sequence_id`	`uint64_t` (counter)	Monotonically increasing admitted-command ID on MCU clock	Increments every 1 ms tick
`timestamp_mcu_ns`	`uint64_t` (ns)	Absolute MCU monotonic timestamp of admission	Latch instant at causal boundary
`parent_trajectory_digest`	`uint8_t[32]` (SHA-256)	Cryptographic link to the admitted trajectory record and chunk lease	SHA-256 of active trajectory record
`admitted_control_vector`	`float32[N_act]` (N·m)	Filtered torque $\mathbf{u}^*$ realized only under the qualified effort-error and response-delay contract; nominal if safe, projected if near boundary	Per-axis qualified torque envelope; 87 N·m only for the characterized arm axis

DRAFT

Field Name	Type & Units	Physical System Invariant & Validation Rule	Mobile Manipulator Parameter / Value
`intervention_vector`	`float32[N_act]` (N·m)	Intervention delta $\Delta\mathbf{u} = \mathbf{u}^* - \mathbf{u}_{\text{nom}}$; zero when the admitted command equals the nominal command	Nonzero only during CBF-QP projection
`barrier_margin`	`float32` (normalized)	Dimensionless $h(\mathbf{x})/h_{\text{scale}}$ with positive scale and barrier identity bound in the contract	Must satisfy $h(\mathbf{x}) \geq 0$
`tracking_error`	`float32` (m)	Instantaneous tracking error norm $e(t) = \|\mathbf{p}_{\text{meas}} - \mathbf{r}\|$	Base position error: $e(t) \leq$ 40 mm; arm channels use their own qualified bounds
`active_fallback_rung`	`uint8_t` (enum)	Active execution state: `PROJECT`, `HOLD`, `STOP`, `INHIBIT`	`0x01` (`PROJECT`) during nominal tracking
`lease_remaining_ns`	`uint32_t` (ns)	Remaining validity duration of current chunk lease	Trips `STOP` / `HOLD` upon reaching zero
`crc32_token`	`uint32_t` (checksum)	CRC-32 over the log entry, for audit integrity	Log reader rejects a corrupt entry; the drive-facing setpoint carries its own safety-layer CRC

Constructing the enforcement record synthesizes four upstream records across the offline and runtime evidence strands, where the offline strand establishes physical plant capabilities and empirical policy competence while the runtime strand tracks live execution state. From the runtime strand, the trajectory record of section 11.8 supplies the admitted reference and its precomputed, dynamically feasible stop suffix. From the offline strand, the evaluation record of section 7.8 provides runtime monitor specifications and the empirical coverage-gap catalog that define the active supervisory channels. The policy manifest of section 6.8 defines the declared ODD so that the enforcer's validity region is restricted to well-sampled operating regimes. The limit records of section 2.7 establish empirical braking rates, actuator onset delays, and torque envelopes alongside their operating preconditions. To these upstream parameters, the enforcement record contributes the formal guarantees of the gatekeeping pipeline. These are the qualified tracking bound ϵ_{track} and the stopping metrics ($T_{\text{stop}}, d_{\text{stop}}$, which bound the duration and displacement required to arrest plant momentum). They also include the control barrier function coefficients, the discrete execution period, the per-check thresholds mapped to fallback-ladder rungs, and the dynamic validity boundary.

The `parent_trajectory_digest` binds each admitted command to its originating trajectory and active chunk lease, providing forensic traceability back to the planner's proposal. Digests bind content for integrity checks; sequence counters and monotonic freshness checks reject stale or replayed commands within the protected drive interface. Sender authenticity additionally requires an authenticated channel or message authentication. Similarly, the `lease_remaining_ns` field conveys remaining execution authority, but this parameter guarantees safety only when the drive firmware actively enforces lease expiration by triggering a deterministic physical fallback. Streaming these fields to the audit log, alongside nominal proposals, intervention deltas, barrier margins, tracking errors, and solver latencies, gives engineers the causal evidence needed to reconstruct anomalous behaviors within the temporal resolution of the sensor pipeline.

This division of responsibilities dictates an architectural split at the fieldbus boundary. Motor drives have no operational need for trajectory digests or barrier margins; they require immediate setpoints, current limits, and active fallback commands delivered with fail-safe transport guarantees. Industrial systems handle this through established safety bus architectures. For example, Safety over EtherCAT (FSoE) implements the **black-channel principle**, treating the underlying communication bus as inherently untrusted (International Electrotechnical Commission 2021). FSoE encapsulates drive commands within a safety container featuring dedicated cyclic redundancy checks (CRCs), unique connection identifiers, strict sequence counters, and independent watchdog timers. These measures detect communication faults; sender authentication against malicious traffic requires a separate security mechanism. When a communication watchdog expires, the drive autonomously engages its safe stop state without waiting for microcontroller intervention. The rich diagnostic context (digests, barrier margins, intervention vectors, and solver runtimes) streams to the audit log

instead. An ad hoc safety-communication scheme for drive control must independently justify the fault detection and response properties covered by established functional-safety standards.

Filled in for the warehouse mobile manipulator, the enforcement record fixes the base's stopping parameters at the rack end alongside the arm's validity region and monitoring channels at the doorway and packing station. The tracking bound ϵ_{track} is 40 mm (matching row 7 of table 12.1), and the resident stopping trajectory is the jerk-limited S-curve suffix, which takes 931.25 ms and covers 605.31 mm from the 1.3 m/s aisle speed, or 1,031.25 ms and 773.44 mm from the 1.5 m/s drive limit. These spatial bounds are evaluated on a 1 ms loop period with a declared WCET of 250 µs inside a 400 µs deadline, supervised by three parallel timers: the 60 ms chunk lease, the 100 Hz host heartbeat with its 30 ms silence timeout, and the 5 ms hardware watchdog.

↪ The authority record's per-tick entries, which log the ladder rung of any active fallback, are developed in section 14.8.2.

For the manipulator, the validity region governs both the doorway and the packing station. The baseline door policy matches the nominal target ODD of the evaluation record (the nominal plate, standard door resistance, a stationary base, and the guarded approach, whereas the recovery update analyzed in section 7.8.1 qualifies the displaced-plate cell under its own distinct record rather than expanding the baseline region). The packing station admits picking a mug from the conveyor under a live intent lease followed by coworker handover. Across these zones, manipulator monitoring channels enforce dynamic velocity ceilings at the TCP. Inside the door zone, the approach-speed channel from the evaluation record's `runtime_monitor_specs` caps tool velocity at 0.03 m/s, whereas in unconstrained space the conveyor mug pick operates under the nominal 1 m/s free-space TCP limit. While a coworker holds `accept_item` (section 14.2), a handover channel engages before the separating distance closes to the arm's biased stop plus its blind-travel displacement and caps the approach toward the coworker's hand at 0.10 m/s, well below the 0.24 m/s contact-force ceiling for a free hand capable of recoil. Because a hand trapped against a rack upright or structural link permits an impact speed of at most 0.053 m/s, this handover cap is valid only when physical workstation geometry provably precludes clamping (section 12.7.2), a condition that the release argument must substantiate.

For the mobile base, operating assumptions distinguish between nominal and low-friction surfaces, each carrying its own cryptographic digest in the release manifest. The standard configuration requires a qualified directional braking lower bound encompassing driven-wheel load share, traction, torque, and stability, where a friction coefficient of at least 0.204 serves only as a necessary optimistic all-weight screen rather than sufficient evidence that the design deceleration holds. By contrast, a restricted configuration accommodates degraded traction down to an inspected-floor friction of 0.12. The restricted illustration stipulates that its 1.177 m/s² braking rate is available (since inspection alone does not establish that lower bound), and its deceleration suffix uses that stipulation to stop in 1015.3 ms across 507.6 mm from 1 m/s beneath the 1.17 m/s complete inspected-floor screen, whose braking premise still requires qualification.

Each base entry incorporates the 63.3 ms dispatch-to-admission allocation and its own scenario-specific remaining clearance. The 48.7 mm stopping reserve belongs to the dry static-obstacle aisle candidate; the restricted configuration must recompute its reserve from its own speed and braking rate. Because this allocation represents an analytical budget, neither configuration is certified for admission until physical deceleration measurements under maximum payload confirm the modeled margin.

Each numerical entry in the record carries the evidence category of its limit record: *measured*, *derived*, *datasheet*, or *illustrative*. These categories reflect fundamentally different degrees of operational confidence. The base's 931.25 ms stopping time, for instance, is a *derived* value. It follows mathematically from the geometry of the S-curve suffix under a stipulated jerk bound and an illustrative deceleration figure, assuming that motor drives faithfully deliver commanded current and tires maintain continuous traction. Only loaded stopping trials on the actual operating surface establish a *measured* value. Physical tests reveal empirical non-idealities that escape closed-form derivations, including electromechanical brake onset scatter, structural compliance, and surface contamination. Even then, empirical data supports a formal bound only when combined with worst-case fault models and defined operating limits. Explicitly recording the evidence category prevents an integrator from mistaking a derived stopping estimate for a verified hardware limit.

The record also carries the routing of section 12.9 as part of its contract. An arriving proposal can neither renew an active command nor revoke its authority merely by being transmitted, and each

lease or heartbeat expiry, cycle loss, or bus undervoltage selects the rung that matches the machine's state and the hardware that survives. Every field of the record is either an integrity token or an operational threshold evaluated against live execution state. These checks examine the proposal's sequence counter and checksum, its stored dispatch age against 51.8 ms, reconstructed perception latency against validity and stopping-margin criteria, active elapsed time against the chunk lease, tracking error against the allowable envelope ϵ_{track}, joint-velocity and torque-slew ceilings, barrier margins, phase-current and bus-voltage limits, and hardware watchdog timeouts. The contract binds each threshold to the independent sensing hardware that measures it and to the specific fallback rung selected upon violation. Table 12.6 organizes these rungs by residual system authority and specifies the hardware timer that triggers each transition.

↪ **Byte layout:** The enforcement record's fields, types, and units are given in section C.15.4.

Table 12.6: Enforcement state contract: The 20 Hz proposal, 60 ms chunk lease, 100 Hz host heartbeat, and 1 kHz MCU loop have distinct renewal and failure paths.

State	Trigger and authority	Timing check	Physical response to validate
`PROJECT`	Fresh proposal, healthy heartbeat, feasible kinetic barrier; an invalid replacement is refused; active setpoints continue only while their own evidence, lease, state, and stop reserve remain valid	1 ms cycle; declared full-cycle WCET 250 µs inside a 400 µs deadline	Track admitted torque within qualified error and brake reserve
`HOLD`	At standstill, active elapsed time beyond the 60 ms lease, host heartbeat silent beyond 30 ms, while powered support remains available	Expiry detected on the MCU clock within one tick	Powered support against gravity and payload; on undervoltage, secure qualified restraint before support expires
`STOP`	In motion, lease or heartbeat expiry, shared-rail undervoltage, tracking error beyond ϵ_{track}, an empty feasible control set, or a tripped disturbance observer or solver deadline, while powered braking remains available	Include detection, dispatch, drive rise, and brake response	Resident stop on the base, state-matched stop on the arm; measured stop distance under load; no claim after viability is lost
`INHIBIT`	Independent wired supervisor or external trip detects MCU cycle loss	Assumed 5 ms detection plus measured drive, contactor, or brake response	STO removes motor torque and the spring brakes set after coil decay; unbudgeted, so no stopping claim rests on it

Because runtime safety guarantees require that plant dynamics remain inside the modeled operational envelope, the enforcement record bounds execution within an explicit validity region. The manipulator's doorway speed ceiling illustrates how empirical evidence defines these bounds. The policy's proposed 0.10 m/s approach, refused in section 12.6 on evidential and physical grounds, passes only the narrowest timing test, since its 2.5 ms unbraked compression time from first contact to the latch force limit exceeds the 2 ms contact-loop cycle. That naive unbraked deadline ignores both the force already accumulated before the tripwire fires and the compression distance the arm still needs to decelerate to rest, so the record keeps both grounds for refusal beside that pass, the post-trip stop that section 12.7.2 sized and the absence of trials at that speed, ensuring that no reader mistakes the timing pass for admission. The enforcer therefore clamps the command to the 0.03 m/s evidence-based ceiling, evaluates full contact dynamics, and records the active constraint in the audit log. In contrast, the coworker handover ceiling is derived from the structural impact model (equation 12.13), which caps approach velocity below the contact-force limit where modeled impact forces meet allowable biomechanical thresholds for an unconstrained hand. Faster proposals are projected onto this boundary and logged as intervention vectors.

When onboard estimators detect a state outside the validity envelope, such as an undeclared payload mass, the supervisory monitor flags the violation, revokes policy authority, and commands a state-matched stop. Environmental conditions that lack direct onboard sensing, however, cannot trigger dynamic runtime vetoes. Surface friction at the wheel-floor interface represents an unobservable state, because mobile bases carry no transducers to measure instantaneous traction coefficients beneath their wheels. Consequently, the standard configuration relies on verified floor friction

as an operating precondition, while low-friction operations require manual floor inspection and commissioning of the restricted configuration.

An enforcement record connects proposed neural trajectories to validated physical invariants, operational thresholds, and deterministic fallback responses. Algorithmic correctness, however, cannot compensate for an execution platform that violates its timing or braking commitments under load. An enforcer whose control barrier functions are mathematically verified will still fail if the couplings it still shares with the host, the board-link DMA into its memory, a supply rail, or a clock, delay its cycle under load during high-speed transit. In physical artificial intelligence, safety failures manifest in the time domain just as decisively as in algorithmic logic.

↪ The floor-friction premise is enforced as an entry of the residual-claims register in section 18.3.3.

12.12 Fallacies and Pitfalls

A physical safety filter prevents collisions only as long as its control loop meets hard real-time execution deadlines and its state feedback accurately reflects reality. Safety qualification cannot rely solely on evaluating nominal control barrier equations under idealized laboratory conditions; real systems fail when host processors lock up, state estimators drift, or perception pipelines misclassify obstacles. Production testing must therefore exercise system response precisely when these core execution and sensing assumptions break down.

Pitfall: *Assuming high-level policy computers can be relied upon to execute graceful shutdown.*

A software exception handler on an application processor cannot arrest physical momentum when the operating system kernel panics. Consider a warehouse mobile manipulator whose high-level application processor experiences an operating system kernel panic while navigating an aisle at 1.3 m/s. Once the host kernel crashes, it can no longer generate deceleration trajectories or dispatch motor setpoints. Cutting the drive enable line to zero torque is equally hazardous, leaving the unbraked base to coast under momentum directly into the aisle racks. Relying on an operating system shutdown handler or a user-space exception hook assumes that the host software stack remains functional, an assumption that fails during kernel panics, hardware lockups, or memory exhaustion. Physical fail-safety requires stopping clearance and torque authority that persist independently of the host. In a robust architecture, the downstream MCU detects the missing heartbeat within its 30 ms timeout, comfortably within the stopping budget's reserved lease margin. The MCU then immediately executes its resident jerk-limited stop suffix, decelerating the base to a complete stop in 931.25 ms across 605.31 mm. While host shutdown routines manage orderly transitions during routine operation, true fault tolerance demands that stopping authority resides in hardware and low-level firmware that survive host death.

Architect's countermeasure: Decouple physical stopping authority from host processor lifecycles with two MCU timers that the host cannot service on the MCU's behalf. The heartbeat timer, refreshed by the host's periodic heartbeat, catches a host that has gone silent, which is what a kernel panic produces. The chunk lease, refreshed only by a valid admitted proposal, catches a host that is still alive and still sending heartbeats but no longer delivering valid motion. When either expires, the MCU intervenes without waiting for host acknowledgment, selecting the precompiled, state-matched stop suffix within its validated entry envelope and actively commanding motor torques to bring the robot to a controlled halt.

Fallacy: *A mathematically correct safety filter guarantees safety even when underlying state feedback has drifted.*

A barrier certificate evaluated against a drifted or corrupted state estimate provides zero physical protection. The mobile base's 40 mm tracking certificate bounds true physical position error only under qualified state feedback assumptions. In practice, comparing the reference trajectory against encoder-reported position serves merely as a runtime proxy; that agreement alone cannot verify the actual physical bound. Wheel slip or an optical encoder with an undetected scale bias can lead the state estimator to report that the base is farther from the aisle rack than its true physical location. The CBF-QP solver then easily satisfies its barrier inequality on the corrupted estimate, while the physical base exhausts clearance margins that the stopping budget never granted. Only an independent sensing channel, such as an IMU or a safety lidar measuring direct range to the rack, can expose this divergence, and only if the tracking error exceeds the diagnostic monitor's observability threshold. System qualification must bound how far the estimate can drift before

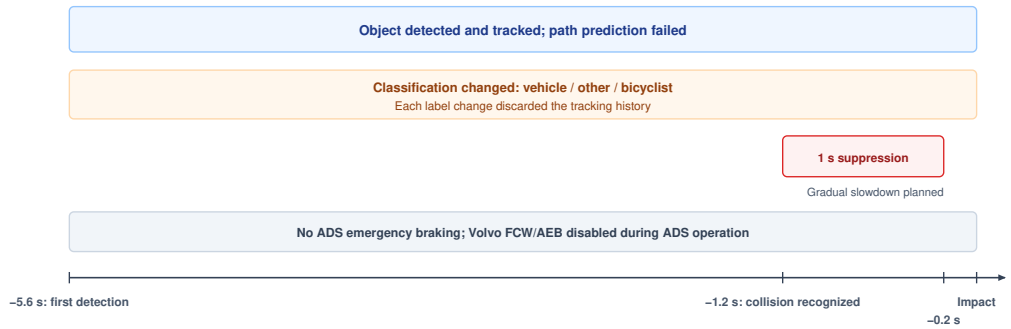

Figure 12.11: Tempe detection and braking timeline: The NTSB reports first detection 5.6 s before impact and recognition of imminent collision 1.2 s before impact. The ADS suppressed its motion plan for one second and then planned gradual slowing; it did not perform emergency braking. Classification and path prediction failed: at each change of class the ADS discarded the object's tracking history. The Volvo forward-collision warning and automated emergency braking functions were disabled while the developmental ADS operated. (Adapted from NTSB/HAR-19/03 (National Transportation Safety Board 2019).)

detection occurs. The stopping budget must account for this worst-case drift in its localization allowance δ_{loc}, rather than crediting that same uncertainty to the dynamic tracking inset. To preserve formal safety guarantees, the qualification framework must explicitly document which physical error source each budget allowance covers.

Architect's countermeasure: Implement redundant, heterogeneous sensor cross-checks that continuously validate kinematic wheel odometry against independent physical channels, such as optical flow, time-of-flight lidar, or secondary motor encoders. Expand the safety filter's localization allowance δ_{loc} to absorb the maximum unobservable drift that can accumulate before diagnostic cross-checks trip, guaranteeing that the contracted safe set remains physically invariant even under worst-case sensor degradation.

Pitfall: *Coupling safety braking authority to stochastic semantic classification rather than deterministic spatial clearance.*

Emergency stopping authority must be bound to deterministic spatial clearance rather than upstream semantic classification. When an automated vehicle conditions collision avoidance on object classification and trajectory forecasting, perception errors can silently disable emergency intervention. The March 2018 Tempe collision, analyzed in section 1.8, shows the sequence (figure 12.11). Although the developmental automated driving system (ADS) first detected the pedestrian pushing a bicycle 5.6 s before collision, repeated perception toggling between vehicle, other, and bicyclist classifications reset the tracking filter, discarding historical motion at each switch and treating the obstacle as an unpredicted static entity (National Transportation Safety Board 2019, sec. 1.5.5.2). When the pipeline finally registered an imminent crash 1.2 s before impact, high-level policy suppressed actuator intervention for a full 1-second delay to avoid vehicle swerving, after which the planner issued only a gradual deceleration request. The architectural failure sits at the base of the timeline. The vehicle's factory-installed Volvo autonomous emergency braking (AEB) interlock had been suppressed during ADS operation. An independent geometric safety barrier avoids these cascading failures by separating spatial clearance from semantic inference. It commands an emergency stop based solely on physical distance and closing speed, regardless of what label the neural perception pipeline assigns to the obstacle.

Architect's countermeasure: Enforce the causal separation of perception and safety by establishing an independent, non-semantic geometric barrier. A safety-rated sensor channel, such as a time-of-flight lidar curtain, radar, or safety scanner, must maintain direct hardware veto authority to command a Category 1 stop. This safety layer evaluates occupancy and closing rate directly, completely bypassing the neural perception pipeline, semantic classifiers, and trajectory forecasting models.

Fallacy: *Assuming a continuous-time barrier certificate holds under discrete Zero-Order Hold sampling without an inter-sample kinematic buffer.*

Checking a continuous-time barrier inequality at discrete sampling instants does not guarantee inter-sample safety. In digital control architectures, an actuator applies a constant torque or current command over the entire zero-order hold (ZOH) interval $T_{\text{tick}} = 1$ ms. If an active-set QP solver computes a minimally invasive control input at sample t_k that places the plant directly on the boundary of the safe set ($\partial\mathcal{C}$), continuous physical dynamics unfold during the intervening hold period. Between t_k and t_{k+1}, physical acceleration under the held actuator command can drive the true state across the boundary before the next control cycle executes. Equating a continuous barrier certificate $\dot{h} + \gamma_{\text{cbf}} h \geq 0$ directly with discrete-time invariance without an inter-sample buffer invites boundary violations whose severity grows with velocity and sample period.

Architect's countermeasure: Contract discrete-time barrier certificates by the worst-case inter-sample kinematic drift buffer, $\Delta d_{\text{ZOH}} = v T_{\text{tick}} + \frac{1}{2} a_{\max} T_{\text{tick}}^2$ evaluated at the highest reachable speed v. In a 1 kHz control loop operating at the 1.5 m/s drive limit with an independently stipulated approach-acceleration upper bound of 2 m/s², this inter-sample displacement bound equals 1.501 mm, the drift that the discretization condition of section 12.7.3 charges. Enforcing the barrier condition against the tightened safe set $\mathcal{C}_{\text{discrete}} = \{\mathbf{x} \mid h(\mathbf{x}) \geq \Delta d_{\text{ZOH}}\}$ preserves physical clearance throughout the hold duration when the barrier measures spatial distance. When accounting for this margin in the stopping budget, architects must avoid double-counting, because any travel already allocated to the budget's one-tick fault detection interval already covers this displacement. Furthermore, when evaluating non-spatial or kinetic barriers, engineers cannot rely solely on a geometric displacement bound; the implementation must bound the worst-case evolution of the barrier function itself under the held input across the full sample interval $[t_k, t_{k+1}]$.

12.13 Summary

Runtime enforcement grants an admitted plan continuing, conditional permission to drive physical hardware. On every control cycle the enforcer evaluates live plant state against the tracking bound, the stopping reservation, and the actuator authority that remains. It passes a safe proposal through, projects a correctable one back into the admissible set, and selects a resident fallback, without waiting for the learned proposer, when no correction exists or the proposer falls silent.

Clearance is a composite margin, not a distance read from a map. At the warehouse mobile manipulator's 1.3 m/s aisle speed, travel during the pre-brake delay τ_{delay} takes 173.68 mm, the C^2 stop suffix 605.31 mm, localization and protective margin 150 mm, and the tracking inset 40 mm, for 968.99 mm of the 1.10 m available at the rack end. The remaining 131.01 mm pays for dispatch-to-admission travel ($v\Delta_{\text{da}} = 82.3$ mm) and leaves a 48.7 mm reserve, so the aisle speed remains a candidate until loaded timing measurements confirm that allocation. A budget built on instantaneous, constant-deceleration braking would have admitted the drive limit, where the jerk-limited stop no longer fits. The budget also holds only while the actuators deliver their assumed deceleration; gravity on a descending payload, bus sag, current ceilings, and thermal throttling all shrink braking authority, so the enforcer must contract the speed envelope before that authority is spent rather than after.

The kinetic barrier turns that reservation into a constraint on the next command. Raw clearance has relative degree two with respect to torque, so a barrier on distance alone leaves the motor no authority at the boundary. Folding approach speed and net braking deceleration into equation 12.5 lowers the relative degree to one, and its zero level set is the single-joint stopping budget written in state space. Under the qualified delivered-effort error and response-delay contract, the least-change quadratic program removes only the part of a proposal that violates the tightened half-space, which preserves useful task progress when the corrected motion remains task-admissible. An independent per-axis clamp can leave the coupled constraint broken. When contact is the task, force replaces clearance as the margin. Force keeps building through the response interval, so the latch and handover ceilings are approach speeds derived from the force at brake onset and from the effective mass a free or a clamped hand meets, each valid only under its stiffness, deceleration, and geometry premises.

When a lease lapses or a checked premise fails, the arbiter selects directly among `PROJECT`, `HOLD`, `STOP`, and `INHIBIT` by the plant's state and the hardware that survives; the rungs are alternatives,

not an escalation. Three timer duties detect different failures: the 60 ms chunk lease bounds a stale proposal, the 30 ms host-heartbeat timeout catches a host stall, and the 5 ms MCU self-watchdog catches a firmware deadlock. Beneath these responses sit the certified functions of the drives, the safety scanner, and the arm's safety controller, which carry the formal protective claim. On the permission path itself, only the safety MCU's watchdog that revokes authority when the chunk lease expires or the host heartbeat falls silent is a rated safety function. The admission checks are an unrated performance layer whose job is to reduce unnecessary trips of the assumed qualified protective floor (section 12.9.3). The enforcement record ties each check to its detector, its fallback, and the evidence category of every number it uses, so that what the permission path verified stays distinct from what it assumed. The checks and ceilings the permission path applies reduce to the relations in table 12.7.

Table 12.7: Key equations of safety enforcement: Each equation fixes one check or ceiling the permission path applies. Every result holds only while its inputs (delays, braking authority, bias, contact stiffness, and timing) stay inside their qualified bounds.

Equation	What it bounds or decides	Derived in
$v\,\tau_{\text{delay}} + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} \le D_{\text{clear}}$	Stopping subtotal before dispatch travel; complete admission additionally charges that interval	equation 12.1
$v_{\max} = -a_{\text{brake}} T_{\text{eff}} + \sqrt{(a_{\text{brake}} T_{\text{eff}})^2 + 2 a_{\text{brake}} D_{\text{avail}}}$	The pre-dispatch speed ceiling and unallocated timing allowance left below it	equation 12.2
$\alpha_{\text{net}} = (\tau_{\max} - \tau_{\text{bias}})/J_{\text{eff}}$	Braking authority left when gravity loads the joint in the direction of motion	equation 12.3
$h(\mathbf{x}_0) \ge 0 \wedge \dot{h} \ge -\kappa(h) \implies h(\mathbf{x}_t) \ge 0$	Forward invariance of the safe set under the model, actuator, and timing assumptions	equation 12.4
$h(\theta_{\text{clear}}, \omega) = \theta_{\text{clear}} - \omega^2/2\alpha_{\text{net}}$	A barrier with relative degree one: remaining clearance minus the cost to stop	equation 12.5
$\tau \le -\tau_{\text{bias}} + J_{\text{eff}} \alpha_{\text{net}} (\gamma_{\text{cbf}} h/\omega - 1)$	The torque half-space a proposal must satisfy on the next tick	equation 12.6
$\min \frac{1}{2}\lVert\mathbf{u} - \mathbf{u}_{\text{nom}}\rVert^2$ s.t. $\mathbf{a}_{\text{cbf}}^\top \mathbf{u} \le b_{\text{cbf}}$	The least-change correction of a proposal inside the actuator envelope	equation 12.7
$\mathbf{u}^* = \mathbf{u}_{\text{nom}} - \lambda^* \mathbf{a}_{\text{cbf}}$	Closed-form projection onto one active half-space	equation 12.8
$\dot{E}_{\text{tank}} = \dot{\mathbf{q}}^\top \mathbf{D}_{\text{virt}} \dot{\mathbf{q}} - \mathbf{u}_{\text{active}}^\top \dot{\mathbf{q}}$	The work a contact controller may still inject before its energy reserve is spent	equation 12.9
$F_{\text{cmd}} = F_{\text{trip}} + k_{\text{latch}} v_{\text{latch}} T_c$	Contact force already reached when braking begins at the latch	equation 12.11
$F_{\text{unbraked}} = v_{\text{approach}} \sqrt{k_H m_{\text{red}}}$	Peak hand force at an approach speed, and so the handover speed ceiling for a free or clamped hand	equation 12.13

Key Takeaways: Conditional enforcement and physical stopping

- **Tracking is a bounded premise:** Steady-state tracking guarantees do not bound transient overshoot. Clearance insets must incorporate worst-case transient tracking errors validated experimentally across the robot's full operating envelope.
- **The stopping budget dictates allowable speed:** Sensing latency, reaction delays, C^2 braking trajectories, tracking error insets, and localization margins all compound into a single admission check. True physical clearance, rather than motor drive limits, determines how fast the machine may safely move.
- **Control barriers must account for kinetic energy:** Because spatial distance has relative degree two with respect to joint torque, a position-only barrier cannot guarantee immediate forward invariance. Formulating a kinetic barrier that incorporates velocity yields an affine torque half-space for safe single-step execution.
- **In physical contact, force replaces distance as the margin:** Mechanical force continues to build throughout the latency of a braking response. Latching stops must be dimensioned

DRAFT

from the projected peak force at brake onset, and approach velocities during human handover must be capped based on effective inertia and structural compliance.

- **Distinct timer duties expose different failure modes:** Trajectory chunk leases, host-to-controller heartbeats, microcontroller watchdog cycles, and sensor timestamps expose different failure modes. No single software timeout can protect against all failure modes.
- **Fallback execution is state- and hardware-dependent:** Safely executing a least-change projection, powered zero-velocity hold, controlled deceleration ramp, or torque inhibit requires specific surviving hardware and dynamic state. The fallback must be selected while the admissible control set is still nonempty; an empty chosen intersection loses that filter's claim, while an alternate response needs its own qualified claim.
- **The software permission path complements certified hardware:** Safety-rated laser scanners, certified drives, and emergency stop interlocks provide the formal protective baseline. The running architecture assumes a rated lease-expiry and heartbeat watchdog on the permission path. The algorithmic admission checks are unrated and operate above this floor to keep operation smooth without tripping certified hard stops.
- **Every intervention requires an audit record:** The enforcer must bind every command token to verified sensor inputs and log all constraint modifications or fallback triggers to an audit log. This logging ensures system designers can audit safety margins on physical hardware and validate assumptions before production deployment.

This chapter is where the third law, proposal is not permission, stops being a design stance and becomes a mechanism. A learned proposal reaches the drives only as a candidate. It earns authority one tick at a time, and only while its evidence is fresh, its lease unexpired, its tracking error within bound, and the stop it would need still inside the clearance. Nothing the proposer emits can extend that authority, and the response that replaces it never waits for the proposer.

A complete runtime enforcement architecture joins the flexibility of learned policies to the determinism of physical safety guarantees. It reserves stopping clearance dynamically, projects candidate controls when a feasible correction exists, and selects a state-matched fallback when communication fails or an invariant breaks. Mathematical safety certificates and algorithmic barrier functions, however, are only as dependable as the underlying real-time compute fabric. Interference through whatever the permission path still shares with the proposers, a board link, a supply rail, a clock, or in some placements a die and a memory bus, can silently consume time that the physical budget already assigned to braking. The final engineering obligation is therefore empirical: verifying that the entire permission pipeline strictly meets its real-time deadlines under worst-case system load on the physical hardware.

12.14 Historical Perspective and Further Reading

The safety certificates developed in this chapter trace their intellectual lineage to classical questions about boundary invariance that predate digital computing. In 1892, Aleksandr Lyapunov demonstrated that one can prove the asymptotic stability of a dynamical system by constructing a scalar, energy-like function, bypassing the intractable problem of solving nonlinear differential equations directly. Mitio Nagumo extended this geometric intuition from isolated equilibrium points to entire sets (Nagumo 1942): a closed set traps all future trajectories if and only if the vector field at every point along its boundary points inward or tangent to the boundary surface. Decades later, Aubin formalized this boundary principle for controlled systems within viability theory (Aubin 1991), characterizing the viability kernel as the set of states from which at least one admissible control input can prevent constraint violations indefinitely. The differential games of Isaacs (1965) introduced an adversarial perspective against worst-case disturbances, which Mitchell, Bayen, and Tomlin later computed on numerical grids through Hamilton-Jacobi reachability analysis (Mitchell et al. 2005). Prajna and Jadbabaie translated these boundary arguments into barrier certificates for algebraic system verification (Prajna and Jadbabaie 2004), and Wieland and Allgöwer framed the barrier condition as an affine inequality directly over the control input (Wieland and Allgöwer 2007). Ames and collaborators then combined this affine formulation with real-time optimization, creating the

control barrier function quadratic program (CBF-QP) whose solve time can lie in the microsecond range for selected problem sizes and platforms (Ames et al. 2014; Ames et al. 2019). Contemporary systems engineering treats control barrier functions, reachability analysis, and predictive backup sets as a unified family of safety filters, each continuously monitoring an unverified control proposal against a verified fallback action that remains physically executable (Hsu et al. 2024).

The structural pattern that wraps an analytical certificate around a complex model originates in runtime assurance for aerospace and industrial automation. To deploy advanced, unverified control software without risking catastrophic failure, Sha and colleagues designed the Simplex architecture (Seto et al. 1998; Sha 2001). Simplex allowed a high-performance experimental controller to drive a live plant while an analytically verified baseline controller and a deterministic switching monitor stood ready to reclaim authority whenever the state neared the edge of the recoverable envelope. Alshiekh and collaborators later transplanted this runtime assurance principle into reinforcement learning under the rubric of shielding (Alshiekh et al. 2018), using reactive temporal logic specifications to intercept and correct unsafe exploratory actions before they reached the actuators. Physical embodiment, however, introduces contact dynamics that purely kinematic boundary checks cannot govern. Hogan transformed robotic manipulation by introducing impedance control (Hogan 1985), which regulates the dynamic relationship (stiffness, damping, and inertia) between environmental forces and manipulator motion instead of tracking brittle position trajectories. Willems provided the rigorous foundation for analyzing such interactions through dissipativity theory (Willems 1972), which formalizes the energy bookkeeping required to guarantee stability across interconnected subsystems. Ferraguti and co-authors embedded that bookkeeping directly into digital software via virtual energy tanks (Ferraguti et al. 2013). By tracking energy dissipation within the controller's internal state, energy tanks restrict command authority when stored reserves deplete, preventing explosive instability during abrupt contact or communication latency.

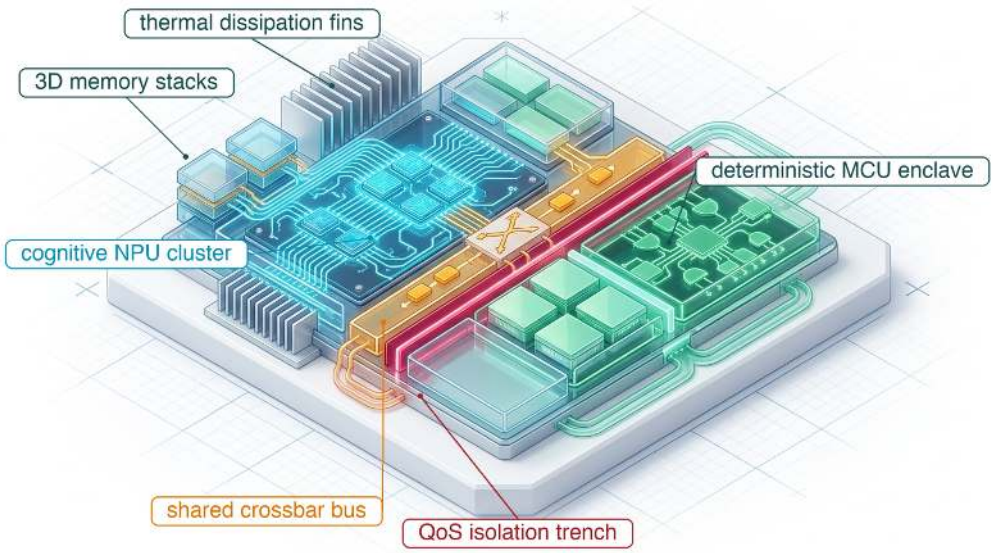
The requirement that a fail-safe mechanism must operate independently of the software it monitors emerged from painful engineering lessons. The Therac-25 accidents recounted earlier in this chapter illustrated the fatal cost of replacing electromechanical safety interlocks with software routines (Leveson and Turner 1993); race conditions in unverified code bypassed intended protections and delivered lethal radiation doses to patients. International functional safety standards codified this experience by mandating strict architectural isolation between rated safety functions and the operational systems they supervise (International Electrotechnical Commission 2010a; International Organization for Standardization 2023a). In robotic drivetrains, this separation extends down to hardware-level stop functions, such as safe torque off and safe operating stop, implemented directly within power electronics and drive logic (International Electrotechnical Commission 2016b). When runtime enforcement relies on software, temporal predictability becomes just as vital as functional correctness. Worst-case execution-time (WCET) analysis, surveyed comprehensively by Wilhelm and colleagues (Wilhelm et al. 2008), combines execution models, platform assumptions, and timing evidence to justify latency bounds; empirical observations alone do not establish a certified worst case. The architecture presented in this chapter unites these distinct traditions. A learned policy proposes high-performance actions, an online filter derived from physical stopping budgets preserves forward invariance under its qualified assumptions, and an isolated safety floor supplies its separately qualified protective response. A tamper-evident enforcement log records the exact state evidence that justified each intervention. For further reading, six works trace these ideas from their foundations to current practice:

- Blanchini (1999) surveys set invariance in control, tracing the theory from Nagumo's boundary conditions to algorithmic methods for computing polyhedral and ellipsoidal invariant sets, providing the clearest geometric map of the state space that barrier certificates supervise.
- Aubin (1991) develops viability theory, the mathematical framework governing the states from which a constrained system can remain safe indefinitely, and the formal theoretical foundation for the kinetic barriers and viability kernels used throughout this chapter.
- Sha (2001) presents the foundational runtime-assurance argument: a complex, unverified controller may retain command authority only while an analytically verified baseline controller, operating within a known recoverable region, stands ready to safely intervene.

DRAFT

- Leveson and Turner (1993) reconstructs the Therac-25 radiation therapy accidents and remains the definitive case study demonstrating why safety interlocks must never depend solely on the software systems they are designed to protect.
- Ames et al. (2019) provides a comprehensive tutorial on control barrier functions and quadratic programming safety filters, covering both mathematical underpinnings and physical robotics deployments, and serving as the natural follow-up to section 12.7.
- Hsu et al. (2024) unifies control barrier functions, Hamilton-Jacobi reachability, and predictive backup sets into an overarching safety-filter framework, analyzing how learned neural policies can be trained alongside runtime filters to avoid boundary chattering, directly addressing the co-design challenges raised in section 12.8.1.

What's Next: From barrier certificates to SoC placement



Can the learned proposers share a chassis, and in some placements a die and a memory bus, with the permission path without delaying it? The enforcement record declares a worst-case cycle inside the permission deadline on every tick. That deadline is a claim about silicon, and a barrier result holds only while the permission path meets it. Every budget in this chapter has assumed the placement Part I adopted as a hypothesis, a discrete safety microcontroller physically separate from the proposers' processor. Chapter 13 puts that hypothesis under load. It partitions the learned proposers and the permission path across compute fabrics and names the loaded tests that would show whether memory starvation, clock throttling, or bus contention can delay permission or fallback, recording them in the placement record.

Purpose

Why can a safety check miss its deadline even when it runs on its own processor core?

A correct refusal computed too late does not stop the motion it was meant to prevent. Separating a learned proposer from its permission path in software does not make the two independent while they still share memory, electrical power, clocks, or cooling. A burst of inference can then delay the check that should stop the machine, heat from the accelerator can slow the core that runs that check for seconds after the burst has ended, and a single supply or reset fault can silence both paths at once. None of these couplings appears on a software architecture diagram, and none shows up in average utilization, so a safety argument that has never been loaded on its real silicon rests on an untested premise. Moving the check to separate hardware removes some couplings and adds others, a communication delay and a longer chain of supplies and wiring, so no placement is independent by construction. Where each workload runs therefore decides whether the permission path can still refuse in time, and an action that crosses the causal boundary on a late refusal cannot be taken back.

Learning Objectives

- Conduct a dependent-failure inventory of the caches, memory controllers, interconnects, supply rails, clocks, resets, and thermal paths that each candidate placement leaves shared between the proposal and permission paths
- Explain why average bus utilization cannot bound a deadline, and identify which contention mechanism (bandwidth queueing, bank conflicts, or shared-cache miss handling) threatens a declared worst-case execution time
- Evaluate whether shared power and reset paths can defeat a selected permission placement
- Analyze thermal coupling and clock throttling hysteresis between multi-tenant workloads across disparate physical timescales
- Size a windowed watchdog's service window from justified completion and inter-tick jitter bounds for a non-blocking record exchange
- Select among static reservation, spatial partitioning, workload reduction, and physical silicon relocation from measured interference and timing allowances, and allocate the dispatch-to-admission interval of an on-board or off-board proposer against the stopping budget
- Design an adversarial stress campaign whose falsification threshold is the permission path's declared worst-case execution time (T_{wcet})
- Construct a placement record formalizing the deployment envelope that scopes loaded observed maxima, thermal headroom, bus arbitration, mitigations, and untested conditions for release review

13.1 The Silicon Substrate

When the warehouse mobile manipulator's permission check finishes late, its motor drives keep executing the last admitted command, and the loaded base covers distance that the stopping budget of chapter 12 never reserved. The control barrier filter, the stopping reservation, and the fallback ladder developed there hold only while the permission path completes its check inside its hard real-time deadline on every cycle. The enforcement record declares a worst-case execution time inside that deadline, a bound on the check running alone, and whether the bound survives while the learned proposers run beside it is a question about the silicon underneath. Workload placement decides which silicon executes each computation, and with that choice, which memories, interconnects, clocks, power supplies, and thermal paths each task shares with the others. In conventional computing, placement is an optimization over throughput, latency, or energy. On a machine whose refusals must arrive on time, it becomes a safety problem.

Modern silicon integration works directly against the separation the permission path needs. A contemporary heterogeneous system-on-chip (SoC) integrates general-purpose application cores, neural accelerators, real-time microcontrollers, and specialized safety islands onto a single monolithic die. On that die, these subsystems share memory controllers, dynamic random-access memory (DRAM) channels, system-level caches, on-chip network interconnects, voltage regulators, clock governors, and the physical package that carries away heat. While silicon integration lowers unit cost, board area, and inter-processor communication latency, it quietly couples through shared hardware the very execution paths that the software architecture keeps apart. The question placement must answer is whether the deterministic permission path can keep its deadline and its authority to refuse unsafe motion while the proposal path runs at full load on shared hardware. Answering it requires a bound on hardware interference for every shared physical resource, derived from worst-case timing analysis and validated under loaded stress tests.

On the warehouse mobile manipulator, the software architecture draws the proposal boundary between the Brain and the Nervous System as a clean logical boundary. Part I adopted a working hypothesis about where that line falls in hardware. That hypothesis places the permission path on a discrete safety microcontroller physically separate from the application SoC. The machine's two physical jobs show what that separation must guard against. For the mobile base, whose mass-

dominated mobility spends stopping clearance, an interconnect stall during visual feature extraction on the proposal engine could delay the permission path's refusal while the loaded base approaches a rack end. Every tick of delay beyond the single cycle accounted for in the stopping budget is travel distance the machine never reserved. For the arm, whose contact-dominated manipulation spends force margin, a burst of neural accelerator traffic that evicts the permission path's lookup tables from a shared cache could delay contact force validation while the gripper presses against a spring-latched cage door. The monolithic SoC is therefore an architecture the machine must be able to reject on evidence, and the discrete microcontroller is a design claim that must survive a loaded test rather than be assumed.

Assigning the permission filter to a dedicated processor core does not create an isolated failure domain. A core running in isolation may still stall on memory arbitration, slow down under dynamic clock throttling, or suffer transient voltage drops when adjacent accelerators become active. Memory protection units and operating system process boundaries enforce spatial partitioning by preventing unauthorized reads and writes across address spaces. However, memory protection hardware governs access permissions rather than access timing. The underlying interconnect crossbar, memory controllers, and DRAM banks determine when memory transactions actually complete. Establishing a sound safety case requires both spatial partitioning to prevent memory corruption and temporal partitioning to guarantee bounded service times for shared hardware resources (Kopetz 2011; Rushby 1999).

↩ The independence requirement on the permission path, and the two-processor split as a hypothesis that loaded tests must support, are established in section 4.2.

Definition 13.1: Operational independence

Operational independence is the property that no activity, fault, or overload in the proposal domain can push the permission path's execution past its deadline or disable its authority to refuse, through any resource the two paths share.

1. **Significance**: It is the premise under which the stopping budget charges exactly one permission tick of detection delay. Every tick that proposal-side load adds beyond that one is travel at speed v that the irreversibility test $d_{\text{stop}} \leq D_{\text{clear}}$ never reserved, and a stall of unbounded length leaves the test with no bound at all.
2. **Distinction**: Unlike spatial isolation, which private address spaces and separate cores supply, operational independence also covers time, supply, clock, reset, and heat. It is the placement-level form of what functional-safety standards call freedom from interference, the absence of cascading failures from one element into another of higher integrity (International Organization for Standardization 2018).
3. **Common pitfall**: Arguing independence from the separation alone. A separate core, or even a separate chip, is the hypothesis the Nervous System adopted, not its proof; independence is argued one shared resource at a time, and a loaded test on the real silicon can refute the claim for any one of them.

Every placement claim must therefore name the physical and architectural resources that could delay or disable enforcement, alongside the mechanisms that bound their mutual interference. A shared die and a discrete safety microcontroller are competing hypotheses about those hardware dependencies, not interchangeable processor choices. Testing either hypothesis starts with what each path computes and the deadline it must meet.

13.2 Two Paths and the Resources They Share

The third law, proposal is not permission, separates the machine's two paths in authority; placement decides whether the hardware keeps them separate in time when the proposer is working hardest. Whether a candidate placement preserves that separation depends on the execution profile of each path, the physical resources that could couple them beneath software access controls, and which of those resources remain shared across the compute board.

13.2.1 Proposal and permission execution profiles

If a 40 ms neural proposer and a 400 µs-deadline safety loop share the same operating-system scheduler or memory controller, a single kernel preemption tail or memory-bus burst can stall the 1 kHz permission tick past its deadline. To prevent that stall, the mobile manipulator splits control across two execution paths with different systems requirements. The proposal path runs the chunk policy on the application processor at 20 Hz, ingesting synchronized navigation and wrist camera streams to emit coordinated base velocity and arm joint targets. Its 99th-percentile (p99) inference latency, vision processing included, consumes 40 ms (an illustrative benchmark; see the Reader Guide) of each 50 ms chunk period. Running in unprivileged user space, the proposal path holds no direct hardware authority over the motor drives. In the reference design from Part I, the permission path executes on a discrete safety microcontroller (MCU) at 1 kHz. On every tick, it checks the active trajectory and any candidate replacement against the stopping envelope from section 12.3, staging admitted setpoints into the outbound EtherCAT frame destined for the drives. This routine must finish within a chosen 400 µs deadline inside its 1 ms tick. It runs in a privileged real-time domain on a dual-core lockstep controller,[1] whose cycle-by-cycle comparator flags divergent execution. That hardware guard is needed because a software envelope check cannot diagnose a silent fault in the CPU core executing it. Only the permission path holds memory-mapped input-output (MMIO) access to the fieldbus master carrying drive commands.

> Definition 13.2: Heterogeneous silicon partitioning
>
> ***Heterogeneous silicon partitioning*** is the architectural allocation of stochastic, high-capacity cognitive workloads (perception, learned policy evaluation) and deterministic safety loops (safety invariant checks, admission and fallback) across specialized execution domains isolated in hardware.
>
> 1. **Significance**: Placing high-capacity neural deliberation and real-time safety enforcement on the same general-purpose operating system or compute engine creates common-mode failures. Kernel thread preemption, dynamic memory allocation, and time-slicing between accelerator contexts add tail delay that no measured average bounds, and a permission path exposed to that tail can miss its physical control deadline.
> 2. **Distinction**: Unlike logical software process isolation (such as Linux containers or POSIX process priorities), silicon partitioning enforces isolation across independent hardware registers, tightly coupled memories (TCM), and dedicated peripheral buses.
> 3. **Common pitfall**: Treating multicore CPU affinity as failure-domain separation. Cores on one die still share caches, memory controllers, clock trees, and power rails, the resources that operational independence (definition 13.1) must bound one by one.

These two processors run separate software stacks. Proposal inference, global scene-map updates, telemetry streaming, and fleet networking run on the application processor under Linux. While a real-time kernel patch shortens scheduler dispatch latency, it cannot bound latency tails added by unvetted device drivers, bus arbitration, or shared memory controllers.[2] Similarly, zero-copy buffers reduce internal memory-bus traffic, but they do not remove contention at the physical memory controller.

By contrast, enforcement and sensor validation run on the discrete safety microcontroller as bare-metal firmware governed by a hardware memory protection unit (MPU).[3] Quadrature encoder counters, the inertial measurement unit (IMU) on its Serial Peripheral Interface (SPI) bus, and hardware timer capture channels are mapped directly to dedicated physical pins. Each candidate proposal arrives from the application processor across a board-level serial link and is published into local memory via the seqlock mailbox of section 4.3.2. No dynamic random-access memory (DRAM) is shared between the two paths. The memory protection unit isolates local state, while the dedicated peripheral bus insulates the enforcer's execution path from the host's memory traffic.

Admitting an entire plan is a different computation from running the cyclic permission tick. For example, the whole-plan validation routine of section 11.3.1 cannot run uninterrupted inside a 1 ms control loop without breaking timing guarantees. Instead, the runtime scheduler must preserve

[1] **Dual-Core Lockstep**: Dual-core lockstep runs identical instruction streams across two physical cores, typically offset by several cycles so that a single transient fault cannot corrupt both pipelines in the same way, while a hardware comparator flags any divergence. While lockstep execution catches internal CPU faults, it cannot catch bad envelopes computed from corrupted sensor inputs or common-mode voltage sags on shared power rails. Lockstep is therefore one piece of the safety microcontroller's watchdog design rather than a complete integrity defense.

[2] **PREEMPT_RT**: The Linux real-time patch set makes most kernel code preemptible and runs interrupt handlers as schedulable threads, and it was merged into the mainline kernel in Linux 6.12 in 2024 after about two decades out of tree (KernelNewbies 2024). It shortens the scheduler's latency tail but cannot bound delays that drivers, firmware, or shared memory add, so a PREEMPT_RT host needs a measured bound before it may carry any part of the permission tick.

[3] **MPU and IOMMU**: A memory protection unit (MPU) checks each CPU access against a few fixed address regions without translating addresses, so its cost is constant and analyzable. An input-output memory management unit (IOMMU) applies the same check to direct memory access (DMA) from accelerators and camera interfaces. Both govern *where* a memory transaction may access without arbitrating *when* the interconnect serves it; they enforce spatial partitioning while delegating deadline guarantees to hardware bus arbiters.

the real-time tick either by running admission as bounded, interruptible work or by moving it to a separate processor whose own timing is verified. In either case, admission ends with an atomic check of current state and sensor evidence right before activation. The running machine splits admission across these domains. The host performs the global geometry checks of section 12.8. The microcontroller checks the resulting record against bounded local evidence as background work below the tick's priority, so the tick preempts it. Section 13.6.2 lists the bounds that keep this background work from delaying the tick through the microcontroller's own buses and memory. The resource budget must cover the active trajectory buffer, the resident fallback plan, the temporary admission workspace, and worst-case interruption overheads. The proposal generation rate also does not set the interval between successful admissions. Qualification must show that the end-to-end pipeline (transfer, admission, and activation) preserves the lease renewal bound, a guarantee the tick deadline alone cannot provide.

Similarly, the full volumetric scene map stays on the application processor. The permission path receives only a compact, bounded local evidence snapshot whose spatial coverage, state uncertainty, observation timestamp, expiration horizon, and transport integrity have been pre-validated for the proposed motion and its fallback maneuver. Updating the host map, serializing the snapshot, transporting it across the bus, validating admission, storing it locally, and running per-tick spatial queries are separate computational costs that need their own entries in the timing budget. A synchronous query to the host processor must never stall the permission tick. If a proposed trajectory strays outside the validated bounds or lifetime of the local snapshot, the MCU rejects it immediately. The microcontroller's static memory budget must therefore show that the local snapshot buffer and resident fallback trajectories fit alongside the compiled enforcement binary.

Electrically, the power delivery network isolates the microcontroller, low-voltage drive logic, and electromechanical spring-brake coils onto a dedicated safety rail. This rail carries a local capacitive hold-up of 2 s and draws zero load from the proposal subsystem. Hardware qualification must verify that voltage transients from motor acceleration or neural accelerator bursts on the shared battery pack cannot trigger an undervoltage reset on this isolated rail. This local energy reserve keeps the logic alive and holds the mechanical brakes released throughout a controlled stop without supplying traction power. Achieving the powered deceleration profiles of section 12.9.1 requires both an intact high-voltage drive path and a sink for regenerative braking energy. If either fails, the system must trigger a certified fail-safe fault response rather than relying on powered stopping-distance assumptions.

On an unloaded machine, the initial compute budgets look generous. Representative baseline costs on the safety microcontroller allocate 40 µs to sample motor encoders, read the IMU over SPI, and check the proposal's evidence epoch. They allocate 80 µs to check kinematic and dynamic envelope constraints and 15 µs to stage admitted setpoints into the outbound drive frame. That gives an unloaded enforcer execution time of 135 µs, or 54,000 cycles at the microcontroller's 400 MHz clock. Measured against the 400 µs hard deadline, this baseline path leaves 265 µs of slack. Even the declared worst-case execution time (WCET) of 250 µs, the design envelope from section 12.7.4, leaves 150 µs of headroom.

↩ The isolated permission rail and its hold-up sizing are established in section 2.8.2.

This timing margin cannot be spent entirely on shared-hardware contention. The response bound of equation 4.3 already charges the tick for blocking B_i by lower-priority tasks (50 µs) and interference I_i from higher-priority tasks and interrupts (40 µs), both from the microcontroller's own workload (section 4.5.1). Delay from hardware shared with the proposer is a separate cost because it lengthens the execution term C_i itself. A loaded tick meets its deadline only if its execution time, including all shared-hardware interference, stays below the deadline minus those internal overheads (90 µs), leaving an execution ceiling of 310 µs. Under the declared WCET bound, shared-hardware contention can add at most 60 µs of delay before the tick misses its deadline, and every placement analysis must account for this full budget.

The declared bound, not the deadline, is what a placement must defend. It bounds the tick's execution in isolation, and the chosen placement claims that proposal-side load adds nothing to it. A loaded tick that runs longer than 250 µs therefore refutes that claim even when it finishes before the 400 µs deadline, because every margin downstream of the bound was computed on the premise it just broke. Each coupling in this chapter is priced against that *falsification threshold*, which section 13.7 formalizes and turns into a test campaign.

On the application processor, meanwhile, the neural policy's 40 ms inference latency leaves 10 ms of margin within its 50 ms period. The enforcer's sub-costs above are a baseline model rather than an integrated measurement, and local spatial-query overheads must also fit inside the cyclic budget. Full qualification requires measuring the loaded control cycle on the target to establish which spatial queries fall inside constraint evaluation and to account for any separate overheads. Neither an unloaded benchmark nor an isolated query model can verify the declared WCET bound.

↩ The spatial-query workload the safety microcontroller must answer each tick is established in section 9.6.1.

13.2.2 Shared failure domains and attack surfaces

A single stalls-per-tick coupling across shared silicon can consume the entire 60 µs shared-hardware allowance even when the proposal and permission paths run on separate processor cores.[4] Beneath software access controls, four physical channels can bind the two paths without appearing on a software architecture diagram: memory subsystems, power rails, thermal paths, and clock distribution networks. The physical architecture from Part I is designed to sever each of them at the board level.

Memory contention is the first and often most severe coupling. On cores sharing an address space, operating-system page-table updates trigger inter-processor interrupts for Translation Lookaside Buffer (TLB) shootdowns,[5] while coherent direct memory access (DMA) from high-throughput camera pipelines incurs cache-invalidation stalls.[6] More fundamentally, a time-critical control loop cannot read its sensor buffers if an asynchronous accelerator monopolizes the physical interconnect. In a Unified Memory Architecture (UMA), neural accelerators, application cores, and real-time cores arbitrate for a single pool of DRAM across a shared crossbar. A high-resolution vision pipeline or an aggressive DMA engine can then saturate the bus and starve the permission routine of encoder and IMU feedback, whatever its software thread priority. This mismatch between software priority and unmanaged interconnect contention is the **UMA crossbar trap**, and section 13.3 prices the queueing delays and bank conflicts behind it. The chosen design avoids the trap by giving the safety controller exclusive ownership of its memory. Candidate proposals cross an isolated board-level serial bus into dedicated local SRAM, so no DRAM is shared between the two domains.

Power delivery represents the second coupling vector. Although the host processor and the safety controller draw from a common battery, they do not share a power rail. The host application processor draws from the nominal 47.7 V motor drive bus through a dedicated DC-DC step-down converter that triggers an undervoltage lockout (UVLO) if the supply sags to 33 V. The steady-state margin analysis in section 2.6 ensures that even a depleted battery pack remains above this threshold during simultaneous drive acceleration and peak neural inference. Unmodeled transients or supply faults (a blown fuse, or a battery management system (BMS) contactor trip), however, can depress the bus and crash the application processor. Had the safety microcontroller shared this unisolated supply, that same brownout would reset the safety monitor simultaneously. Motor gate drivers incorporate internal hardware protections for such events: integrated undervoltage lockouts disable power MOSFET outputs when gate-drive rails collapse, and pull-down resistors prevent floating logic pins from triggering destructive shoot-through currents. Those protections mitigate electrical switching faults; they do not establish a harmless coast or a controlled stop. A shared brownout would also extinguish the permission path, leaving no MCU-controlled response to manage the robot's kinetic energy. The dedicated, held-up rail preserves supervision while the host browns out and reboots. The safety microcontroller detects the bus undervoltage interrupt and commands the fault response whose resources survive. Powered deceleration requires an intact drive-energy path and regenerative sink; if the supply fault removes either, the separately qualified mechanical or passive response governs.

Thermal dissipation and clock distribution introduce the third and fourth coupling channels. When co-located on a shared silicon die or bonded to a common heat spreader, heavy sustained compute workloads on the application processor raise junction temperatures toward thermal trip points. Dynamic voltage and frequency scaling (DVFS) governors configured to protect the silicon package can throttle clock frequencies in shared clock domains, slowing real-time safety cores that share no code with the proposal pipeline. As demonstrated in section 13.4, thermal throttling introduces hysteresis that outlasts the transient compute burst that triggered it. Similarly, relying on a shared external crystal oscillator creates a single point of failure, because thermal drift, mechanical shock, or a fractured crystal desynchronizes both execution domains at once. A discrete microcontroller removes the shared die and oscillator dependencies by providing a physically separated package,

4 | **Multicore Interference Certification (FAA AC 20-193)**: Avionics met this problem first. The 2016 CAST-32A position paper named shared caches, interconnects, and memory controllers as interference channels, and FAA Advisory Circular AC 20-193, issued in 2024 and aligned with EASA's AMC 20-193, replaced it with formal acceptance criteria (Federal Aviation Administration 2024). Its lesson for this machine is that a timing bound measured on one core is void on a multicore until every shared row of table 13.1 has been analyzed or mitigated.

5 | **TLB Shootdown**: When an operating system modifies page tables, it broadcasts inter-processor interrupts (IPIs) to invalidate stale Translation Lookaside Buffer entries across all active cores. Receiving cores must pause thread execution and flush affected entries, adding unbudgeted multi-microsecond stalls. On shared silicon, these synchronization pauses break the cycle determinism needed by inner motor loops.

6 | **DMA Cache Coherence**: Direct memory access transfers bypass CPU caches, requiring explicit cache-line invalidation or writeback to keep peripherals and cores consistent. Without hardware snoop filtering or explicit barriers, processors read stale sensor frames or overwrite pending actuator commands. These cache maintenance steps inject variable delay into high-rate control loops unless static, uncached SRAM regions are dedicated to peripheral transfers.

DRAFT

dedicated heat dissipation, and an independent quartz crystal oscillator. Its own clock, supply, and thermal operating limits, including exposure to the common chassis environment, still require qualification.

Any safety-critical design must still evaluate the alternative it rejects, a single shared die carrying both paths. On one die the four couplings collapse into one semiconductor package, so real-time cores that execute their instructions independently of the application cores remain coupled through each resource. Bursts of camera DMA, neural accelerator memory access, and high-volume diagnostic logging can stall the real-time cores' cache fills and delay their interrupt handling unless hardware arbiters enforce deterministic bandwidth caps. At the same time, high-slew current transients can droop a shared core rail and a software-initiated host reset can take down a common reset chain unless power and supervisor domains are strictly isolated. Even when memory and power are partitioned, heat from the neural processing units raises the substrate temperature under the real-time cores, which share the package's only route to the chassis. A unified on-die governor throttles the real-time cores' clock together with the accelerator's when that substrate temperature reaches its trip point. A shared PLL or crystal also carries any clock fault to both.

Beyond accidental contention, these shared silicon pathways expose a **cyber-physical attack vector**. An adversary who compromises the unprivileged proposal stack can generate malicious memory traffic or toggle accelerator power states rapidly. The traffic starves the permission routine of memory service, and coordinated current surges pull the shared supply down (section 13.3 prices both). An isolation claim must therefore hold against the worst contention the proposal domain can generate within its authorized hardware limits, and benchmarks of benign workloads cannot establish that bound.

Functional-safety engineering provides formal tools to analyze this shared inventory. On the mobile manipulator, the intended certified safety scope is deliberately narrow; this illustrative platform has not established certification. The trajectory admission algorithms that validate learned proposals carry no formal safety integrity rating; the intended integrity claims belong to the scoped protective stop functions implemented in the motor drives and safety laser scanner. The function selected for a safety rating on the microcontroller is the watchdog that revokes authority when the chunk lease expires or the host heartbeat falls silent. It then commands a certified drive-level stop, safe stop 1 (SS1, a controlled deceleration followed by torque removal) or safe torque off (STO), whichever the risk assessment assigns to the machine's state. Keeping that intended rated function apart from unrated software components (the trajectory admission checks and the neural proposer) is a formal *safety decomposition*. The decomposition requires evidence that faults and interference from the unrated elements cannot defeat the claimed protective functions under the declared fault model. Workload placement determines which shared dependencies that evidence must address. A **dependent failure analysis** identifies the shared hardware resources whose failure or overload could compromise both paths at once. ISO 26262 Part 9 (International Organization for Standardization 2018) requires it, and IEC 61508 (International Electrotechnical Commission 2010a) treats it as common-cause failure analysis. The warehouse machine answers to industrial and mobile-robot safety standards rather than automotive ones (ISO 10218-2:2025, for instance, incorporates the collaborative-robot protections first defined in ISO/TS 15066 (International Organization for Standardization 2025b, 2016)), but the requirement of freedom from interference is the same in every domain. The resource audit of this chapter is that dependent-failure analysis carried out on physical silicon, with every coupling priced in the tick's timing budget.

Because each shared dependency names a physical or adversarial mechanism that could defeat the decomposition, qualification must test the isolation by injecting faults rather than by reviewing schematics. The timing stress campaign designed in section 13.7 validates these boundaries against the declared WCET threshold across four stress regimes, three aimed at the supply, clock, and link and one at the proposals themselves:

1. *Power-rail droop testing*: Injecting maximum-slew current transients into the drive bus to verify that the noise coupled onto the safety rail stays inside the microcontroller's specified supply tolerance, the limit the placement record's droop field carries.
2. *Clock glitching and frequency margining*: Verifying that the real-time core maintains deterministic instruction cycle counts under clock jitter and voltage fluctuation.

↩ The certified drive functions beneath the permission path, and the stop each failure triggers, are established in section 12.9.3.

↪ The industrial and mobile-robot standards that govern this machine, and where each one's evidence is generated, are developed in section 16.3.4.

3. *Communication link flooding*: Saturating shared interconnects to confirm that safety-critical heartbeat frames and trajectory proposals retain their deterministic transmission windows.[7]
4. *Numerical and semantic fault injection*: Streaming synthetic proposals populated with out-of-range floats, subnormal numbers, and IEEE 754 NaNs to verify single-cycle rejection without pipeline stalls or exception traps.

[7] **CAN Arbitration**: Controller Area Network protocols resolve bus contention at the physical layer using wired-AND dominant ('0') and recessive ('1') signaling. If a defective transceiver continuously drives a dominant state (a "babbling idiot" fault), it monopolizes the shared wire and blocks all other traffic. Hardware bus guardians and dominant-timeout clamp circuits time each transmission and physically disconnect jabbering nodes to keep the bus available for remaining safety nodes.

↪ The physical injection apparatus for supply, clock, and bus disturbances is developed in section 15.8.

13.2.3 Four candidate placements against one shared-resource inventory

On the mobile manipulator's compute board, four candidate placements for the permission loop span the options from sharing every silicon resource to sharing only the battery (table 13.1). Scoring each candidate row by row exposes the common-cause faults that a high-level chip block diagram hides, including whether a commercial module actually routes an on-die safety island's pins and rails to the integrator. At the least isolated extreme, *shared application cores* (a) expose the permission loop to operating-system scheduling jitter, driver interrupt stalls, and kernel preemption tails, delays that can push execution past the 400 µs deadline and even the 1 ms control period. Moving to *a real-time cluster in the host clock and power domain* (b) dedicates execution cores to safety enforcement, yet it still shares the die's cache hierarchy, memory controller, core supply rail, clock governor, and thermal path. Section 13.3 prices its memory exposure, and section 13.4 shows the clock throttling that rules this candidate out.

To sever those host-domain couplings without leaving the package, modern automotive and industrial SoCs provide *an on-die safety island* (c). For instance, the Functional Safety Island of NVIDIA's Orin-class SoCs integrates four dual-core lockstep Cortex-R52 processors, each with private tightly coupled memory, around 3 MB of on-island SRAM (NVIDIA 2023b). The island runs from an independent crystal oscillator and a dedicated voltage rail behind hardware firewalls that block unauthorized access from the rest of the die. The application governor therefore cannot throttle its clock, and an enforcement routine whose code and data stay in island memory never waits on host DRAM arbitration. Even so, several couplings remain inside the package: shared substrate temperature, common reset and power sequencing logic, arbitration across the on-chip fabric carrying proposals or island DMA, and the common board-level power supply. Adopting an on-die island therefore requires reading back the configured firewall registers, tracing the power-sequencing logic, and running the loaded stress campaign of section 13.7 while the safety loop executes. Where those remaining die-level couplings cannot be bounded or the module does not expose the island, *a discrete safety microcontroller* (d) removes every on-die coupling altogether, trading silicon integration for an explicit board-level link from the application processor that section 13.6 budgets and characterizes.

Laid out on the machine's compute board, the four candidates differ in how many shared blocks stand between the permission tick and the proposer (figure 13.1). Candidates (a) and (b) sit behind the application die's last-level cache, DRAM controller, clock governor, core rail, and fabric. The island (c) moves cores, crystal, and SRAM behind a firewall but stays in the same package and heat path. Only (d), a separate package clocked at 400 MHz with local TCM and a 2 s rail hold-up, leaves the die entirely and reaches it through a checked board link.

Table 13.1: Dependent-failure inventory of four placements: Each row is a resource whose fault or overload could delay or disable both the proposer and the permission path. "Separated" means the placement removes the resource from the permission tick's path; it is still a claim that register readback and loaded tests must support. Only the discrete controller removes the die-level rows, and none of the four removes the common board supply.

Shared resource	(a) Shared cores	(b) RT cluster, host domain	(c) On-die safety island	(d) Discrete MCU
Cores and scheduler	Shared	Separated	Separated	Separated
Last-level cache and miss handling	Shared	Shared	Separated (private caches, TCM)	Separated (TCM)
DRAM controller and channels	Shared	Shared	Separated if the tick stays in island memory	Separated
On-chip fabric carrying proposals	Shared	Shared	Shared, behind a firewall	Replaced by a board link

Shared resource	(a) Shared cores	(b) RT cluster, host domain	(c) On-die safety island	(d) Discrete MCU
Core supply rail	Shared	Shared	Separated (dedicated rail)	Separated (isolated rail)
Clock source and governor	Shared	Shared	Separated (dedicated crystal)	Separated
Reset and boot chain	Shared	Shared	Evidence needed	Separated if the supervisor is independent
Die temperature and package	Shared	Shared	Shared	Separated
Board supply and battery	Shared	Shared	Shared	Shared; evidence needed
Proposal transport	In-process memory	Shared-memory mailbox	Shared-memory mailbox through the firewall	Board link into a local mailbox

On the inventory alone, candidate (c) is a strong contender. It separates the cache and miss handling, DRAM, core rail, and governed clock, the rows behind the strongest mechanisms the next two sections price. It leaves shared the die temperature, the fabric its proposals cross, the board supply, and a reset chain whose independence still needs evidence, each of which a qualification would have to cover. This verdict is provisional, since nothing has yet been priced, but the machine does not wait on it, because it adopts candidate (d) for a reason outside silicon capability. While the safety island exists on the physical SoC die, commercial edge modules packaging the application processor do not expose it to system integrators, reserving access for dedicated industrial platforms (table 13.2). Because an unexposed, unprogrammable safety island cannot serve as a valid deployment target, safety enforcement must move off the primary module.

Table 13.2: Safety-island exposure on edge AI platforms, as of 2026: The same silicon can carry an island that one product line exposes and another does not. Which island a placement can use is a property of the module and its software support, not of the SoC's block diagram, and a later edition should refresh this table.

Platform (vendor statement date)	Safety island on the SoC	Available to the integrator	Source
Jetson AGX Orin module (2023)	Cortex-R52 island present	No	NVIDIA (2023a)
IGX Orin platform (2023)	Same island	Announced as offered	NVIDIA (2023a)
DRIVE AGX Orin (2023)	Island with dedicated crystal and rail, 3 MB SRAM	Yes, through DRIVE OS	NVIDIA (2023b)
Jetson Thor module (2026)	Not supported	No	NVIDIA (2026a)
IGX Thor platform (2026)	Supported	Yes	NVIDIA (2026a)

Commercial platform exposure is therefore itself an architectural constraint. A vendor block diagram illustrating isolated silicon domains establishes what the hardware could theoretically execute, but system developers can use only the execution resources unlocked by board support packages and platform firmware. While specific commercial product tiers change over time, the engineering requirement to audit software accessibility before committing to a workload placement remains permanent.

The third law (principle 3) says a proposal is not permission, and that separation is empty if the proposal can delay the permission decision through hardware the two share. The four candidates differ in which resources they force the paths to share, and even for the discrete microcontroller the separation remains a hypothesis about timing under load that only a measurement of the loaded tick can support.

Choosing candidate (d) before pricing the shared die does not make the quantitative analysis of shared resources superfluous, for three reasons. First, each mechanism priced in section 13.3 and section 13.4 turns the rejection of candidates (a) and (b) from an architectural assumption into empirical evidence. Second, each mechanism names an obligation that the discrete design carries in miniature, because the microcontroller has its own DMA engines, interrupt controller, internal

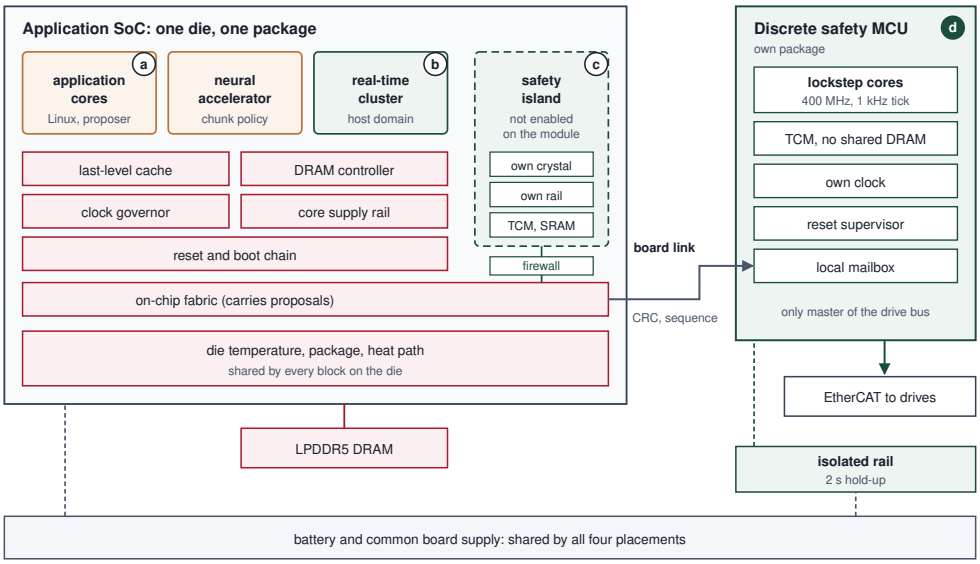

Figure 13.1: Where each candidate placement runs: Badges (a) to (d) mark where the permission tick would execute. Tinted blocks are shared with the proposer on the application die (cache, memory controller and external DRAM, clock governor, core rail, reset chain, fabric, and the package's heat path), so a tick placed on the die can lose them to proposal-side load. The safety island carries its own crystal, rail, and memory but remains behind the shared fabric and in the shared package; the discrete controller, the machine's choice, reaches the die only through a checked board link and still shares the battery and chassis environment with it.

buses, and power supply, as detailed in section 13.6.2 and section 13.7. Finally, the same analysis provides the qualification blueprint for an integrator whose platform firmware exposes an on-die safety island. Unless a passage says otherwise, the calculations in section 13.3 and section 13.4 evaluate the permission tick placed hypothetically on the application die, using the sub-costs and timing budget assigned to the microcontroller. On a shared die, the first place proposal-side load encounters that tick is the memory system.

13.3 Contention for Shared Resources

Had the mobile manipulator placed its permission path on the application SoC, camera DMA, neural weight fetches, telemetry writes, cache writebacks, and enforcement reads would compete for memory service. Their simultaneous bursts determine the queue seen by the enforcer. On the selected machine, those host-side bursts delay the observation and chunk rather than the permission tick. The permission path encounters their effects as evidence age, refusing stale evidence and entering fallback if no admitted chunk renews the lease.

↩ How host-side memory contention, including camera DMA, ages observations is established in section 8.5.

13.3.1 DRAM bank conflicts, AXI4 burst slicing, and arbiter starvation

A small urgent read can wait behind a large transfer even when the memory bus is mostly idle over a longer interval. The deadline depends on the traffic already ahead of that read and on whether the controller lets it pass. This queueing delay, which arises when memory and DMA transactions share an interconnect and controller, is the mechanism inside the UMA crossbar trap, and its bound depends on transaction size, queue policy, and bank timing.

Each claimant's average demand follows from its transfer size and event rate. On a shared multi-channel LPDDR5 interface, camera DMA streams, weight fetches at the policy rate, the enforcer's reads, drive writes, cache writebacks, and logging together occupy a modest fraction of theoretical peak bandwidth on average. An engineer who inspects only that average concludes that most of the memory bus remains free. Memory crossbar arbiters and DRAM schedulers do not schedule average rates. They arbitrate discrete, bursty transactions, and two workloads with identical average

throughput interfere with radically different latency profiles if one streams in small, sporadic packets while the other arrives in long, saturating blocks. The weight transfers that set the memory wall (Wulf and McKee 1995) of section 3.4.1 are the long blocks here, and on a shared controller the proposer's throughput limit becomes the permission path's queue.

How long a safety read waits depends on transaction arbitration and DRAM scheduling. An accelerator moving weights in large 256 KB tiles generates discrete memory transactions across the internal system interconnect. The example assumes an arbiter that completes each granted burst before serving a different requester.[8] Although bus protocols provide quality-of-service (QoS) priority signals (`ARQOS`), commodity memory controllers frequently treat these tags as advisory unless strict hardware priority bypass with bounded preemption latency is explicitly certified in register configurations. Whether an in-flight transfer can delay the urgent read, and whether queued tensor transactions can pass it, depends on the selected interconnect and arbiter. AXI burst limits alone do not establish a service-time or starvation bound.

Every memory request passes through four stages: the requester issues it, the interconnect arbiter grants it a slot, the memory controller queues it, and the target bank serves it. Each DRAM bank holds one open row in its **row buffer**. An LPDDR5 channel has 16 banks, divided into 4 bank groups at the higher data rates, or 8 larger banks, each formed by merging two, in an alternative mode (Steiner et al. 2022). A read to the open row (a *row hit*) needs only a column access. A read to a different row of the same bank (a *row conflict*) must first close the open row with a precharge (t_{RP}) and then open the new one with an activation (t_{RCD}). The memory standard sets a minimum time in nanoseconds for each step, 18 ns for both, and the controller can only wait whole cycles of its command clock. At the 6,400 MT/s data rate of the machine's application SoC, that clock ticks every 1.25 ns, each step rounds up to 15 cycles, or 18.75 ns, and a conflict adds 37.5 ns (H. Luo et al. 2024). Bank-group spacing, refresh, and bus turnaround add further terms, which section C.6 treats.

The controller also decides the order of service. Controllers that use **first-ready, first-come-first-served (FR-FCFS)** scheduling serve ready row hits before older requests that need a new row, which maximizes throughput (Rixner et al. 2000). A streaming accelerator supplies an unbroken run of row hits across its weight matrices, so an FR-FCFS scheduler can keep passing the safety core's sporadic read until an internal starvation counter expires. Under a FIFO queue that lets no later arrival pass the safety read, the idealized wait is

$$t_{\mathrm{queue}} = \sum_{k \in Q} \frac{D_{\mathrm{vol}_k}}{\mathrm{BW}_{\mathrm{peak}}} + N_{\mathrm{conflict}}(t_{\mathrm{RP}} + t_{\mathrm{RCD}}) \tag{13.1}$$

where Q holds the transactions ahead of the read, D_{vol_k} is each one's byte count, N_{conflict} counts changes to a different row within an already active bank, and $\mathrm{BW}_{\mathrm{peak}}$ is an optimistic service rate. The application SoC achieves that aggregate peak bandwidth across parallel 16-bit LPDDR5 channels, each containing its own sixteen internal banks, so dividing a backlog by $\mathrm{BW}_{\mathrm{peak}}$ holds only when physical address bits interleave transactions evenly across all channels rather than funneling them into a single channel queue. Arbitration overhead and refresh add to the result. Exceeding the sensing allowance first violates the allocation to that subtask; it does not by itself imply that the whole tick misses its deadline. The worked comparison below keeps the sense allocation, declared execution bound, and physical deadline separate.

[8] **AXI4 (Advanced eXtensible Interface 4)**: Arm's AMBA on-chip bus protocol permits incrementing bursts of up to 256 beats and forbids any burst from crossing a 4,096-byte address boundary. At a 16-byte beat, one full burst is exactly one such page, which is why the notebook below splits a weight tile into one transaction per page. An urgent read that waits for the granted burst to finish, as this example assumes, is a property of the chosen arbiter, not an AXI guarantee.

Napkin Math 13.1: The backlog budget

Problem: Suppose the same permission tick, with the same sub-costs and the same blocking and interference budget, ran on a core of the application SoC and read its sensor snapshot from the SoC's shared DRAM. How much queued traffic could precede that read before the tick exceeds its sense allowance, its declared worst-case execution time, and its deadline?

Variables:

- Sense allowance 40 µs and 95 µs of constraint evaluation and drive-frame write (Illustrative sub-costs), declared worst-case execution time $T_{\mathrm{wcet}} = 250$ µs and deadline $T_{\mathrm{deadline,enf}} = 400$ µs (Chosen), with 90 µs of blocking and interference charged as in equation 4.3 (Illustrative).

DRAFT

- Peak DRAM bandwidth $\mathrm{BW}_{\mathrm{peak}} = 204$ GB/s (Datasheet), served at that aggregate rate because the controller interleaves addresses across all channels (Illustrative premise).
- One backlog ahead of the read: a weight tile (64 transactions), a camera transfer, and a telemetry record, 88 transactions and 360,448 bytes, with 3 same-bank row conflicts (Illustrative), each costing $t_{\mathrm{RP}} + t_{\mathrm{RCD}} = 37.5$ ns (Datasheet). The snapshot itself is 4,096 bytes (Illustrative).

Math: By equation 13.1, one backlog waits 360,448 B / 204 GB/s + 3 × 37.5 ns = 1.879 µs, and the snapshot then reads in 0.020 µs. The number of backlogs n that fit a read ceiling R is $\lfloor (R - t_{\mathrm{own}})/t_{\mathrm{queue}} \rfloor$. The sense allowance gives $\lfloor (\ 40 - 0.020\ )/\ 1.879\ \rfloor = 21$. The declared bound leaves 155 µs for the read after the 95 µs of later work, so it is crossed beyond 82 backlogs. The deadline, less blocking and interference, leaves 310 µs for the tick and 215 µs for the read, and it is crossed beyond 114. With validated priority bypass, only the one in-flight transaction waits ahead, and the read takes 0.04 µs.

Result: Between 82 and 114 backlogs, the tick still meets its deadline but exceeds T_{wcet}. Within this stipulated FIFO model, the fixed isolated sub-costs remain unchanged, so the excess comes from shared-memory queueing. It refutes the placement's timing premise even though this tick was on time. A measured overrun would instead require distinguishing an underestimated baseline from interference, as section 13.7 explains.

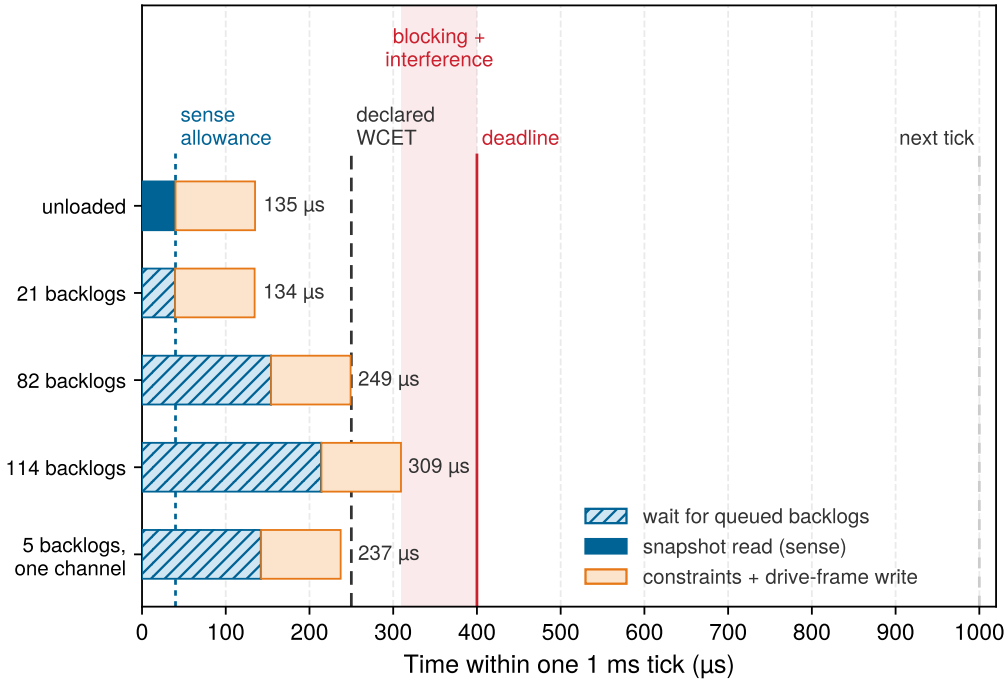
Systems insight: The read's bound belongs to the memory controller, not to the workload. The bound exists only if the controller limits how much traffic it admits ahead of a safety read or lets that read bypass the queue. An FR-FCFS controller serving a streaming accelerator provides neither unless its configuration is qualified to do so. At the SoC's full bandwidth, though, plain queueing is a weak threat, since the allowance absorbs 21 backlogs. The interleaving premise carries much of that result. If the backlog and the snapshot shared one of the interface's 16 channels, each backlog would take 28.4 µs, the allowance would absorb 1, and more than 5 would cross the declared bound. The address mapping therefore belongs in the placement evidence. The mechanisms that actually threaten the declared bound are the ones this FIFO model omits, which section 13.3.2 prices next.

Drawn to scale on one 1 ms period, the thresholds show how far the declared bound sits from the deadline and the period (figure 13.2). The unloaded tick ends at 135 µs. The next three rows carry the largest backlog counts that keep each bound: 21 for the 40 µs sense allowance, 82 for the declared 250 µs, and 114 for the 400 µs deadline once 90 µs is reserved for blocking and interference. The bottom row confines the traffic to one memory channel, where 5 backlogs already reach the declared bound.

13.3.2 Which interference mechanism threatens the declared bound

The notebook's arithmetic makes the shared die look safe, and that impression is the danger. The permission tick can absorb a stretch of its unloaded 135 µs cycle by a factor of 1.85 before it crosses the declared worst-case execution time. The allowed stretch is 2.30 before the tick crosses the deadline, once blocking and interference take their 90 µs. Bandwidth queueing at the SoC's full rate does not come close. Two other mechanisms do, and both live in the shared cache rather than in DRAM.

A non-blocking cache tracks each outstanding miss in a *miss status holding register* (MSHR) and parks each dirty line it evicts in a *writeback buffer* until DRAM accepts it. Both structures are small and shared by every core behind the cache. When a streaming co-runner keeps them full, each miss of the victim core waits until an entry drains, so the victim's delay grows with its own miss count times the aggressor's drain time, not with the bytes it reads. Partitioning cache capacity does not help, because the partition divides the lines and leaves the MSHRs and the writeback buffer shared. Measured on commercial embedded multicores, MSHR contention raised a task's worst-case execution time by up to 21× with the cache partitioned (Valsan et al. 2016). A deliberate attack on the writeback buffer slowed a victim on a dedicated core by more than 300×, partitioned or not (Bechtel and Yun 2019). DRAM adds its own multiplier on top. An analytical bound for commercial controllers shows that each of the victim's requests can wait behind every request that other cores



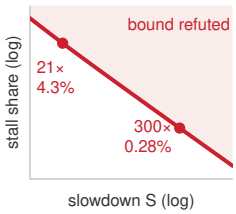


Figure 13.2: How many backlogs one tick absorbs: Each row is one permission tick on the rejected shared-die placement, drawn to scale on the 1 ms period, with the FIFO wait for queued backlogs ahead of the snapshot read followed by the 95 µs of constraint evaluation and drive-frame write. With addresses interleaved across the interface, 21 backlogs fit the sense allowance, 82 the declared bound, and 114 the deadline once blocking and interference take their 90 µs; confined to one channel, 5 already reach the declared bound. Every row still ends well inside the period, which is why the declared bound, not the period, is the test the placement must pass.

may place ahead of it in the same bank. That number is set by queue depth and the reordering window rather than by average bandwidth (Kim et al. 2014).

These slowdowns were measured on other platforms, on victims whose time was mostly memory stall, so they cannot be charged to the enforcer directly. Using them as assumed multipliers on its memory-stall share provides a sensitivity calculation, not a prediction of target behavior. If a fraction f of the unloaded tick waits on shared-cache misses and interference slows that fraction by a factor r_{slow} while the rest runs unchanged, the tick takes $t_{\text{unloaded}}[(1-f)+fr_{\text{slow}}] = t_{\text{unloaded}}[1+f(r_{\text{slow}}-1)]$. Setting that no larger than T_{wcet} and solving for f shows that the loaded tick stays within the declared bound only while

$$f \le \frac{T_{\text{wcet}}/t_{\text{unloaded}} - 1}{r_{\text{slow}} - 1}. \tag{13.2}$$

At the MSHR-class 21×, the declared bound falls once more than 4.3 percent of the tick is miss stall, and the deadline once more than 6.5 percent is. At the writeback-buffer attack's 300×, the threshold is 0.28 percent. A target profile must establish whether the constraint evaluation exceeds those fractions; touching tables in shared memory alone does not establish its stall share. The mechanism that threatens the declared bound is therefore miss handling in the shared cache, amplified by bank queueing. The only placements that remove it are those whose tick runs from private memory, candidates (c) and (d) of table 13.1. On (a) and (b), the measured stall share on the target and a regulation mechanism that bounds r_{slow} (section 13.6) are what a qualification must supply.

At a 21× slowdown, 4.3 percent miss stall breaks the bound.

13.3.3 Power-rail interference

When a neural accelerator steps its current draw in nanoseconds on a core supply rail shared with a permission core, the voltage droops across the package inductance and resistance before board regulators can respond. The droop stretches logic gate delays or triggers adaptive clock stretching

inside the permission tick. The rail at issue here is not the drive bus or the microcontroller's isolated rail; it is the on-die core supply that a shared-die placement, candidate (a) or (b), would share with the accelerator inside one package. A sudden accelerator current step lowers the voltage available to every core on that supply, and the first-order package model is

$$\Delta V_{\text{droop}} = L_{\text{pkg}} \frac{dI}{dt} + \Delta I \cdot R_{\text{pkg}} \tag{13.3}$$

The placement decision depends on whether regulation, decoupling, and stored energy keep the permission path inside its characterized operating range. The package hierarchy and transistor-level delay model are developed in section C.5; here the model identifies the disturbance a shared core rail would carry into the permission tick. The chosen placement keeps its core supply out of that package, and its isolated rail must instead survive board-level events (drive-bus sag, a contactor trip, converter dropout), the disturbances of stress regime 1 and the transient generators of section 13.7.

For the illustrative package parameters, a 6 A step with a 2 ns rise through 30 pH gives 90 mV of inductive droop. The same step through 8 mΩ gives 48 mV of resistive droop, 138 mV in all from a 0.850 V nominal rail. This pure $L_{\text{pkg}}\, dI/dt$ term ignores on-die decoupling capacitance, and does not resolve the actual transient. Power-integrity engineers instead design the delivery network to a target impedance[9] across frequency, and the first droop is set by package inductance resonating with on-die capacitance. The alpha-power model[10] (Sakurai and Newton 1990) relates the resulting voltage to gate delay:

$$\frac{t_{\text{prop}}(V_{\text{droop}})}{t_{\text{prop}}(V_{\text{nom}})} = \frac{V_{\text{droop}}}{V_{\text{nom}}} \left(\frac{V_{\text{nom}} - V_{\text{th}}}{V_{\text{droop}} - V_{\text{th}}} \right)^{\alpha}$$

Here V_{th} is the modeled threshold voltage, stipulated as 0.420 V, and α is the technology-dependent exponent, stipulated as 1.3. With those inputs, the modeled delay increases by 39 percent. This is a sensitivity calculation, not a measured reset threshold or a universal delay increase for every gate, and ignoring decoupling does not establish a guaranteed upper bound on a resonant transient. The stretch lasts nanoseconds, so it does not lengthen the tick by that percentage. It threatens the setup-time margin of the paths switching during the droop, and it grows without bound as the drooped voltage approaches V_{th}. Many current processors detect the droop and stretch the clock until the rail recovers (Grenat et al. 2014), which turns a timing violation into lost cycles that the tick must absorb. Device characterization must establish whether the actual critical paths still meet setup time, how many cycles adaptive clocking removes, and whether undervoltage protection trips.

9 | **Target Impedance**: Power-integrity engineers hold the delivery network's impedance, seen from the die, below the allowed ripple divided by the largest current step, at every frequency the load can excite (Smith et al. 1999). A flat impedance bounds the droop from a current step of any shape, which a single $L_{\text{pkg}}\, dI/dt$ term cannot. That documented bound is what a shared-die placement would owe the permission core's rail, and what the discrete placement owes only its own isolated rail.

10 | **Alpha-Power Law**: The model was proposed in 1990 (Sakurai and Newton 1990) because short-channel transistors no longer followed the long-channel square law: carrier velocity saturates, and drain current grows as $(V - V_{\text{th}})^{\alpha}$ with α falling from 2 toward 1. Delay therefore depends on the headroom between supply and threshold, not on the supply alone. A low-voltage core chosen for efficiency has the least headroom, so it is also the most droop-sensitive home for the permission path.

> **Checkpoint 13.1: Which shared resource breaks the bound**
>
> Queueing, miss handling, and rail droop all delay the permission tick through hardware the two paths share. Before moving to heat, confirm that the distinctions among these physical mechanisms are clear:
>
> - ☐ **Resource inventory**: Can you list, for candidates (b) and (c) of table 13.1, which shared rows could delay the tick and which could disable it?
> - ☐ **Averages versus order**: Can you explain why a memory controller at low average utilization can still hold a safety read behind a long backlog, and what a controller must provide for the read to have a bound?
> - ☐ **Miss-stall estimate**: If interference slowed the tick's memory stalls by 10× instead of the measured 21×, what share of the 135 µs unloaded tick could be miss stall before the loaded tick crossed the declared 250 µs?
> - ☐ **Droop timescale**: Can you explain why a droop that stretches gate delay by tens of percent for nanoseconds does not stretch the tick by the same percentage, and what it threatens instead?

A separate permission rail removes the modeled shared core-supply path, but the common battery, wiring, converter behavior, and return paths remain qualification obligations. Rail probes and independent timing instruments must observe them under simultaneous motor and proposal

load. Droop and queueing both end within microseconds of the burst that causes them. The heat that the same accelerator dissipates does not, and it couples the paths on a timescale a million times longer.

13.4 Thermal and Timing Coupling

A permission core can suffer execution delays long after a heavy proposal workload has terminated, because thermal capacitance traps heat inside the package. While electrical droop and interconnect contention manifest over nanoseconds and microseconds, thermal coupling operates over seconds. When an accelerator and a real-time permission core share a silicon die, a cooling path, and an on-chip power management governor, sustained neural network inference can lower the clock frequency available to safety enforcement, and keep it lowered after the inference stops.

Thermal clock throttling is the automatic, hardware-enforced reduction of processor clock frequency triggered when sustained power dissipation pushes the silicon junction temperature (T_{j}) beyond a critical trip threshold (T_{trip}). On-die thermal sensing diodes alert the power management controller, which scales down clock frequency through hardware dividers or phase-locked loop (PLL) reconfiguration to prevent gate dielectric breakdown and thermal runaway. Because the physical die, package substrate, and heat spreader require time to dissipate this accumulated thermal energy, the reduced clock frequency persists long after the compute burst ends. For a co-located real-time task, this persistent slowdown can turn a nominal execution margin into a deadline overrun that lasts as long as the package takes to cool.

In this illustrative warehouse scenario, the robot's electronics bay operates at an ambient temperature of 45 °C. The thermal dissipation path follows the package row of figure 13.1, shared by every computational component on the application SoC die. The selected warehouse enclosure seals out airborne dust and conductive debris and uses conduction cooling rather than open fan vents. For a shared-die architecture in this enclosure, the conduction path must transfer all heat generated by sustained proposal inference to the chassis without driving the real-time permission core into a throttled clock state.

For a conduction-cooled enclosure, the total thermal resistance from junction to ambient ($R_{\text{th,JA}}$) sums three distinct mechanical layers:

$$R_{\text{th,JA}} = R_{\text{th,JC}} + R_{\text{th,TIM}} + R_{\text{th,chassis}}.$$

Here, $R_{\text{th,JC}}$ is the junction-to-case resistance of the silicon package, $R_{\text{th,TIM}}$ is the resistance through the thermal interface material, and $R_{\text{th,chassis}}$ represents heat conduction through the metal enclosure to the ambient air. Over extended operation, mechanical shock and thermal cycling can degrade the interface material, increasing $R_{\text{th,TIM}}$. Simultaneously, battery discharge losses and motor drive electronics inject parasitic heat into the bay; battery Joule heating scales with the square of the discharge current (I^2R). A robust thermal envelope must therefore account for both the mechanical cooling path and the peak concurrent actuator workload. A quiescent bench test on a cold board cannot replicate the thermal reality of a warm, multi-hour operating shift.

Consider an application SoC inside this bay modeled with a lumped **junction-to-ambient thermal resistance** $R_{\text{th,JA}}$ and a **thermal time constant**[11] τ_{th}. Under a continuous power dissipation P_{device}, the silicon junction reaches a steady-state temperature of $T_{\text{amb}} + P_{\text{device}}R_{\text{th,JA}}$. When power steps to a new level, the junction temperature converges toward this new equilibrium along a first-order exponential trajectory governed by τ_{th}. This time constant represents the fast pole of the die and package thermal network. While heatsink and structural chassis poles operate on timescales of minutes to hours, holding the chassis at a constant baseline temperature provides an optimistic lower bound on junction heating.

Under the clock and thermal assumptions below, these dynamics eliminate the modeled configuration of candidate (b) in table 13.1. In that candidate design, the permission path runs on a real-time CPU cluster located on the main application SoC. Suppose this cluster shares the SoC's primary clock and power management domain, sized so that the permission tick's worst-case cycle count, run at the nominal clock, exactly meets its declared worst-case execution time. The sizing is not chosen to make the case fail. The declared bound is the worst execution the placement may assume, so judging the placement at that bound is the honest test, and a tick that executes at its bound has no slack against any slowing of the clock. When sustained neural network inference

[11] **Thermal RC Analogy**: Heat flow is mathematically equivalent to electric current, temperature difference to voltage, thermal resistance (K/W) to electrical resistance, and heat capacity (J/K) to capacitance. Under a single dominant heat path, the silicon junction behaves as a first-order RC circuit with $\tau_{\text{th}} = R_{\text{th,JA}}C_{\text{th}}$. The parameters in this scenario imply a lumped thermal capacitance of 4 J/K, representing the stored thermal energy the package must shed through $R_{\text{th,JA}}$ before the governor can restore the clock. Much like an electrical RC low-pass filter smooths voltage spikes, this physical thermal mass integrates fast fluctuations in proposal compute power into a slow, sustained temperature rise that directly governs the permission core's clock.

DRAFT

drives the junction temperature beyond the trip threshold T_{trip}, the hardware governor halves the cluster's clock frequency. As a consequence, every instruction cycle in the tick takes twice as long. The safety software executes the exact same code, but the shared governor injects an unmodeled cross-domain delay that isolated execution time profiling cannot detect. A discrete microcontroller, in contrast, runs on an independent oscillator and dedicated power rail beyond the reach of the SoC's thermal governor. An on-die safety island fed by its own clock tree and voltage rail would likewise isolate clock generation from the governor, although it would still share the silicon substrate and require rigorous thermal qualification.

A throttled tick outlasts the workload burst because hardware governors enforce **state-dependent hysteresis**. To prevent the clock frequency from chattering rapidly around the trip line, the controller restores the nominal clock only after junction temperature drops below a lower clearance threshold T_{clear}. Once proposal inference halts and chip power falls back to baseline, the junction relaxes toward its baseline equilibrium:

$$T_{\text{j}}(t) = T_{\text{j,target}} + (T_{\text{j,start}} - T_{\text{j,target}})e^{-t/\tau_{\text{th}}} \tag{13.4}$$

where $T_{\text{j,start}}$ is the junction temperature when throttling begins, $T_{\text{j,target}}$ is the baseline equilibrium under quiescent load, and τ_{th} is the package thermal time constant. Solving equation 13.4 for the time required to cool from T_{trip} to T_{clear} gives $t_{\text{recov}} = \tau_{\text{th}} \ln[(T_{\text{j,start}} - T_{\text{j,target}})/(T_{\text{clear}} - T_{\text{j,target}})]$, which fixes how long the hangover lasts in this scenario.

Napkin Math 13.2: The thermal hangover

Problem: Candidate (b)'s permission cluster shares the application die's package and clock governor. Under continuous proposal inference, does the junction reach the trip threshold, what does the throttled clock do to the tick, and for how many ticks does the overrun persist after the load stops?

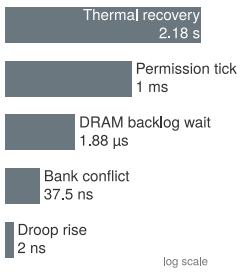
Variables:

- $T_{\text{amb}} = 45\,^{\circ}\text{C}$, $R_{\text{th,JA}} = 2$ K/W, and $\tau_{\text{th}} = 8$ s (Illustrative; conduction-cooled bay).
- $P_{\text{base}} = 4$ W for the permission loop with idle and memory power, and $P_{\text{load}} = 26$ W with continuous proposal inference (Illustrative). The scenario holds this loaded power constant after throttling; a real device whose governor reduces power requires a coupled power-and-temperature model.
- $T_{\text{trip}} = 95\,^{\circ}\text{C}$ and $T_{\text{clear}} = 85\,^{\circ}\text{C}$ (Illustrative governor thresholds).
- $f_{\text{nom}} = 1.2$ GHz, halved to $f_{\text{throt}} = 600$ MHz (Illustrative). The tick is sized to $T_{\text{wcet}} = 250$ µs at f_{nom} inside the 400 µs deadline and the 1 ms tick (Chosen), with 90 µs of blocking and interference charged as in equation 4.3 (Illustrative).

Math: The steady states are $T_{\text{j,target}} = 45 + 4 \times 2 = 53\,^{\circ}\text{C}$ and $T_{\text{load}} = 45 + 26 \times 2 = 97\,^{\circ}\text{C}$, above the trip. Rising from the baseline, the junction trips after $\tau_{\text{th}} \ln[(T_{\text{load}} - T_{\text{j,target}})/(T_{\text{load}} - T_{\text{trip}})] = 8 \ln[(\,97 - 53\,)/(\,97 - 95\,)] = 24.7$ s. The tick needs $N = T_{\text{wcet}} f_{\text{nom}} = 300{,}000$ cycles, which at 600 MHz take 500 µs. With blocking and interference the response grows from 340 µs to 590 µs, 190 µs past the deadline. If the load stops just as the junction trips, equation 13.4 returns the clock after $t_{\text{recov}} = 8 \ln[(\,95 - 53\,)/(\,85 - 53\,)] = 2.18$ s, which spans 2,175 ticks of 1 ms. If inference has run long enough for the junction to settle at T_{load}, cooling starts there instead and takes $8 \ln[(\,97 - 53\,)/(\,85 - 53\,)] = 2.55$ s, or 2,547 ticks.

Result: After about 24.7 s of continuous inference, every tick overruns its deadline by 47.5 percent for as long as inference continues, and for another 2.18 s to 2.55 s after it stops, depending on how close the junction had climbed to its loaded steady state.

Systems insight: While inference continues, the junction stays near T_{load}, above the trip, so the cluster remains throttled for as long as the proposer runs, which is the worse case on a machine whose chunk policy runs continuously while it moves. The hangover is the subtler one. Pausing the proposer (at a stop, or when the policy idles) does not restore the clock for at least another 2.18 s, so a remedy that sheds proposal load cannot rescue the tick in time.



Throughout, a refusal misses the drive frame timed to the deadline and waits for a later one. Because the throttled response still ends inside the period, each late refusal slips by about one tick, a distance the stopping budget can absorb (section 13.7). The case still disqualifies this modeled configuration, because the loaded tick has crossed the declared bound, every margin downstream was computed on the premise it breaks, and nothing in the premise limits a real governor to halving the clock. The lever is the heat path, not the tick's code. Any $R_{\text{th,JA}}$ that keeps $P_{\text{load}} R_{\text{th,JA}}$ below $T_{\text{trip}} - T_{\text{amb}}$ never trips, and an independently clocked placement is unaffected by that host governor. Its own thermal and clock limits remain separate qualification obligations.

The two timescales meet in one picture: a cooling curve measured in seconds holds the clock at 600 MHz, and every tick inside it, measured in microseconds, ends 190 µs past the deadline (figure 13.3). The scenario is also optimistic. Over a full shift, heat accumulating in the chassis raises the baseline $T_{\text{j,target}}$, which flattens the cooling gradient and lengthens recovery, and higher-order thermal poles in the enclosure can stretch the hysteresis by minutes. A shared-die placement would need a separately timed hardware fallback to stay safe across every exposed tick.

Heat completes the set of couplings, and placing it beside the other two shows how far apart they sit in time. The rail droop of section 13.3 acts within nanoseconds (10^{-9} s) of an accelerator current step, while thermal coupling develops over seconds (10^{1} s) as heat diffuses through silicon, package, and chassis. The separation is also a diagnostic: a latency spike that correlates with rail voltage points to power delivery network (PDN) impedance, and a slowdown that correlates with temperature points to the governor. Together with the tick they threaten, the couplings span about thirteen orders of magnitude on one machine, from nanoseconds to hours:

1. 10^{-9} **s (Nanoseconds)**: Simultaneous tensor core switching generates $L_{\text{pkg}} \cdot dI/dt$ inductive rail collapse, stretching transistor gate delays under the α-power law within individual clock cycles.
2. 10^{-6} **s (Microseconds)**: AXI4 crossbar arbitration and head-of-line FIFO queueing stall memory reads, as row-buffer precharge and activation penalties ($t_{\text{RP}} + t_{\text{RCD}}$) of tens of nanoseconds each accumulate across a queue.
3. 10^{-4}–10^{-3} **s (Sub-milliseconds to milliseconds)**: The protected work itself. Sensor ingestion and the control barrier filter's quadratic program run inside the permission tick, and fieldbus frames (such as EtherCAT) repeat on deterministic 1 ms cycles.
4. 10^{0}–10^{1} **s (Seconds)**: Macroscopic silicon die and package heatsink thermal capacitance stores dissipated energy, enforcing governor throttling hysteresis (at least 2.18 s in this scenario) that degrades thousands of control ticks.
5. 10^{2}–10^{4} **s (Minutes to hours)**: Structural chassis thermal mass and battery Joule heating accumulate heat, shifting bay ambient temperature T_{amb} upward and eroding cooling headroom across a multi-hour shift.

Because thermal mass and heat dissipation operate across seconds and hours, dynamic thermal management (DTM) (Brooks and Martonosi 2001) and reactive thread migration cannot restore a co-located permission loop before its next deadline expires. A safety-critical permission path requires guaranteed lower bounds on clock frequency and power supply integrity that survive sustained accelerator workloads. When a shared die cannot guarantee them, moving the permission engine onto an independently clocked and independently powered microcontroller removes the host-governor coupling, though the microcontroller must still stay within its own qualified supply, clock, and thermal limits under the common chassis conditions.

Coupling on one chassis spans nanoseconds to seconds.

Checkpoint 13.2: Junction temperature and clock throttling

The cooldown and overrun in figure 13.3 follow from the stipulated thermal scenario, not from measured hardware behavior. Use them to check the consequences of the selected model:

DRAFT

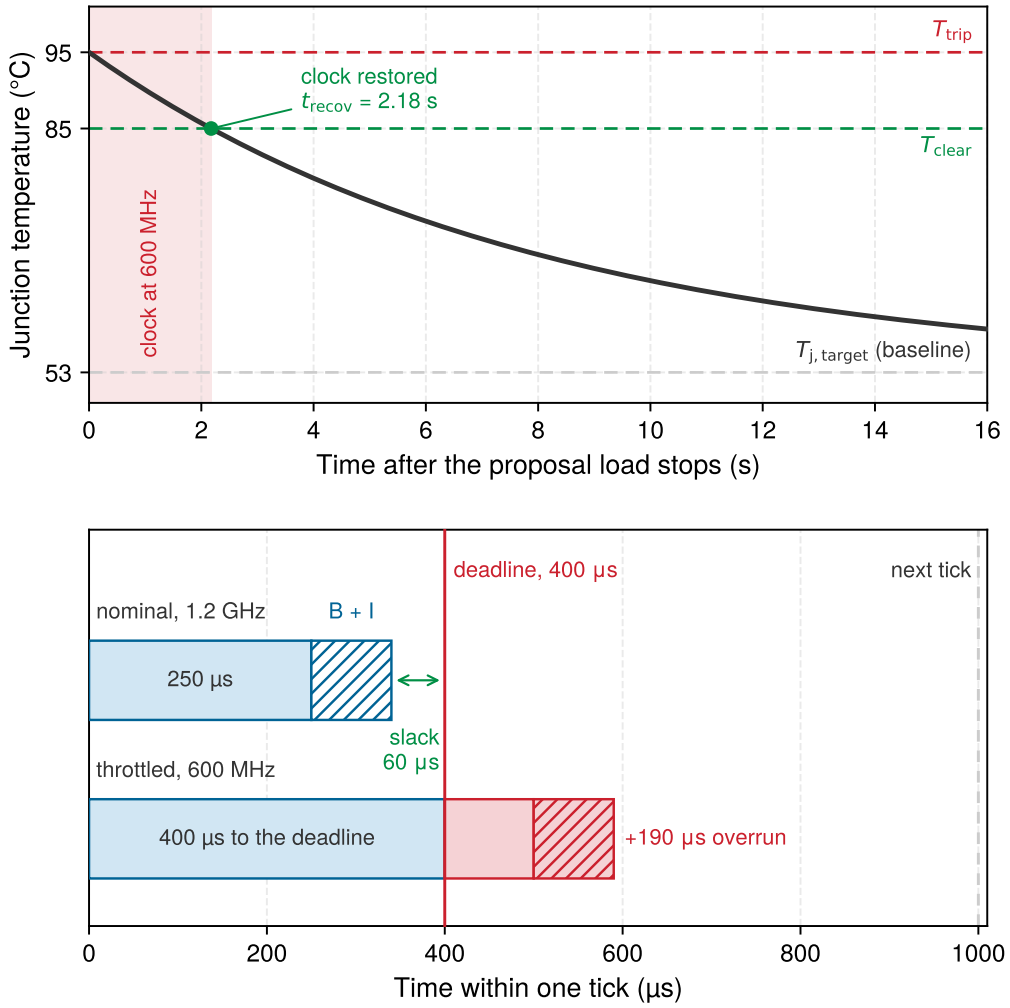


Figure 13.3: A cooldown that outlasts the load: Top, the junction relaxes from the 95 °C trip threshold toward its 53 °C baseline along equation 13.4, falling fastest at the moment the load stops and flattening afterward; the clock stays halved until the curve crosses 85 °C at 2.18 s. Bottom, one tick drawn to scale, with 90 µs of blocking and interference after the execution: the same work that meets the deadline at 1.2 GHz overruns it by 190 µs at 600 MHz, on every one of the 2,175 ticks inside the cooldown. The scenario is stipulated, not measured.

- ☐ **Thermal memory**: Can you explain why the package's thermal mass keeps slowing a real-time task after the proposal workload that heated it has stopped?
- ☐ **Cooling recovery sizing**: How long, in seconds and in 1 ms ticks, does the clock stay throttled while an SoC with thermal time constant $\tau_{th} = 8$ s cools from $T_{trip} = 95\,^{\circ}\mathrm{C}$ to $T_{clear} = 85\,^{\circ}\mathrm{C}$ under a 53 °C baseline equilibrium?
- ☐ **Governor hysteresis purpose**: Can you explain the purpose of temperature hysteresis (T_{trip} vs. T_{clear}) in hardware thermal governors and describe how it prevents high-frequency clock oscillation?
- ☐ **Physical segregation decision**: What measured clock, power, and timing evidence would justify a shared die, and when would a separate controller be needed?

13.5 The Boundary Contract

Relocating the permission path isolates the execution domains on separate processors, but the two still have to talk. Consider an upstream proposal writer, such as the chunk policy on the application processor, that stalls or crashes halfway through publishing an action chunk. The downstream safety enforcer running on the real-time microcontroller still owes the physical plant a deterministic actuation decision on its very next tick. Partitioning the compute engines isolates them only if the protocol lets the real-time reader inspect and reject an incomplete or in-flight record without ever waiting for the producer. The boundary contract therefore ties memory consistency directly to the deadline of the sensing and constraint-checking pipeline, and it is the one piece of the design that every placement, discrete or shared, must get right.

13.5.1 Immutable record mailboxes and non-blocking synchronization

Passing raw pointers into an application processor's working buffer or coordinating across a blocking lock lets a slow or crashed planner expose the real-time reader to torn data structures, stale cache lines, or unbounded waits. To prevent those stalls, the boundary contract demands an immutable, self-contained record whose publication integrity the safety enforcer can verify in constant time. The proposal header and seqlock mechanism fix the message structure and publication rules, and workload placement adds the requirement to verify on the hardware that this channel meets its execution budget even when the interconnect is saturated.

Across heterogeneous silicon or separate physical chips, communication splits into two stages: link transport across the board and local publication inside the microcontroller's memory domain. An ingress peripheral or DMA engine receives the payload over a physical link (SPI, PCIe, or Ethernet) and stages it into local memory. Where the target allows peripheral access to tightly coupled memory, this may be the mailbox directly; otherwise a bounded local copy publishes the received record into the mailbox. Link transport and local publication are therefore two separate timing obligations, and the boundary protocol governs only the second.

Inside that mailbox, the receive handler publishes fixed-size records with the single-attempt seqlock from the Nervous System, which discards a torn or in-flight record for this tick without a retry. Placement adds two obligations that the protocol alone does not discharge. Memory attributes, barriers, and cache maintenance on the target must keep the local copy coherent, and the copy itself, at its largest payload, must fit inside the tick's declared WCET.

Memory consistency shows only that a proposal arrived without tearing, not that the command is safe to execute. Once the record passes sequence validation, the admission pipeline checks its algorithmic certificates, dynamic feasibility, transport integrity, and lease validity. Rejecting a corrupted or late proposal neither renews an expiring lease nor revokes an active, previously vetted command early. The actuator keeps executing the current plan while that plan's lease, kinematic bounds, and state checks hold. If the current plan expires or the machine leaves its safe operating bounds, the microcontroller invokes the fallback ladder immediately. Host-side operating-system stalls, neural accelerator throttling, and asynchronous logging queues can never backpressure or delay this local decision.

↩ The single-attempt seqlock protocol, whose reader never spins or retries within a tick, is established in section 4.3.2.

Every cross-boundary exchange therefore carries two separately measured costs: board-level physical transport before publication, followed by a single bounded local read during the enforcement tick. Qualification test suites must record payload sizes, cache and memory settings, and worst-case rejection paths. Even a real-time enforcer that reads without blocking remains vulnerable if its own execution stalls, so software decoupling must be paired with independent hardware supervision of processor liveness.

13.5.2 Windowed watchdog timers and execution liveness

A standard countdown watchdog refreshed from a timer interrupt keeps getting fed after the control task has hung (Barr 2013). A single late-only threshold cannot catch a corrupted program counter or a runaway phase-locked loop (PLL) clock that jumps into the watchdog service routine ahead of schedule. The single-attempt seqlock catches torn publication, and memory protection blocks cross-domain writes, but neither verifies that the safety enforcer software is alive and running its checks at the intended rate. The Nervous System feeds the microcontroller's self-watchdog only when a tick finishes all of its checks, which catches a late or missing feed. On shared or heterogeneous

silicon, the enforcer can fail in either direction: bus contention and memory starvation can stall its progress, while PLL clock glitches or control-flow corruption can make instructions run too early. Protecting the plant therefore requires a two-sided bound on watchdog servicing.

↩ The supervisory timers, from the chunk lease to the self-watchdog timeout, are established in section 4.4.1.

High-integrity physical AI systems enforce this discipline with **windowed watchdog timers**. Unlike standard countdown timers that catch only late feeds, a windowed watchdog enforces both a lower threshold (the closed window, T_{lower}) and an upper threshold (the open window, T_{upper}), rejecting any refresh that arrives too early or too late:

1. **Early-kick violation ($t_{\textbf{service}} < T_{\textbf{lower}}$)**: If software refreshes the watchdog before the lower threshold has elapsed, the hardware watchdog controller flags an immediate fault and trips the emergency safe state. An early refresh signals disrupted control flow: a corrupted program counter may have skipped safety barrier checks to branch straight into the housekeeping routine, a stack overflow may have aborted intermediate kinematic checks, or a PLL multiplier glitch may have sped up the clock. Because a compromised execution path could still happen to feed the timer inside the valid window, primary hardware monitors (independent clock monitors and rail supervisors with isolated voltage references) must catch PLL runaways and supply dips first, leaving the windowed watchdog as a backstop.
2. **Late-kick violation ($t_{\textbf{service}} > T_{\textbf{upper}}$)**: If the timer counts past T_{upper} without a valid refresh from the enforcer, the counter underflows and asserts an unmaskable hardware reset line. A late kick shows that the safety enforcer stalled, whether starved of bus cycles by neural accelerator traffic on a shared crossbar, deadlocked in an unhandled exception handler, or delayed by cache evictions.
3. **Valid service window ($T_{\textbf{lower}} \leq t_{\textbf{service}} \leq T_{\textbf{upper}}$)**: A refresh inside this interval confirms only that the service call arrived on time. It does not prove that the software ran every required check in the dispatch loop. Full diagnostic coverage combines windowed timing with challenge-response checks or independent hardware supervision.

If the controller feeds once after each successful tick, the watchdog measures the interval *between feeds*. Let completion offset c_n from tick n start lie in $[c_{\text{min}}, c_{\text{max}}]$, and let J_{phase} bound the deviation of the interval between consecutive tick starts from T_{period}. A conservative range for the inter-feed interval is given by equation 13.5:

$$T_{\text{feed}} \in [T_{\text{period}} - (c_{\text{max}} - c_{\text{min}}) - J_{\text{phase}},\ T_{\text{period}} + (c_{\text{max}} - c_{\text{min}}) + J_{\text{phase}}] \tag{13.5}$$

This formulation captures the two extreme consecutive tick completions:

- *Shortest interval (late-to-early compression):* Tick n finishes as late as possible (c_{max}), and Tick $n+1$ finishes as early as possible (c_{min}); the elapsed time between consecutive feeds is compressed to $T_{\text{period}} - (c_{\text{max}} - c_{\text{min}}) - J_{\text{phase}}$.
- *Longest interval (early-to-late expansion):* Tick n finishes as early as possible (c_{min}), and Tick $n+1$ finishes as late as possible (c_{max}); the elapsed time between consecutive feeds expands to $T_{\text{period}} + (c_{\text{max}} - c_{\text{min}}) + J_{\text{phase}}$.

Engineers set T_{lower} and T_{upper} around this range once timing analysis and test evidence justify its bounds, while keeping the late-trip threshold inside the plant's fault budget. A single tick's nominal execution time is not enough to set a watchdog window. On the running machine, T_{period} is the 1 ms tick, and the declared worst-case execution time of 250 µs gives the execution contribution to c_{max}. The completion offset must also include the internal blocking and interference charged to the tick, so both offset bounds must use the same tick-start reference. Conversely, the nominal unloaded measurement of 135 µs cannot serve as c_{min}; early-exit paths, short branches, or trivial constraint checks can finish much faster than nominal paths. The shortest tick-start-to-completion interval observed during a stress and fault-injection campaign gives evidence for c_{min}, and a justified lower bound must also cover healthy paths the campaign did not exercise. Similarly, measured cycle-to-cycle period jitter under peak bus contention supports the bound J_{phase}, with allowances for unobserved conditions, rather than an idealized absolute phase offset. If a team has only absolute phase bounds, it must take the maximum difference between consecutive phase offsets before using this expression.

The two ends of the window are set by different arguments. The lower end of equation 13.5 sets T_{lower}. Once c_{min} and J_{phase} have justified bounds, supported by a campaign and allowances for

DRAFT

unobserved healthy paths, any feed earlier than the resulting lower bound lies outside the qualified healthy range. This gives the machine's self-watchdog, which has only a late trip, the early trip it lacks. The upper end is not used as T_{upper}. It marks the latest a healthy tick can feed, so T_{upper} must sit at or beyond it. How far beyond is a separate choice of fault-detection latency, judged against what the plant can tolerate while a dead enforcer goes undetected. The machine keeps the selected 5 ms timeout, several ticks beyond the window, so that transient delays do not trigger spurious resets; problem 5 converts that timeout into base travel. The late trip also answers a different question from the falsification threshold. A tick that runs past the declared WCET but still feeds within the window refutes the placement's timing premise, and the loaded campaign, not the watchdog, must catch it. The watchdog's upper end catches only an enforcer that has stopped feeding altogether.

Setting a multi-tick timeout is an engineered fault-detection latency, not proof that missing several control cycles is harmless. If the microcontroller crashes or resets, it cannot run MCU-controlled powered deceleration. A drive-autonomous SS1 remains available only if its independent trigger, drive controller, supply, and drive-energy and regenerative-sink paths survive the fault and are qualified for that response. Otherwise, the platform falls back to its separately qualified passive braking, friction deceleration, or hardwired mechanical interlocks. Total fault-handling latency (watchdog trip delay, supervisory reset propagation, and brake engagement) must therefore fit inside the plant's certified safety-stop budget. Engineers cannot justify a slow watchdog timeout by citing powered braking distances when the fault being detected disables the processor that commands those brakes.

To catch control-flow corruption where a broken loop still passes through the watchdog service call inside the valid time window, high-integrity designs add **challenge-response checkpointing**. An external hardware supervisor or isolated safety coprocessor sends pseudo-random seeds to the enforcer at runtime. Instead of writing a fixed value to a register, the enforcer must return a signature computed from fresh sensor frame hashes, constraint-barrier checks, and intermediate trajectory stages. Diagnostic coverage depends on whether a corrupted execution path can replay or compute a valid signature by chance. If the enforcer fails the challenge or misses the window, the external supervisor asserts a hardware torque-inhibit line (such as Safe Torque Off on an electric drive). Direct torque removal stops actuators from driving into hazards, but it is not a controlled powered stop; the resulting passive coast-down or mechanical braking profile needs its own qualification and safety-case evidence.

Both the boundary contract and its hardware supervision apply to every workload placement. Whether the learned policy and the real-time safety enforcer sit on separate boards, separate chiplets, or partitioned cores on one SoC, the design must pass records without blocking and verify liveness in hardware. What changes from one placement to another is how much cross-domain interference the tick must absorb, and every mechanism that bounds that interference carries its own price in silicon area, bus bandwidth, and board complexity.

13.6 Silicon Isolation Decisions

Suppose a loaded test catches one of these couplings, a tick that exceeds the declared bound under proposal load. The team then has four remedies, each paid for in a different currency: static reservation, spatial partitioning, workload reduction, and physical relocation to separate silicon (table 13.3). Each remedy targets a specific coupling layer and leaves a residual vulnerability; when that residual interference still exceeds the timing or fault-containment bound, the design must escalate to the next row, culminating in the mobile manipulator's choice of physical relocation and the board-link transport budget it requires.

Table 13.3: Workload re-placement and isolation decision matrix: Remediation pathways for when a test falsifies independence on shared silicon. Each remedy trades distinct engineering currencies (throughput, capacity, latency, board footprint) to eliminate contention channels before escalating to physically segregated silicon.

Remediation Strategy	Target Coupling Layer	Implementation Mechanism	Systems Engineering Trade-Off	Residual Vulnerability	When to Escalate
Static Reservation	CPU execution time, OS scheduling preemption	Fixed-priority scheduling, ARINC 653 time slots, per-core memory-bandwidth regulation (MemGuard)	Capacity withheld from other work, including during quiescent states	Micro-architectural contention beneath OS visibility (shared L3, DRAM bank conflicts)	Memory bus or cache stalls violate real-time deadlines despite 100% CPU core allocation
Spatial Partitioning	Cache capacity thrashing, DRAM bus contention	Cache coloring or way partitioning, DRAM bank partitioning (PALLOC), Arm MPAM, MPU/IOMMU domains	Structural fragmentation; smaller perception working set may increase off-chip traffic	Unpartitionable DRAM controller queues, row-buffer locality reordering, PDN voltage droop	Measured rail disturbances violate characterized limits, or DRAM queue stalls exceed the bound
Workload Reduction	Memory throughput saturation, peak thermal power	Model quantization (INT8/FP8), context downsampling, halved policy rate	Degraded policy tracking fidelity; increased control phase lag near dynamic stability boundaries	Common clock distribution trees, shared Power Management Units (PMU), unified reset domains	Model accuracy drops below operational limits, or shared clock/reset faults propagate across domains
Physical Relocation	Shared power, clock, reset, or unbounded controller interference	Separate enforcer MCU with independently assessed power, clock, memory, and sensor/actuator path	More board area and an external communication budget	Harness, transceiver, and common-supply faults remain	Choose when the shared die cannot provide evidence for required timing and fault containment

13.6.1 Four remedies for shared-silicon contention

A remedy that does not match the active coupling channel leaves the deadline overrun intact and strands compute capacity. Examples include reserving CPU cores when the stall lives in the DRAM controller queue, and coloring cache sets while miss status holding registers remain shared. A queueing bottleneck requires an enforced bound on service time, a cache capacity conflict requires physical separation of working sets, and a power-supply or clock disturbance requires an isolated fault domain. Trimming proposal demand can recover operating headroom, but only a bound on worst-case residual interference can support a safety claim.

Under **static reservation**,[12] physical workload placement stays the same while the critical path gets dedicated CPU time slices or interconnect slots. Reserving CPU time alone does not bound memory access latency; the interconnect needs its own service guarantee, such as periodic time-division multiple access (TDMA) slots with fixed transaction beat quotas. When hardware crossbars lack slot arbitration, system software must step in. **Memory-bandwidth regulation** gives each core an access budget per regulation epoch, counts memory transactions with hardware performance counters, and stalls any aggressor core with an interrupt once it spends its quota until the next epoch begins (Yun et al. 2013). By capping how much traffic an aggressor can queue ahead of a critical transaction, bandwidth regulation provides a demand bound from which the controller model and service guarantee can bound the queueing multiplier r_{slow} of section 13.3.2. Throttling reads alone is not enough; defending against writeback-buffer saturation requires charging both reads and dirty-line writebacks against the aggressor's budget (Bechtel and Yun 2019). The predictable execution model takes this separation further on the real-time core. It splits each task into an initial memory phase that pulls its working set into private scratchpad memory, followed by an isolated compute phase that touches no shared interconnect resources (Pellizzoni et al. 2011). That pattern matches the boundary contract of section 13.5, which performs one bounded read followed by local computation.

12 **Time Partitioning (TDMA)**: Time-division multiple access gives each requester a fixed recurring slot, so its worst wait is one schedule cycle whatever the others demand. Integrated modular avionics made the same idea the basis of processor sharing: the ARINC 653 interface schedules partitions in fixed windows of a repeating major frame, and the assurance argument for such partitioning treats spatial and temporal separation as distinct obligations (Rushby 1999). The price is capacity reserved even when its owner is idle, the cost this paragraph charges to the proposer.

DRAFT

The cost is stranded capacity, because memory throughput stays reserved for the safety path even when the enforcer is idle. Had the warehouse mobile manipulator kept its permission path on the SoC, reserving memory-bus slots for sporadic 4 KB sensor reads would throttle policy weight streaming across the accelerator even with the robot base parked.

When contention comes from competing working sets thrashing shared caches or banks, **spatial partitioning** isolates cache ways or physical memory channels. For example, splitting an 8 MB last-level cache into 6 MB for the proposal policy and 2 MB for enforcer permission tables prevents cross-domain cache-line evictions, though shrinking the perception working set can increase off-chip memory traffic. Operating systems can enforce this split without special hardware through **cache coloring**: the page allocator assigns physical pages whose index bits map to disjoint cache sets (Mancuso et al. 2013). Extending address-bit coloring to the bits that select DRAM banks gives each domain private banks, removing the inter-core row-buffer conflicts of equation 13.1. Arm's Memory System Resource Partitioning and Monitoring (MPAM) extension puts these controls in hardware, combining cache-portion bitmaps across shared caches with memory-bandwidth throttling registers downstream of the last-level cache (The Linux Kernel Documentation 2026). Even so, spatial cache partitioning does not separate the shared MSHRs or writeback queues (section 13.3.2). Spatial partitioning must therefore be paired with bandwidth regulation, and neither removes a shared DRAM controller queue. Giving the safety path its own DRAM channel and controller removes controller contention, at the cost of permanently taking that channel's bandwidth away from the proposal accelerator.

A **static-partitioning hypervisor** combines these mechanisms across one SoC. At boot, it statically binds CPU cores, physical memory ranges, and memory-mapped peripherals to isolated guest partitions, runs without a dynamic runtime scheduler, and colors cache sets across partitions, as in microkernels such as Bao (Martins et al. 2020). This is the standard way to host a hard real-time safety enclave beside a Linux stack on one die. The scheduling model behind the asymmetry between proposal overruns and enforcer guarantees is **mixed-criticality scheduling** (Vestal 2007; Burns and Davis 2017). In the standard mixed-criticality model, execution budgets depend on the assurance level: if a high-criticality task overruns its lower-assurance budget, the scheduler drops low-criticality work so the high-criticality task keeps its larger budget. On the running machine, the safety enforcer is the high-criticality task and the generative proposer is the low-criticality workload. The lease protocol enforces the same priority: a proposer that misses its inference window forfeits lease renewal, while qualified hardware isolation protects the enforcer's periodic permission tick.

When an application can accept coarser tracking, **workload reduction** lowers memory traffic and heat through model quantization, smaller intermediate tensor transfers, pruned telemetry logging, or a lower policy rate. The trade-off is tracking fidelity. On the mobile manipulator, stretching the action-chunk period past the 60 ms lease lets leases expire between renewals; keeping continuous control authority requires chunk admissions above 16.7 Hz, even before renewal jitter is charged. Average producer throughput cannot verify this condition. Post-training quantization also requires fresh testing to confirm that manipulation accuracy stays within tolerance. Finally, lowering average power does not remove fast current steps (ΔI) or inductive voltage droop ($L_{\text{pkg}} \cdot dI/dt$), which remain separate electrical qualification items.

When on-chip software and hardware controls cannot bound shared-die interference, **physical relocation** moves the permission path to a dedicated microcontroller with private SRAM, its own crystal oscillator, a separate reset domain, and an isolated power supply. Private TCM removes DRAM bus contention, while an isolated rail with hold-up capacitance keeps the safety monitor alive through host-side voltage collapse. Relocation does not remove verification work; it trades on-die contention analysis for board-level signal integrity, transceiver qualification, and common-cause electrical fault containment.

Moving the permission enforcer to separate silicon shifts the cost from on-chip arbitration to board-level link latency and PCB routing. The drive command bus delay (T_{bus}) does not change because joint drives sit on an EtherCAT fieldbus regardless of compute placement. What relocation adds is proposal transport across an inter-chip link (a DMA-driven SPI link, an isolated PCIe Non-Transparent Bridge, or a differential serial bus) from the application processor to the safety microcontroller. While this board hop does not delay an enforcer tick running on already admitted evidence, it ages the observation behind every newly admitted plan and must be charged to the

dispatch-to-admission interval (section 13.6.2). Jitter in transport and admission also spends the 5 ms renewal-jitter margin that the lease rule reserves between the 50 ms chunk period and the 60 ms lease. Host-side memory contention spends the same margin: an illustrative 12.5 percent stretch of the inference uses up the entire jitter allowance by itself, leaving nothing for link delays or validation variance. Lease renewal must therefore be checked against measured end-to-end admission timestamps rather than upstream inference rates.

↩ The renewal-jitter margin and lease renewal rule are established in section 4.4.

Physical relocation also changes where sensors attach. On the running machine, joint encoders and the IMU wire directly to peripheral controllers on the safety microcontroller (hardware quadrature counters and synchronous SPI channels), keeping host-processor arbitration out of the real-time feedback loop. Driver latency and register-read jitter on those peripherals still need measurement. By contrast, high-bandwidth perception sensors feed the application processor directly: RGB cameras over MIPI CSI-2 lanes, and lidar packets over Ethernet. Those heavy streams fill perception buffers without crossing the microcontroller's internal buses. Every placement choice thus reshapes the board, trading on-die memory arbitration for pin counts, differential trace routing, and serial link overhead.

13.6.2 The board-link budget and the dispatch-to-admission interval

That board-level serial hop and split validation pipeline age sensor observations while the base keeps rolling down the aisle, closing the interval left unallocated in section 8.4.1. This span, from perception dispatching an observation frame to the safety enforcer admitting the resulting action chunk, is called the **dispatch-to-admission interval** Δ_{da} (the second row of table 4.1). It covers the remaining proposer inference after dispatch, serialization across the board link, frame receipt and deserialization on the microcontroller, host geometry checks and bounded local admission checking, trajectory buffer activation, and the wait for the next permission tick. Because the stopping budget starts at sensor capture, every millisecond of Δ_{da} is base travel on aging evidence, paid for out of the stopping budget's spare clearance.

↩ The composite stopping budget, which leaves the dispatch-to-admission interval out of the pre-brake delay and pays for it from the remaining clearance, is established in section 12.3.1.

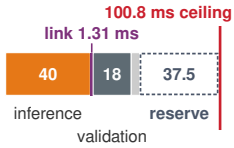
Napkin Math 13.3: The board-link toll

Problem: The machine's permission path runs on a discrete microcontroller that receives each chunk over a board link. How long may the interval from perception dispatch to admission last before the finished stopping budget has nothing left at the aisle speed?

Variables:

- Chunk policy p99 inference 40 ms (Illustrative), charged in full after dispatch, which is conservative because its vision stage already lies in the dispatch age of section 8.4.1.
- Serialized chunk $D_{\text{vol,chunk}} = 4{,}096$ bytes on a $f_{\text{link}} = 25$ MHz SPI link (Illustrative).
- Deserialization 2 ms, aggregate trajectory validation 18 ms, and activation 1 ms (Illustrative allowances), and up to one 1 ms permission tick of waiting (Chosen).
- At $v = 1.3$ m/s the finished budget leaves $d_{\text{spare}} = 131.0$ mm (Derived).

The validation allowance covers both the host geometry check and the MCU's bounded local admission check, including their scheduling delays. The example does not allocate a separate duration to each. Their combined elapsed contribution must fit this allowance; qualification cannot omit host validation or count the entire allowance again on the MCU.



Math: Serialization takes $8\,D_{\text{vol,chunk}}/f_{\text{link}} = 1.31$ ms. The allocation totals $\Delta_{\text{da}} = 40$ ms $+ 1.31$ ms $+ 2$ ms $+ 18$ ms $+ 1$ ms $+ 1$ ms $= 63.3$ ms, which the base covers as 82.3 mm of travel. The spare pays for at most $\Delta_{\text{da,max}} = d_{\text{spare}}/v = 131.0$ mm / 1.3 m/s $= 100.8$ ms, so the allocation leaves 37.5 ms, or 48.7 mm of positive reserve. Doubling the chunk or halving the link clock adds only another 1.31 ms; adding one more inference's worth of delay, 103.3 ms in all, exhausts the spare.

Systems insight: The board link that buys silicon separation costs about one millisecond, a small fraction of Δ_{da}; proposer inference and aggregate trajectory validation dominate the interval. The stipulated discrete-placement allocation therefore fits the stopping budget,

whereas a slower policy or a heavier validation kernel could exhaust it. The allocation is a target that qualification must confirm, not a relaxed runtime margin. The deterministic portion of Δ_{da} ages observation evidence and is charged here, while runtime variance between renewals drains the 5 ms renewal-jitter budget, which host-side memory contention alone can saturate. Because host inference and local validation overlap as a pipeline across consecutive 50 ms chunk periods, a 63.3 ms dispatch-to-admission interval does not expire the 60 ms lease as long as the time between consecutive admissions stays within the chunk period plus that renewal-jitter allowance.

With Δ_{da} formally allocated, the event timing table (table 4.1) contains no undefined intervals. Total plan replacement latency from sensor capture to chunk admission (equation 11.3) is 114.9 ms, while total elapsed time from capture to emergency brake onset in the event of an unresponsive proposer is 196.9 ms. Both figures represent budget allocations that the loaded stress-testing campaign in section 13.7 must validate using physical hardware trace timestamps.

Allocating the interval also exposes interference that the discrete placement keeps inside the microcontroller. The link's receive DMA engine and its completion interrupt, the fieldbus master dispatching motor drive frames, background local admission checking, and the periodic ingestion of evidence snapshots all contend for the microcontroller's internal crossbar, interrupt controller, and memory banks. Every potential interference path demands an enforceable bound: assigning SPI and fieldbus interrupt priorities strictly below the deterministic permission tick, allocating dedicated DMA channels, and mapping safety state to independent tightly coupled memory banks. The loaded validation campaign in section 13.7 must saturate the communication link and execute maximum-length plan validation while simultaneously triggering the refusal branch. Classical response-time analysis for the periodic tick, with its higher-priority preemption and lower-priority blocking terms, provides the formal static counterpart to those empirical stress tests.

The board link costs 1.31 ms of a 63.3 ms allocation under a 100.8 ms ceiling.

These remediation pathways determine which computing resources engineers must statically reserve or physically isolate. Two subsequent architectural decisions govern the remaining placement budget: whether any portion of proposal generation may be offloaded across an external network, and which candidate accelerator silicon completes autonomous missions within the chassis energy reserve. Off-board compute is first a timing question, and it comes first because energy efficiency matters only among architectures that already meet their deadlines.

↪ Response-time analysis for a periodic tick, with its preemption and blocking terms, is developed in section C.3.

13.6.3 Off-board compute and mission energy

Querying a remote data center over factory Wi-Fi or private 5G subjects an offloaded policy to radio multipath fading, base-station handoffs, and packet retransmissions, yet the returned trajectory must still arrive inside the local 55 ms lease-renewal window. Off-board computation operates under the exact same timing windows as a local board interconnect, so an offloaded result must fit the target admission window before it can be considered for admission:

$$t_{\text{net}}^{\text{tail}} + t_{\text{proc}}^{\text{tail}} \leq W, \tag{13.6}$$

where W is the allocation for the network-and-remote-processing interval of a particular transaction. The complete dispatch-to-admission interval must also charge host validation, local deserialization and admission, activation, and tick waiting against the 100.8 ms ceiling (notebook 13.3). A continuing pipeline must satisfy that evidence-age ceiling and the accepted-result gap required for lease renewal. The lease less renewal jitter (55 ms on the running machine) directly limits transaction latency only under a serial, non-overlapping convention; with overlapping requests, stage capacity and actual inter-admission gaps require separate checks. Qualification must measure the complete end-to-end tail at the required reliability level and retain the same evidence, state, and lease checks as local admission.

Empirical robotics deployments demonstrate how severely this constraint restricts offloading. In RT-2, large vision-language-action (VLA) models ran in a multi-TPU data center queried over wireless networks; under real network conditions, the 55-billion-parameter model executed at only 1 to 3 Hz, while the 5-billion-parameter model reached approximately 5 Hz (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023). Wireless links in industrial deployments (whether Wi-Fi or private

5G) introduce severe latency tails from radio-frequency multipath fading, base-station handoffs, and packet retransmissions. At 5 Hz, a fresh plan arrives only once every 200 ms, 3.6 times the renewal window, while the 55-billion-parameter model delivers outputs at best every 333.3 ms. Neither remote pipeline could sustain lease renewal on this machine. Because the published study documents overall throughput frequencies rather than an explicit breakdown between network latency and remote execution phases, one cannot determine whether a lower-latency wireless link could close the gap. Qualifying any remote lease-renewal pipeline requires profiling the full tail distributions of both components. Instead, large remote foundation models are best positioned to synthesize coarse semantic goals or task decompositions, leaving high-frequency action chunk generation to an onboard policy. Coarser planning workloads operating on second-scale horizons are better candidates for edge offloading. FogROS2, for example, offloads ROS 2 compute graphs to cloud and fog instances, reducing grasp-planning latency from 14 s on local edge silicon to 1.2 s (Ichnowski et al. 2023). That acceleration speeds macro-task completion while leaving high-frequency microcontroller execution untouched. Packet loss or complete link disconnection must leave the onboard enforcer and its certified safe-stop routine fully operational. Neither remote offloading nor offline compilation eliminates the obligation to guarantee timely execution on local silicon.

Placement also decides which accelerator hosts the proposal path, and that choice reaches the permission path through energy as well as time. The chip's power is the load term that set the junction temperature in section 13.4, and it draws on the same battery whose sag the isolated rail must ride through. Among architectures that satisfy these timing bounds, candidate silicon must also complete the physical mission within the chassis energy reserve. Energy optimization often presents a subtle engineering trade-off. A lower-power edge accelerator draws fewer watts during active inference, yet if it extends execution latency, peripheral loads (lidar, depth cameras, cooling fans, and motor holding currents) remain energized longer. Conversely, a higher-throughput neural accelerator reduces mission energy only as long as faster compute actively shortens overall task duration. Once physical manipulator kinematics or vehicle velocity limits dominate the execution timeline, accelerating compute further merely burns excess power without saving task time, driving up total energy consumed per completed cycle.

For an assigned physical workload with steady-state compute power and baseline chassis power draw, total mission energy follows the relation:

$$E_{\text{mission}} = (P_{\text{chip}} + P_{\text{chassis_static}}) \times T_{\text{mission}}$$

Evaluating this expression requires an empirical or rigorously modeled mission duration T_{mission} for each candidate silicon configuration. Transient motor acceleration spikes, DC-DC converter losses, task retries, and quiescent dwell intervals demand explicit energy accounting whenever they diverge across platforms. Systems engineers cannot rank candidate SoCs simply by comparing datasheet figures such as peak tera-operations per second (TOPS) or nominal thermal design power (TDP). The workload to measure is the machine's own proposal pipeline, from camera ingestion through the chunk policy, and final silicon placement requires evaluating the compiled neural graph, its memory footprint, and the thermal assembly as one system. This chapter does not rank accelerators for the running machine, whose record carries no measured mission duration for any candidate; the relation states what such a ranking must measure. With reserved memory bandwidth, board-level transport latency, and battery energy draw accounted for in the allocation model, the next step is experimental verification. It tests on the physical hardware whether these isolation choices keep the permission tick within its bound and preserve braking response under worst-case concurrent load.

13.7 Empirical Verification of Silicon Isolation

The thermal hangover refuted candidate (b) from a model, but a placement that survives every model still has to face a measurement that could refute it. A claim of silicon isolation between an unverified learned workload and a safety enforcer must therefore reduce to a testable bound on enforcement latency and refusal availability. This bound must hold across all declared proposal workloads, junction temperatures, and operational modes. If shared-resource contention delays an enforcer refusal past its physical deadline, the claimed operational separation has failed, whatever architectural isolation was promised on paper.

13.7.1 The worst-case execution time falsification threshold

When a loaded permission tick runs for 260 µs against a declared isolated worst-case execution time of 250 µs, it finishes well inside the 400 µs deadline yet still refutes the claim that shared hardware added zero interference. The budget section of section 13.2 introduced the permission tick's declared worst-case execution time (T_{wcet}) as this falsification threshold, and a test designed to refute a placement must name the exact measured quantity it compares against that bound. In this example, the declared worst-case execution time bounds the task in isolation, whereas a qualified execution model can instead include bounded resource interference. Here, microarchitectural interference from hardware shared with co-running workloads lengthens the execution term rather than appearing as a separate term of the response-time bound (equation 4.3). The loaded C_i includes that penalty, beside the blocking B_i and interference I_i that the microcontroller's own tasks contribute.

The pass-fail threshold for silicon isolation derives directly from the system specification. The machine's permission path specifies a declared worst-case execution time $T_{\text{wcet}} = 250$ µs, representing the isolated execution parameter C_i in equation 4.3. It must complete each permission evaluation within a chosen enforcer deadline $T_{\text{deadline,enf}} = 400$ µs, which is nested inside the overall permission period $T_{\text{tick}} = 1$ ms. When measured under operational load, total enforcer execution time is the sum of isolated execution latency and cross-workload hardware interference, as formalized in equation 13.7:

$$t_{\text{enf}} = t_{\text{iso}} + T_{\text{interf,shared}}, \qquad t_{\text{iso}} \leq T_{\text{wcet}} < T_{\text{deadline,enf}} < T_{\text{tick}} \tag{13.7}$$

where t_{iso} represents the execution time of the permission path running with zero contention, and $T_{\text{interf,shared}}$ captures the cumulative delay inflicted by proposal-side activity competing for shared DRAM channels, caches, interconnects, clock trees, power distribution networks, and thermal budgets.

An ideal isolated placement claims that proposal-side execution introduces zero cross-workload interference ($T_{\text{interf,shared}} = 0$), making the declared bound T_{wcet} the **falsification threshold**. Because isolated execution cannot exceed T_{wcet} by definition, any measured cycle under load that exceeds T_{wcet} demonstrates that either the declared baseline WCET was underestimated or the shared hardware introduced an interference penalty that the architecture failed to eliminate. Either outcome refutes the timing contract of the placement, even if the cycle completes before $T_{\text{deadline,enf}}$, because every downstream margin, from the deadline itself to the stopping distance budgeted for each tick, depends on that premise. Conversely, observing a loaded execution cycle below T_{wcet} does not establish that $T_{\text{interf,shared}}$ is zero. Empirical testing can decisively falsify a declared bound, but measurements alone cannot prove its universal validity. Any test campaign samples only the microarchitectural states it reaches, and microarchitectural timing anomalies can push the true worst-case latency beyond every observed cycle.[13]

Even a small overrun invalidates the declared premise. It need not cause a collision on that tick, but it removes the guarantee beneath every downstream stopping and lease-renewal margin. Response-time verification charges the full bound from equation 4.3, $t_{\text{enf}} + B_i + I_i \leq T_{\text{deadline,enf}}$, in which $T_{\text{interf,shared}}$ inflates the execution term t_{enf}, while B_i and I_i remain the blocking and interference from the safety microcontroller's own workload. Under the declared bound, shared platform hardware can introduce at most 60 µs of cross-workload delay before the enforcer violates its deadline, and every candidate in this chapter, chosen or rejected, is judged against that allowance.

Because a single permission tick at 1.3 m/s corresponds to only $vT_{\text{tick}} = 1.3$ mm of vehicle displacement, engineers often underestimate the severity of a missed deadline. The stopping budget, however, leaves little margin for error. Under the baseline assumptions compiled in table 12.1, bringing the vehicle to a controlled stop from 1.3 m/s requires 969.0 mm, which leaves 131.0 mm of clearance within the 1.10 m clear distance. That subtotal accounts only for the onboard stopping maneuver; it excludes the dispatch-to-admission latency Δ_{da}, which is an allocated system budget rather than a measured property. Deducting the 63.3 ms allocated to Δ_{da} in notebook 13.3 shrinks the stopping reserve to 48.7 mm. While the stopping budget can absorb the loss of an isolated T_{tick}, unmitigated microarchitectural contention does not produce predictable single-tick delays; it produces open-ended stalls that exhaust the stopping margin entirely. That asymmetry is why the thermal case of section 13.4 disqualifies candidate (b) even though each of its late refusals slips only about one tick. The distance lost is small, but the placement has broken the bound on which every distance was computed, and a broken bound no longer limits how far the next stall can run.

13 **Microarchitectural Timing Anomalies**: A local speedup, such as an unexpected cache hit, can reorder subsequent pipeline or interconnect resource contention and paradoxically lengthen total execution time (Lundqvist and Stenström 1999). Although first identified in dynamically scheduled out-of-order processors, timing anomalies also appear in pipelined in-order cores coupled to shared buses or caches (Wilhelm et al. 2008). Consequently, composing local worst-case assumptions at each pipeline stage does not guarantee the global worst-case execution time, and empirical observation on an in-order core cannot substitute for formal timing analysis.

Guaranteeing that the enforcer finishes before $T_{\text{deadline,enf}}$ also stabilizes the downstream feedback loop. When the system dispatches motor-drive command frames at a deterministic phase offset scheduled no earlier than $T_{\text{deadline,enf}}$, execution jitter never propagates to the actuators. Instead, the feedback controller encounters a constant computation delay equal to 0.4 of the tick period. Control engineers model this fixed latency directly as phase lag at the loop crossover frequency, mirroring the phase delay introduced by a zero-order hold.

↪ The zero-order hold's phase lag, about half a sample period of delay, is developed in section B.5.5.

13.7.2 Worst-case execution time analysis methods

Measuring ten thousand clean cycles on a quiet laboratory bench cannot reveal the worst-case stall that occurs when an out-of-order core suffers a cache-eviction cascade at the exact instant a DMA controller locks the memory bus. A declared worst-case execution time is a formal timing commitment, and systems engineers establish it through one of four methods, each resting on distinct premises (Puschner and Koza 1989; Wilhelm et al. 2008).

Static analysis operates entirely without executing the binary on hardware. The analyzer reconstructs the control-flow graph directly from machine instructions, bounds every loop iteration, and applies abstract interpretation (Cousot and Cousot 1977) to model the processor pipeline and cache states so that memory references are classified as definite hits, definite misses, or unresolvable states. The tool then solves an integer linear program (Li and Malik 1995) to identify the longest feasible execution path. It uses basic-block execution frequencies as decision variables constrained by structural flow conservation and loop bounds, while the objective function maximizes total cycle count based on block-level worst-case latencies. Static analysis yields a sound upper bound only with valid loop and path bounds and a model of the actual binary, memory and peripheral accesses, and relevant processor and resource states. The reference microcontroller's in-order execution and private tightly coupled memory make these obligations more tractable, though they do not establish model fidelity by themselves. On application multicores, out-of-order execution, undocumented interconnect arbitration, and shared non-blocking caches make a static bound difficult to justify when relevant resource states and co-running demand remain uncontrolled or unmodeled.

Where an exhaustive microarchitectural model is unavailable, *measurement-based analysis* executes the binary directly on target hardware under the most demanding synthetic test harnesses the engineer can construct, appending an empirical safety margin to the observed maximum latency (the high-water mark). That directness explains its ubiquity in complex systems, yet it provides no mathematical guarantee against unobserved execution paths or rare microarchitectural collisions. The adversarial stress testing suite developed below targets contention states that ordinary workloads may leave unexercised, and its coverage limits remain part of the qualification record. *Hybrid analysis* bridges those two regimes. It measures the execution latency of isolated code snippets or basic blocks directly on physical silicon, then composes those empirical timings across the program's control-flow graph using static path-analysis techniques. It thus relies on target measurements at the sub-routine scale while adopting the structural path bounds of static modeling. Alternatively, *probabilistic analysis* models execution times as random variables, fitting extreme value distributions to empirical latency traces to project the probability that an execution exceeds a given threshold (Cucu-Grosjean et al. 2012). Because this methodology assumes that experimental measurement runs faithfully sample the operational probability distribution, unmodeled dependencies on platforms with complex hidden microarchitectural state can invalidate the projection. Section C.3 analyzes these statistical models and their operational limits.

When migrating from an isolated processor to a shared multicore system-on-chip, isolated execution analysis becomes insufficient. Isolated worst-case latency must be augmented with explicit interference penalties for every contended shared resource. Modern multicore response-time frameworks construct these bounds by combining the formal service guarantees of shared arbiters with the maximum request demand generated by co-running cores (Davis et al. 2018). Such composition yields finite, provable bounds only when hardware mechanisms or operating system regulators enforce resource budgets, which is why section 13.6 relies on memory-bandwidth regulation (such as MemGuard) to render shared silicon analyzable. FAA AC 20-193 provides an acceptable means of compliance for airborne multicore systems. Where time interference is not mitigated, it calls for WCET analysis confirmed by testing on the target processor with all software executing in the

intended final configuration. It also permits separate determination when time interference is shown to be mitigated (Federal Aviation Administration 2024).

On the running machine, the available execution models and enforced resource bounds determine the verification method. A discrete microcontroller reduces the shared-resource model, but analysis and testing must still cover local DMA, interrupts, internal buses, background admission, and the board-level supply, clock, and link faults inventoried here. On a shared application SoC, this example's declared 250 µs remains the isolated baseline, not a loaded execution bound. To validate such a shared placement, the engineering team must formally bound $T_{\text{interf,shared}}$ across every shared architectural row identified in table 13.1. It must also verify that the resulting response bound remains safely within $T_{\text{deadline,enf}}$, and it must execute an adversarial campaign capable of refuting both the analytical bounds and the isolation claims.

13.7.3 Adversarial stress testing and end-to-end brake onset timing

Refuting an independence claim requires synthetic workloads engineered to induce correlated worst-case microarchitectural contention rather than standard benchmarks (such as MLPerf) that report average throughput. Standard ML inference pipelines schedule memory transactions to maximize pipeline overlap and average data bus utilization, which conceals transient contention peaks. On physical silicon, maximum interference occurs during synchronized bursts when multiple subsystems demand the exact same physical resources at the exact same clock edge. An adversarial stress suite must synthesize these collision patterns deliberately. The five generators below target the shared die first, because that is where the strongest mechanisms of this chapter live, and they serve two campaigns: refuting a shared-die candidate, or qualifying an island an integrator can use.

1. **Targeted DRAM bank conflict generators**: The stress suite issues unaligned DMA transfers with access strides calibrated to target the exact DRAM bank and bank group assigned to the enforcer's memory buffers. By continuously alternating access across conflicting row addresses, the generator repeatedly evicts open row buffers, incurring the full precharge and activation latency (37.5 ns at the application SoC's memory clock rate) on every subsequent read.
2. **Shared-cache miss-handling engines**: Streaming memory threads cycle through footprints substantially larger than the shared last-level cache. These routines exhaust its MSHRs and saturate writeback buffers with dirty cache lines, triggering the structural interconnect stalls identified in section 13.3.2 as the primary threat to bounded enforcer latency.
3. **Resonant PDN current-step generators**: Microbenchmarks execute rapid, high-amplitude current transients across neural accelerator arrays while sweeping the transient's phase relative to the permission tick. High-bandwidth oscilloscope probes on the PDN capture package-level $L_{\text{pkg}} \cdot di/dt$ voltage droop and ringing, directly testing whether supply collapse induces clock throttling or logic faults on co-located cores.
4. **Correlated peripheral interrupt storms and storage saturation**: High-bandwidth camera deserializers and NVMe storage controllers stream raw telemetry at line rate while asserting uncoalesced hardware interrupts. This flood stresses the interrupt controller, consumes shared crossbar bandwidth, and saturates system write buffers.
5. **Chassis electromechanical transient coupling**: Test benches inject realistic traction-motor current transients and regenerative braking pulses into the shared DC bus. These tests verify whether DC-DC converter dropout, ground bounce, or electromagnetic interference couples into the enforcer's power rails or clock distribution networks under worst-case operating envelope conditions.

The campaign on the chosen discrete microcontroller keeps only the generators that can reach it, and it maps onto the four fault-injection regimes of section 13.2, now applied together rather than one at a time. Supply transients on the shared battery bus (generator 5) are regime 1, power-rail droop testing. Clock margining under those transients is regime 2. Saturating the board link while the microcontroller's own receive DMA, fieldbus interrupts, and background plan validation contend for its internal buses (section 13.6.2) is regime 3, link flooding. Streaming malformed and NaN-laden proposals during all of it is regime 4. The host-side targets of generators 1 to 4 do not reside on the microcontroller, which shares no DRAM, cache, or package with the proposer. Analogous contention

from its own DMA and interrupts remains in regime 3. They drop out because (d) removes those rows, a claim the register readback and the inventory must support, not because the campaign overlooked them.

Hardware instrumentation must trace the complete perception-action timeline: sensor observation capture, coherent ingestion across the interconnect, permission decision completion, drive-frame dispatch over the real-time fieldbus, and physical frame arrival at the motor inverters. While digital bus logs reveal software delays, issuing a bus frame does not equal physical braking. For a controlled powered stop, synchronized motor-phase current probes and external optical tracking must measure the actual onset and dynamic trajectory of vehicle deceleration. The nominal renewal-to-onset budget is 82 ms, combining the software lease duration, one permission tick, fieldbus transit, and motor-drive torque development. Spring-applied mechanical brakes engage only when the vehicle has already decelerated to near-standstill, so mechanical brake contact cannot serve as a proxy for powered deceleration onset. In fault-injection scenarios involving total MCU failure or bus power loss, testing must independently verify the physical stopping distance delivered by the fail-safe emergency circuits. All timing intervals must be reported alongside verified clock synchronization bounds and instrument measurement uncertainties.

Because interference compounds across physical, thermal, and architectural domains, stress testing requires a full factorial experimental matrix to uncover paired-stress vulnerabilities. The evaluation sweeps across four orthogonal axes. The first axis is a cold condition (an illustrative junction temperature of $35\,^{\circ}\mathrm{C}$) vs. a hot one, which on a shared die means junctions held at or above the throttling threshold T_{trip} of section 13.4 and on the discrete microcontroller means the bay at its highest qualified ambient. The second is an idle proposal path vs. a saturated proposal engine executing maximum-batch inference. The next is diagnostic circular logging disabled vs. streaming at full non-volatile memory bandwidth. The last is nominal tracking commands vs. boundary-violating commands that trigger refusal routines. Testing refusal paths under full stress is mandatory because executing a safe clamping trajectory or entering emergency shutdown involves cold branch paths, non-cached error-handling code, and secondary bus transactions that never execute during steady-state aisle driving.

The factorial matrix exists to uncover co-runner collisions that escape isolated unit testing. Consider what happens on the rejected shared-die placement when an unexpected obstacle steps into the warehouse aisle. Detecting the obstacle forces the enforcer to execute its cold refusal branch to initiate an emergency stop. Simultaneously, the application processor flags the anomalous visual scene and triggers a high-priority diagnostic core dump over the shared DMA interconnect. If tested in isolation, the refusal branch executes within its latency budget, and diagnostic dumping runs without error. When triggered concurrently, however, the diagnostic DMA burst floods the shared memory controller precisely when the enforcer must fetch its cold refusal instructions from DRAM. The resulting contention spike stalls the enforcer at the exact moment safe physical actuation is most urgent.

To see how empirical traces refute invalid isolation claims, evaluate an illustrative 10^7-tick stress test conducted on the rejected shared-die configuration (where the enforcer executes on a real-time core cluster within the application SoC). Operating at one tick per 1 ms, this campaign runs for 10,000 s, or 2 h 46 min 40 s of continuous physical execution, excluding platform setup and reset overheads. Under cold, unloaded conditions, enforcer latency remains well within limits: the trace shows a median p50 $= 95$ µs, a 99th percentile p99 $= 128$ µs, and a maximum recorded latency of 152 µs. Under warm, heavily contended conditions, however, resource conflicts degrade the tail latency: p50 rises to 210 µs, p99 climbs to 330 µs, p99.9 reaches 395 µs, and the observed maximum spikes to 468 µs.

Because the loaded p99 alone exceeds the declared isolated bound $T_{\mathrm{wcet}} = 250$ µs, the trace invalidates the joint claim that the isolated baseline is bounded and proposal-side interference is zero. The overrun alone does not distinguish an underestimated baseline from interference; attributing it to interference requires independently justifying the baseline. Once the 90 µs of local blocking and RTOS task interference is charged, the loaded 99th percentile also pushes the response beyond the enforcer deadline $T_{\mathrm{deadline,enf}} = 400$ µs. A loaded trace of this shape would reach the verdict that the thermal analysis of section 13.4 reached from a model, without relying on that model,

and the verdict would stand even if the model were wrong. The percentiles here are illustrative; the point is that a real trace on the target, not an argument, is what can refute a placement.

Even if a 10-million-tick stress trace records zero deadline violations, that outcome demonstrates only that interference remained bounded across the specific microarchitectural states generated during the test. A qualification report must document the full latency distribution, observed maximums, total sample counts, and test durations, while explicitly listing all unexercised physical conditions, such as long-term power delivery degradation, transient electromagnetic interference, and silicon aging.[14] When an empirical contention test fails, the engineering team must re-evaluate its architecture: partition memory channels, implement strict arbiter bandwidth caps, restrict proposal workload concurrency, or relocate the enforcer to physically isolated silicon. Conversely, when a campaign passes, it provides empirical evidence that supports the analytical model within the tested parameters, without mistaking a finite empirical sample for an absolute mathematical proof.

[14] **Transistor Aging (BTI and HCI)**: Bias temperature instability (BTI) and hot-carrier injection (HCI) gradually increase transistor threshold voltages over operational lifetimes. This shift degrades switching speeds across logic gates, an impairment exacerbated during transient voltage droops. Because engineers cannot measure multi-year degradation on fresh silicon, production designs incorporate explicit end-of-life timing guardbands. A physical stress campaign on new development boards cannot certify silicon against aging; the placement qualification record must formally log aging as an analytically budgeted, rather than empirically measured, condition.

Checkpoint 13.3: Refuting a placement

A placement claim is only as strong as the test that could have refuted it. Verify the core empirical criteria that defend this boundary:

- ☐ **Threshold arithmetic**: A loaded campaign on a shared-die candidate records one cycle of 300 µs. By how much does it exceed the declared 250 µs, how much of the 400 µs deadline does it leave once blocking and interference are charged, and which claim does it refute?
- ☐ **Isolation and interference**: Can you explain why a loaded cycle below the declared worst-case execution time does not prove that the shared hardware added zero interference?
- ☐ **Model and resource premises**: Can you explain which binary, path, memory, peripheral, and resource-control assumptions permit a sound execution bound on the discrete microcontroller or a shared multicore SoC?
- ☐ **Paired loads**: Can you explain why the enforcer's cold refusal routine must be evaluated concurrently with the application processor's diagnostic memory dump, rather than measured in isolation?

13.8 The Placement Record

Selecting the discrete safety microcontroller on paper does not clear the mobile manipulator for release while its loaded execution fields remain unpopulated on the target hardware. The machine now has an assigned placement for its permission path, an explicit deadline, an unloaded execution estimate, and a factorial stress campaign designed to falsify hardware isolation, but none of those timing properties can support a release sign-off until they are recorded alongside the exact environmental and operational conditions under which they hold.

The **placement record**, the eleventh record in the record chain, formalizes where the safety permission path executes and supplies the physical evidence that its timing bounds remain invariant. It consumes the enforcement record of section 12.11, inheriting the declared worst-case execution time and hard deadline of the permission path. To these timing constraints it binds the evidence that would show the bound holding under peak proposal load on production silicon. That evidence consists of the assigned execution domain, privilege ring, nominal loop period, unloaded and loaded observed maxima, AXI interconnect QoS arbitration settings, PDN inductive droop limits, thermal trip thresholds, enabled hardware mitigations, and a cryptographic digest of the external test report (table 13.4). An observed loaded maximum that exceeds the declared worst-case execution time immediately refutes the placement claim. Conversely, observed maxima that fall below the bound validate only the specific conditions exercised during testing; for any empirical latency distribution, sample maxima provide supporting evidence for an upper bound rather than an analytical substitute for it.

The placement record bridges architectural configuration registers with direct physical measurements. Register readbacks of `execution_domain_id` and `privilege_and_ring` document the compute domain topology and execution privilege against architectural status registers, while

↩ That measured maxima support but cannot replace an analytical worst-case bound is established in section 4.5.

`shared_axi_channel_qos` records interconnect arbitration configurations and verifies whether unprivileged software can reconfigure bus priorities before stress tests validate the resulting worst-case latency bounds. Alongside those digital settings, `max_pdn_droop_thermal_trip` ties voltage supply margins and junction temperature limits to high-bandwidth oscilloscope probe traces and on-die thermal telemetry gathered under full compute load. Together, `enforcement_record_digest` and `test_report_digest` establish cryptographic provenance by binding the placement record directly to its upstream timing contract and empirical test report.

Table 13.4: Placement record header: Concrete fields defining the physical compute, memory, thermal, and electrical bounds for deterministic safety enforcement. Loaded observed maximum must remain at or below declared WCET, $T_{\text{wcet}} = 250$ µs, under full cognitive stress.

Field Name	Type & Units	Physical System Invariant & Validation Rule	Mobile Manipulator Parameter / Value
`execution_domain_id`	`uint64_t` (enum)	Explicit domain topology; confirms physical silicon segregation	`0x04` (selected dedicated dual-core lockstep MCU; qualification pending)
`privilege_and_ring`	`uint64_t` (privilege)	Record target-specific privilege and memory-protection configuration	Proposer: Unprivileged Linux; Enforcer: Bare-Metal MPU
`nominal_period_ns`	`uint32_t` (ns)	Enforcer tick T_{tick}; matches enforcement record `loop_period_ns`	1 ms (1,000,000 ns)
`hard_deadline_ns`	`uint32_t` (ns)	Physical deadline $T_{\text{deadline,enf}}$; matches enforcement record `deadline_ns`	400 µs (400,000 ns)
`unloaded_observed_max_ns`	`uint64_t` (ns)	Largest cycle without load; must satisfy $t_{\text{unloaded}} \leq T_{\text{wcet}}$	`0xFFFFFFFFFFFFFFFF` (pending; illustrative estimate 135 µs belongs in report)
`loaded_observed_max_ns`	`uint64_t` (ns)	Peak execution duration under adversarial stress; all ones until qualified	`0xFFFFFFFFFFFFFFFF` (Awaiting empirical test report)
`shared_axi_channel_qos`	`uint64_t` (QoS mask)	Bus QoS configuration plus measured or justified service bound	Selected TCM-local bus; topology and access bounds pending verification
`max_pdn_droop_thermal_trip`	`uint32_t[2]` (mV; m°C)	Maximum tolerable rail droop and junction thermal trip threshold	Pending target-device characterization; shared-die example values are not MCU limits
`hardware_mitigation_flags`	`uint8_t[32]` (bitmask)	Qualified hardware isolations only; selections remain in report	Pending verification; selected rail, TCM, lockstep, and watchdog listed in report
`enforcement_record_digest`	`uint8_t[32]` (SHA-256)	Cryptographic link to upstream enforcement record	SHA-256 digest of table C.13
`test_report_digest`	`uint8_t[32]` (SHA-256)	Cryptographic link to full factorial stress campaign report	Unset until a test report exists

The record architecture separates concerns into two distinct structures. A compact, fixed-size header stores critical platform configurations and observed execution maxima for low-overhead verification at boot time. This header anchors an external test report by its cryptographic hash. The report holds all non-fixed evidentiary records: complete hardware inventories, empirical latency distributions, total sample counts, environmental conditions, active hardware mitigations, and unresolved operational boundaries.

↪ **Byte layout:** The placement record's field offsets and sizes are given in section C.15.5.

For the mobile manipulator, the header records the nominal 1 ms tick period and 400 µs hard deadline, while the test report archives the preliminary 135 µs unloaded execution estimate. Both observed-maximum fields remain initialized to all ones (`0xFFFFFFFFFFFFFFFF`), and the dedicated power rail cannot yet be documented as an approved mitigation because full empirical qualification remains pending. The loaded execution field remains unpopulated because no stress campaign has yet been executed on this machine. Populating this value requires running the factorial contention campaign of section 13.7 directly on physical hardware. In that campaign, the discrete microcontroller executes its safety loop while the host application processor saturates neural accelerator clusters with trajectory proposals and writes continuous trace logs at maximum junction temperature, triggering

the refusal branch across stress trials. Every cycle time recorded during this contention benchmark must remain at or below the declared worst-case execution time, $T_{\text{wcet}} = 250\ \mu\text{s}$. In addition, the onset of powered deceleration, timed from the arrival of the last valid trajectory renewal, must occur within 82 ms. Until physical instrumentation confirms these bounds, the permission-independence claims of the safety case rest on unverified assertions, preventing any deployment safety release.

The external test report inventories all shared silicon and platform resources: memory channels, cache partitions, DMA engines, and power rails, alongside every competing bus master. For each resource, the report documents the hardware arbitration configuration and the resulting contention latency. For the safety permission rail, it records the selected 2 s hold-up capacitance and its pending qualification by a supply-loss fault-injection campaign. The report also defines the electrical isolation boundary by enumerating allowable rail claimants, restricting access strictly to the microcontroller, the gate-drive logic, and the spring-applied brake release coils, while entirely excluding unverified proposal-side compute loads.

Any contention measurement is meaningful only in the context of its exact operating state. The test report therefore qualifies each latency distribution with cryptographic hashes of the active neural model and system firmware, DVFS policies, enclosure thermal interface materials, ambient and junction temperatures, power rail voltages, interconnect arbitration weights, synthetic traffic generation profiles, sensor sampling rates, measurement instrumentation calibration, sample counts, and total test duration. The report records these parameters alongside full latency histograms and explicit enumerations of unexercised operational states, while the fixed header exposes only the scalar maxima for fast verification. For example, the 10^7-tick trace evaluated in section 13.7 spans only 2 h 46 min 40 s of operation on a single physical machine. Such exposure demonstrates that the system survived specific benchmark conditions, but it does not exclude rare multi-contender collisions or provide a statistical bound across an entire production fleet.

Every placement record entry requires a predeclared falsification criterion formulated before executing hardware tests. This criterion defines the physical boundary that constitutes architectural failure, such as any safety enforcement cycle exceeding the declared 250 µs worst case during concurrent neural accelerator bursts and DMA transfers. The record documents the empirical execution distribution against this criterion and registers whether the isolation hypothesis survived or failed. When contention violates the latency budget and forces an architectural revision, the record details the specific mitigation deployed, such as configuring bandwidth throttling on the neural accelerator memory bus. The test entry must also explicitly report boundary conditions left unexercised during the test run, such as operating temperatures above the 45 °C bay ambient, multi-bit error injection in tightly coupled memory, or cascading sensor transceiver failures. Chapter 15 then consumes the documented arbitration points and shared power rails as a target map for hardware and software fault injection. It deliberately corrupts shared structures to test whether fault containment matches predicted isolation domains. Chapter 16 incorporates the verified execution bounds and unexercised operational limits into the formal safety case, turning raw physical measurements into auditable evidence for real-world deployment.

With the placement record in place, the stopping budget is specified row by row for a wheeled mobile manipulator whose resident fallback is a brake-to-stop suffix on stable ground. A budget developed for one embodiment earns trust as a method only if it survives a machine with different dynamics. A legged humanoid, whose fallback trajectory must dynamically sustain balance while traversing unstructured terrain, provides the most demanding stress test of these principles (perspective 13.1).

Systems Perspective 13.1: When the fallback is a step

Question: Which rows of the stopping budget survive when the fallback is a step rather than a stop?

When hardware placement supports the deterministic execution contribution to the aggregate pre-brake delay τ_{delay}, the stopping-budget framework applies directly to the mobile manipulator's powered braking maneuver, with dispatch-to-admission delay allocated and drive-energy qualification still open. However, a bipedal humanoid walking mid-stride possesses no sta-

tionary equilibrium into which it can instantaneously brake. Its fallback maneuver is dynamic, a recovery step. Every row of the stopping budget must consequently be re-evaluated for dynamic stepping:

- **Observation age survives.** Temporal latency continues to translate directly into spatial displacement, the conversion stated in section 8.4. On an articulated sensor head undergoing angular rotation, this error scales with viewing distance: a feature at range r traverses space at tangential speed $v_{\text{tangential}} = \omega r$ under an angular rate ω. For instance, an uncalibrated 10 ms camera–IMU temporal offset during a 1.5 rad/s head pan misidentifies the position of an obstacle located 5 m ahead by 7.5 cm.
- **Commitment semantics change.** The latched zero-velocity trajectory suffix established in section 11.5 is replaced by a certified recovery stepping trajectory. Rather than terminating in a stationary rest configuration, this contingency plan must be admitted alongside the nominal motion command to guarantee safe placement of the swing foot onto an admissible support polygon.
- **The safety inset changes.** The geometric obstacle clearance margins derived in section 12.5 no longer suffice to guarantee dynamic balance. A recovery step demands full closed-loop hybrid dynamics, relative-degree constraint analysis, identification of reachable capture regions, and actuation limits under torque saturation. Kinematic tracking uncertainty and ground reaction force disturbances must propagate directly into this forward invariance set before a valid safety inset can be calculated.
- **The placement record expands.** Because a zero-joint-velocity command mid-stride does not establish a balanced terminal state, the hardware isolation boundary must encompass all computational, interconnect, and power resources required to execute the active recovery step. Just as the wheeled manipulator's placement record isolates the energy storage and gate drivers needed for powered braking, the biped's placement record must certify dedicated bus bandwidth, joint controller execution enclaves, and surviving drive-energy paths for active balance recovery. Rail hold-up preserves supervisory logic; it does not by itself supply the recovery step.

13.9 Fallacies and Pitfalls

Placement determines the physical resources shared by complex proposal algorithms and critical enforcement routines. Traces of normal operation cannot prove these systems are truly independent when rare physical events, such as power voltage transients, clock faults, memory contention, or a stalled producer, stress those shared hardware pathways.

Fallacy: *Logical privilege rings protect real-time enforcers from shared-rail electrical droop.*

Privilege checks govern digital access, while the rail supplies the gates that perform those checks. The illustrative droop calculation predicts a 39 percent gate-delay increase under its stated model; only device characterization can determine the resulting setup margin or reset behavior. Lockstep cores sharing a rail can share a failure, so comparator coverage does not establish supply independence. The selected isolated rail removes one coupling path and still requires common-supply fault tests.

Pitfall: *Sharing phase-locked loops or reset controllers across proposal and permission domains.*

A separate core can still stop when a host-controlled reset asserts or slow when a shared governor changes its clock. The topology must trace each clock and reset to the controlling hardware, then test the relevant faults under load. Naming a controller a safety island does not establish that these dependencies are independent.

Fallacy: *Low average memory bus utilization guarantees bounded read latency for real-time safety tasks.*

Average utilization leaves the arrival order and longest queue unspecified. Plain FIFO queueing at the SoC's full bandwidth is not the danger, as notebook 13.1 showed. The read tail comes from an FR-FCFS controller that keeps passing the safety read in favor of a streaming accelerator's row hits, or from the miss-handling contention of section 13.3.2, and neither shows in an average. In an illustrative counterexample, such a tail stretches the snapshot read to 320 µs, which leaves 80

µs before the 400 µs deadline, less than the 95 µs needed for evaluation and staging even before blocking and interference are charged. A service bound, qualified bypass, or independent local memory addresses that failure; a low average does not.

Pitfall: *Using blocking software mutexes across inter-processor communication boundaries with untrusted neural policies.*

A mutex held by a stalled proposer transfers control of the enforcement deadline to that proposer. An unbounded seqlock retry loop has the same defect when publication remains odd. The selected boundary protocol makes one read attempt per tick and discards a collision. That discard leaves an active valid command in force only while its own evidence, state, and lease remain admissible; it neither resets the lease nor forces premature revocation. Memory ordering and bounded copy time remain part of the placement evidence.

13.10 Summary

Part I built the mobile manipulator on a hypothesis: its learned proposer runs on application processors and accelerators and its permission path on a bare-metal microcontroller. This chapter turned that hypothesis into a placement decision that evidence can refute. The allocation alone does not separate the two paths, because privilege boundaries govern none of the physical resources the two paths still share. Partitioning therefore requires a justified timing bound and fault evidence, with loaded tests able to refute the claim.

The evidence must cover the physical resources that the placement still shares. A loaded test supports a scoped claim about its workload, arbitration policy, supply, clock governance, and thermal conditions. Separate processor packages remove some coupling paths, but the board's common supply and communication links remain part of the argument. Across the link, the boundary contract keeps a stalled proposer from holding the permission deadline. The reader makes one bounded attempt per tick and discards a torn record, and a windowed watchdog trips on feeds that arrive too early as well as too late.

The placement record carries that evidence forward. It takes the permission path's declared worst-case execution time and deadline from the enforcement record and adds the loaded observed maxima for the declared test conditions, the shared-resource queue and power headroom, the common power, clock, reset, and memory failure paths, and the conditions left untested. The machine's own record holds a 135 µs illustrative unloaded estimate against the declared 250 µs worst case inside the 400 µs deadline. It still awaits loaded test results, which must name the arbitration policy, clocks, sample count, and physical endpoint before any release claim can rest on it.

The observation contract, belief record, intent lease, trajectory record, enforcement record, and placement record now describe one machine. Its timing must hold across the chain, including the memory, power, and communication paths between stages. Placement makes the execution premise of principle 3 falsifiable through a threshold, a stress campaign, and a record of what remains untested. Part IV inherits the conditional stopping margin, the unverified premise that aisle crossings are procedurally restricted (section 12.3.1), and the placement record's empty loaded field. It also inherits a dispatch-to-admission interval Δ_{da} that this chapter has allocated at 63.3 ms, inside the 100.8 ms the spare can pay for, but not yet measured. Seven relations carry the chapter's quantitative argument, and table 13.5 records each with the decision it settles and the place it is derived.

Table 13.5: Key equations of workload placement: The relations behind the chapter's contention, thermal, supervision, falsification, and offload decisions, with the place each is derived.

Equation	What it bounds or decides	Derived
$t_{\mathrm{queue}} = \sum_{k \in Q} D_{\mathrm{vol}\,k} / \mathrm{BW}_{\mathrm{peak}} + N_{\mathrm{conflict}}(t_{\mathrm{RP}} + t_{\mathrm{RCD}})$	How long a safety read waits behind a FIFO backlog on shared DRAM; a bound exists only if the controller limits the backlog or lets the read pass	equation 13.1
$f \le \dfrac{T_{\mathrm{wcet}}/t_{\mathrm{unloaded}} - 1}{r_{\mathrm{slow}} - 1}$	The largest share of the tick that may stall on shared-cache misses slowed by r_{slow} before the loaded tick crosses the declared bound	equation 13.2

Equation	What it bounds or decides	Derived
$\Delta V_{\text{droop}} = L_{\text{pkg}}\, dI/dt + \Delta I\, R_{\text{pkg}}$	The first-order rail disturbance a current step imposes on a controller sharing its supply	equation 13.3
$T_{\text{j}}(t) = T_{\text{j,target}} + (T_{\text{j,start}} - T_{\text{j,target}})\, e^{-t/\tau_{\text{th}}}$	How long a throttled clock persists after the load stops, and so how many ticks a shared thermal path exposes	equation 13.4
$\lvert T_{\text{feed}} - T_{\text{period}} \rvert \le (c_{\max} - c_{\min}) + J_{\text{phase}}$	The service window a windowed watchdog must accept from a healthy tick, which sets its early trip and the floor for its late one	equation 13.5
$t_{\text{enf}} = t_{\text{iso}} + T_{\text{interf,shared}},\ t_{\text{iso}} \le T_{\text{wcet}} < T_{\text{deadline,enf}} < T_{\text{tick}}$	The falsification threshold: a loaded cycle above T_{wcet} invalidates the joint baseline/isolation contract; the cause may be an underestimated baseline or interference	equation 13.7
$t_{\text{net}}^{\text{tail}} + t_{\text{proc}}^{\text{tail}} \le W$	Whether an off-board result can renew the lease or become an admitted chunk	equation 13.6

Key Takeaways: Silicon placement and memory contention

- **Logical separation is a hypothesis about hardware:** Privilege rings govern which addresses a task may touch, not where its requests wait, which rail feeds it, or which clock and reset tree it depends on. Loaded tests can refute the claim; justified bounds and fault evidence must support it.
- **Averages cannot bound a deadline, and bandwidth is not the main threat:** On a shared die at full bandwidth, more than 82 FIFO backlogs must precede the snapshot read before it crosses the declared worst-case execution time. Shared-cache miss handling is far stronger: measured slowdowns of 21× and more than 300× cross the declared bound once 4.3 percent or 0.28 percent of the tick is miss stall. Only private memory or regulated co-runners bound that multiplier.
- **Couplings act on four timescales around a millisecond tick:** Rail droop acts in nanoseconds and interconnect queueing in microseconds, below the millisecond tick they threaten. Silicon thermal throttling, by contrast, persists for seconds after the load stops, and chassis structural and battery pack self-heating accumulates over multi-hour shifts. In the rejected shared-die placement, a halved clock stretches the enforcer's 250 µs cycle to 500 µs while inference runs and for at least 2,175 ticks after it stops.
- **The declared bound is the falsification threshold:** The declared worst-case execution time bounds the tick in isolation, and the selected placement claims that proposal-side load adds no interference term, so any loaded cycle above it refutes the placement's timing premise even when the deadline still holds. A passing trace supports only the states it tested.
- **A refuted claim forces a priced choice:** Regulation and reservation cost idle capacity, coloring and partitioning cost working set, workload reduction costs policy authority, and relocation adds a board link. On the machine that link costs 1.31 ms of a 63.3 ms dispatch-to-admission allocation dominated by inference and validation.
- **Platform exposure is a placement constraint:** An on-die safety island with its own crystal, rail, and memory removes every die-level coupling except temperature, the reset chain, and the fabric its proposals cross. As of 2026, however, the commercial modules that carry the machine's application processor do not enable it, so the permission path moves to a discrete controller.
- **The placement record bounds the deployment envelope:** It takes its declared worst-case execution time and deadline from the enforcement record and adds loaded observed maxima, thermal headroom, bus arbitration, mitigations, and untested conditions. On the mobile manipulator the measurement fields are still empty, so the independence claim reaches release review without loaded qualification evidence.

Placement is where the third law becomes a property of hardware. Proposal is not permission only while the proposer cannot reach the permission decision through anything the two share, and on a real machine that includes memory, supply, clock, reset, and heat. The useful habit is to read every architecture diagram as a list of claims, one per shared resource, and to ask of each one what loaded measurement would refute it. The running machine leaves Part III with that placement decision and an explicit evidence gap: the record names the resources that must preserve the permission deadline, the measurements that could refute their bounds, and the fallback that must remain available if the proposer fails. Governing the machine means judging such conditional claims, and the next proposer to claim authority will be a person.

13.11 Historical Perspective and Further Reading

Avionics met the placement problem first. Once integrated modular avionics put functions of different criticality on one processor, the certifying question became whether a fault or overrun in one function could reach another. In Rushby (1999), the answer separates into two obligations: spatial partitioning, which protects memory and devices, and temporal partitioning, which protects the time each function is promised. The ARINC 653 interface turned the temporal half into fixed windows of a repeating frame, and Kopetz (2011) built whole architectures on a global time base so that timing could be designed rather than discovered. Automotive practice later wrote the same concern into ISO 26262 as freedom from interference and dependent-failure analysis (International Organization for Standardization 2018).

The bound itself had to be computed before it could be defended. Puschner and Koza (1989) showed how to derive a maximum execution time from program structure. Abstract interpretation (Cousot and Cousot 1977) gave analyzers a sound way to model caches and pipelines, and implicit path enumeration (Li and Malik 1995) turned the longest feasible path into an integer linear program. Wilhelm et al. (2008) surveys the tools that combined them, while Lundqvist and Stenström (1999) showed that local worst cases need not compose into a global one. Vestal (2007) then gave each task a budget per assurance level, the idea that lets a proposer overrun while an enforcer may not (Burns and Davis 2017).

Multicore processors undid the single-core premise. Cores that share caches and memory controllers turn the memory wall (Wulf and McKee 1995) from a throughput limit into a deadline problem. The software answers followed in quick succession: phased execution that confines memory access to a separate phase (Pellizzoni et al. 2011), per-core bandwidth regulation (Yun et al. 2013), and bank-aware allocation (Yun et al. 2014). Measurements then showed that partitioning capacity leaves the miss-handling structures shared (Valsan et al. 2016; Bechtel and Yun 2019), and certification caught up with AC 20-193 (Federal Aviation Administration 2024). What this chapter adds is the physical side of the argument. The enforcer's bound is charged against a stopping distance, heat and supply couple the paths on timescales no scheduler sees, and the evidence travels to release in a placement record.

For further reading, six works trace the ideas this chapter composes.

- Rushby (1999) states the requirements for partitioning processors shared by functions of different criticality and separates the spatial and temporal obligations that the dependent-failure inventory of table 13.1 checks row by row.
- Kopetz (2011) develops real-time system design from a global time base, the discipline behind fixed ticks, deadlines, and time-triggered exchange.
- Wilhelm et al. (2008) surveys static, measurement-based, and hybrid methods for worst-case execution time and the premises each rests on, the comparison behind section 13.7.
- Burns and Davis (2017) reviews mixed-criticality scheduling from its origin to multicore platforms, the theory behind letting the proposer lose renewal while the permission tick survives.
- Yun et al. (2013) introduces per-core memory-bandwidth regulation, the mechanism that turns an unbounded interference multiplier on a shared die into a bounded one.
- Federal Aviation Administration (2024) is the current certification guidance for multicore processors, and it shows what a regulator requires before a shared-die timing bound can be believed.

What's Next: From compute placement to intervention

When the slowest response delay belongs to a human operator, the stopping budget faces an interval that no silicon placement can bound. Every delay examined in this chapter belonged to the machine (a queued read, a stretched gate, a throttled clock), and each can be bounded or refuted by an empirical test on the chassis. Chapter 14 opens Part IV by addressing delays that originate outside the machine. A remote assistant taking over the mobile manipulator in an aisle introduces human reaction time over a network link that the onboard permission path cannot control, spending clearance from the exact same stopping budget. The authority to propose motion must then pass safely between the learned policy and the human operator while the permission path continues to validate every commanded actuation. That handover must never induce the hazardous motion it was intended to prevent, and every control tick must immutably record which entity held proposal authority.

IV

GOVERNING THE MACHINE

DRAFT

DRAFT

Governing the Machine

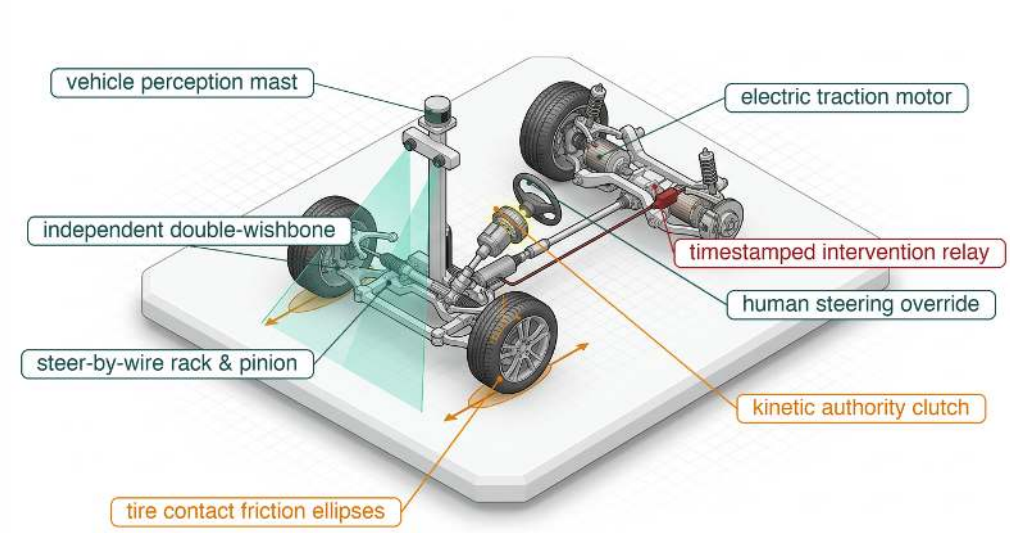
Demonstrating a physical AI model in a controlled laboratory is a milestone. Outside the workbench, dust obscures lenses, lighting changes, wireless networks drop packets, gearboxes wear, and human coworkers share the machine's path. Each change can invalidate a premise used to permit motion. Part III leaves the running machine with conditional answers rather than settled ones: its stopping margin holds only while the unmeasured dispatch-to-admission interval stays inside its allocation, passing a blind rack corner (section 9.7) rests on an unverified procedural restriction of aisle crossings, and the placement record's loaded field remains empty. Part IV turns those open questions into intervention rules, fault tests, an operating decision, and a named owner for each decision behind it, beginning with the one delay that no test on the chassis can bound, a person's. The engineer must be able to explain both the useful work the machine may perform and the conditions that require restricting or stopping it.

Principle 4: Permission must be earned

Invariant: Authority to operate is granted per operating condition by evidence whose age, provenance, and limits are recorded, and it expires when that evidence does. Zero failures in n independent, stationary trials place an approximate upper bound of $3/n$ on the per-trial failure probability at 95 percent confidence (section 7.6).

Implication: The operating decision joins evidence of useful task completion with evidence that the machine contains the specified faults and hazards. Who may command it, what the tests challenged, and which conditions it may enter are decided on that record, not on a demonstration. A premise that evidence cannot settle restricts operation through a reduced envelope, a passive limit, or refusal, and it stays open until a declared test closes it.

- **Supervisory Intervention (chapter 14):** Decides who holds authority over each actuator at each instant when a person and a learned proposer share the machine, and produces the authority record.
- **Adversarial Verification (chapter 15):** Decides which fault tests challenge each claim and how their outcomes count, and produces the fault record.
- **Deployment Release (chapter 16):** Decides whether the machine may operate and under which standing conditions, and produces the release manifest.
- **Responsible Physical AI (chapter 17):** Decides who answers for each decision behind an admitted action, which human roles a person can actually perform, and which people bear the machine's risk and appear in its records. It produces the approval record.



Part IV hands forward a release manifest, an approval record, and the premises they could not close. The release exercise preserves refusal for the illustrative machine with missing qualification evidence, then uses a separately stipulated evidence packet to show how restricted useful service could be supported. Neither branch invents completed tests. The manifest binds the evaluation record, the fault records, the placement record, and the authority record into claims with a verdict (unconditional operation, conditional operation, or refusal) and standing conditions that revoke it. The approval record names the person who approved each decision behind them, so that a decision with no owner refuses operation like an unknown premise. The conclusion in chapter 18 synthesizes

what the engineer can now build and justify, then transfers the method to an unfamiliar machine. Open premises enter a residual-claims register with their restrictions, owners, and closure tests; they guide the next measurement, learning experiment, architectural change, or narrower task.

Purpose

Why can handing a moving robot to a human operator cause the collision the handover was meant to prevent?

Most deployed robots keep a person in reserve for the situations their learned policies cannot handle, and that reserve is usually treated as the final safeguard. A person, however, needs a large fraction of a second to respond even while watching closely and several seconds after only monitoring. A machine moving at walking pace covers meters in that time, so a request for help can consume the very clearance the help was meant to protect. Taking over also creates hazards of its own. Two controllers that each believe they hold a joint can command it at once, a controller that believes the other still holds it can leave it unattended, and an abrupt switch between their commands jolts the drivetrain and the load it carries. A takeover that grants unchecked control lets a startled or lagging operator drive the machine into a rack. A log that does not mark who commanded each instant can neither settle what caused an incident nor keep the machine's own near-failures out of the demonstrations it later learns from. Authority can change hands within a single control cycle, but the momentum already delivered across the causal boundary cannot be recalled, so a takeover must be engineered as a control action with its own deadline, its own limits, and its own record.

Learning Objectives

- Specify operator permissions through capability matrices that bind each authenticated role's operations to physical channels, preemption tiers, and clearance-derived deadlines
- Select a state-dependent local fallback that remains physically feasible while human intervention is pending
- Calculate the latest fallback time and takeover speed ceilings from human reaction latency and remaining physical stopping clearance
- Evaluate the inherited chunk lease and the chosen manual lease against their modes' stopping reserves and available fallback mechanisms
- Design authority handshakes that keep one owner on each actuator output and size fixed-endpoint C^2 command blends within each channel's rate limit
- Diagnose mode confusion in split-channel handovers and specify the per-channel annunciation that keeps an operator's model of ownership current
- Evaluate whether an authority record provides the cryptographic and kinematic evidence needed to reconstruct post-incident fault causality

14.1 Shared Authority

When a pallet blocks an aisle and the warehouse mobile manipulator requests a remote assistant to take over, the transfer introduces a delay that no test on the chassis can bound, because it belongs to a person. Part III left the running machine with a stopping budget whose every term belongs to the hardware, each with a declared bound and a loaded test that could refute it, even where the test has not yet run, as for the dispatch-to-admission interval Δ_{da} that section 13.6.2 allocated but did not measure. Part IV begins where a person enters that loop.

Supervisory intervention transfers the right to propose actions from an autonomous policy to a human operator, and eventually returns that authority to the machine. Nearly every embodied machine learning system operating in the physical world relies on this exchange. Remote teleoperation assistants clear blocked aisles and resolve scenes that warehouse robots and autonomous vehicles cannot interpret on their own. Safety drivers and teach-pendant operators step in whenever an operational policy drifts outside its design envelope, and their corrections protect the hardware and supply demonstration data for later retraining. Engineering block diagrams often reduce this supervision to a single switch or an external arrow pointing into the plant. In the physical world, however, kinetic energy does not pause while a multiplexer toggles inputs. Authority transfer is a control maneuver with its own deadlines, and it must be executed in coordination with the slowest and least predictable element in the loop, the human operator.

How often that exchange happens on a mature fleet is a matter of public record in one jurisdiction. California requires every company testing autonomous vehicles on its public roads to file annual reports of autonomous miles and of the disengagements, transfers of control to a person, that occurred during them (California Department of Motor Vehicles 2026). Figure 14.1 plots the filings of one long-running fleet, Waymo's.

Over the decade the safety-driver rate rose from about 1,200 to about 19,200 miles per disengagement, yet the fleet still reported 174 takeovers in its latest year, and the series is far from monotone. Between 2020 and 2021 the rate fell 3.8× while the miles driven grew 3.7×. Driverless testing reports one disengagement every 71,800 miles, 54 in its latest year. Two consequences follow for the machine. Human authority is not a phase a capable system grows out of; even the most experienced fleet exercises it every year, so the transfer mechanism is a permanent part of the design. The reported rate also depends on where the fleet drove and on what its operator chose to count, which is why an intervention count tells a reviewer how often the exchange happened but not, by itself, how well either party performed it.

↪ The two permit series as two stages of permission to operate, and how a machine leaves one stage for the next, are developed in section 17.4.

The central engineering problem of supervisory intervention is how authority can change hands on a moving machine without exhausting stopping clearance, letting two controllers drive the same actuator at once, or losing track of who commanded each instant. The fourth law, permission must be earned (principle 4), frames the answer, and here Part IV applies it for the first time to a person.

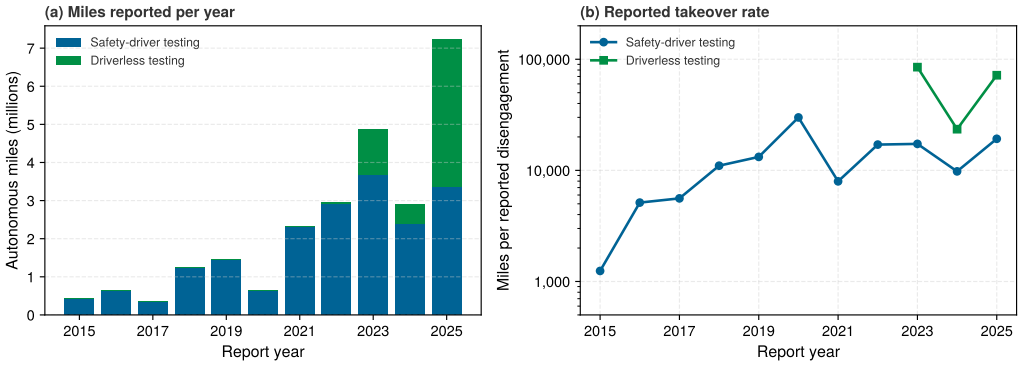

Figure 14.1: A decade of reported takeovers: Waymo's annual filings to the California DMV. (a) Autonomous miles driven on public roads under the safety-driver testing permit and the driverless testing permit. (b) Miles per reported disengagement under each permit, on a logarithmic axis. Each company defines which disengagements are reportable, and the regulator notes that the reports are not designed for comparison across companies; commercial deployment miles are excluded. Early years are transcribed from the filed PDFs. Data from California Department of Motor Vehicles (2026).

Like an autonomous policy, a human operator receives control authority only while valid evidence supports that grant, and loses it the moment that evidence lapses. Until the platform's permission path checks it, every command from an operator is an untrusted request that cannot cross the causal boundary. A safe transfer must therefore bind each authenticated role to explicit actuator channels and timing bounds, commit ownership atomically on a control tick, blend reference changes within drivetrain rate limits, and log who held authority at every cycle for incident review and policy retraining.

For the warehouse mobile manipulator, this timing constraint is direct and unforgiving. When the blocked aisle prompts the machine to request a remote assistant, at its chosen 1.3 m/s aisle speed a 4.5 s pause before braking, the design out-of-loop takeover time that section 14.2.2 derives from driver take-over studies, carries the machine 5.8 m, more than five times its 1.10 m rack-end clear distance. An operator's intervention request reaches a chassis that is already in motion under an admitted command; human intent cannot erase physical momentum or make an actuator respond in zero time. The permission path resolves this transition in two stages. The arbiter that selects among the fallback ladder's rungs also decides, for each channel, which source holds the right to propose: the learned policy, the operator, or, once that authority lapses, a fallback rung. The enforcer then admits or rejects each setpoint from the selected source against physical envelope invariants. Both stages run deterministically on a dedicated safety microcontroller (MCU). Source selection precedes the enforcer's check, and rung selection follows it whenever the check fails, so human intervention adds a new input to the arbiter, a person, rather than a new component. Throughout this process, the plant must keep enough clearance to bring itself to a safe halt. Switching setpoints in a single step demands a sudden torque jump that strains motor drives, gearboxes, and payload stability. Delaying the transfer, in turn, uses up the remaining stopping margin even when both the learned policy and the human supervisor produce sensible trajectories on their own.

Because momentum and kinetic energy sit on the physical side of the causal boundary, the machine keeps moving under the last admitted setpoint while the remote operator pieces together what is happening in the aisle. That mental reconstruction is slow. It is the paradox Lisanne Bainbridge called the *ironies of automation* (Bainbridge 1983): engineers automate routine work to remove human error, yet leave human operators to handle the hardest, unmodeled edge cases that the automation cannot solve, where plant dynamics are abnormal and time is shortest. An operator who only monitors a screen also loses both manual feel and a current mental model of how the plant is moving. When an unexpected hazard forces a sudden takeover, that operator must act under tight time pressure with little context. Human vigilance fades quickly when watching for rare faults, and automation complacency makes the problem worse whenever secondary tasks compete for the supervisor's attention (Parasuraman and Manzey 2010). Decades of human factors research confirm that passive monitoring erodes situation awareness[1] and adds long decision delays when

↪ Whether a human role that needs this much time can count as a safety measure at all, and who is blamed when it cannot, is developed in section 17.3.

1 **Situation Awareness Levels**: Endsley (1995) set out situation awareness as three levels: perceiving the elements of a scene, comprehending what they mean together, and projecting their state forward. The levels fail separately. A remote assistant can see the pallet without projecting that the base will not stop short of it, which is why a console that reports where the operator is looking cannot shorten the response budget (section 14.6).

automation fails without warning (Endsley and Kiris 1995). The machine must therefore protect its own collision-free stopping envelope throughout the takeover window. Faster networks can trim milliseconds from packet transport, but they cannot shorten the time a person needs to see a hazard, decide what to do, and move a hand control.

↩ The causal boundary, across which admitted motion cannot be recalled, is established in section 1.4.

Cutting power to a moving base lets it coast, whereas cutting power to a loaded manipulator arm without a holding brake drops the payload. Each stage of an intervention therefore needs a fallback matched to the machine's current state: a moving base may need controlled regenerative braking followed by a mechanical brake once stopped, while an arm carrying a tote needs an active, gravity-compensated position hold. Each response depends on the specific sensors and power rails qualified to carry it out. Because local damping, torque inhibition, and full power isolation produce different physical trajectories, the system cannot treat them as interchangeable steps on a generic escalation ladder; a protective input must invoke the validated fallback built for the plant's current motion state.

↩ The fallback ladder, from which the arbiter selects a state-matched protective response on every tick, is established in section 12.9.

Autonomous and manual proposal rights operate under separate, explicit leases. The learned policy proposes trajectories under the action-chunk lease established in section 4.4, while a teleoperation session receives a distinct, clearance-budgeted manual lease. Rejecting an invalid replacement command from an operator does not invalidate an active, previously admitted setpoint whose evidence, state bounds, and lease duration remain healthy. If either controller exhausts its lease duration or violates its underlying safety premises, the permission path immediately triggers the appropriate local fallback.

The permission path prevents split-brain command contention by pairing an upstream source arbiter with **exclusive actuator-output ownership**. In the 1 kHz control architecture analyzed here, the right to propose on a set of channels is a single object, the **proposal token**, and the arbiter grants it to one source at a time. An authority commit revokes the learned policy's proposal token and latches its last approved setpoint; the admission enforcer remains the sole, non-bypassable writer to the physical actuators before, during, and after the transition. Standard bus protocols such as Controller Area Network (CAN) arbitration serialize message frames from multiple transmitters, but bus-level arbitration does not establish control-layer authority. If two nodes broadcast conflicting yet syntactically valid frames to the same motor drive, the actuator chatters between setpoints and loses stability. Gating the output path in firmware and selecting a single source per tick prevents that contention. Across continuous state spaces, the enforcer executes a bumpless transfer, a command handoff without reference step discontinuities (section 14.4), interpolating between validated endpoints while enforcing command-rate limits and honoring measured plant limits.

Intervention events also directly shape the machine learning lifecycle. If a flight recorder or logging pipeline captures a rescued episode without marking the exact handover instant, imitation algorithms treat the near-failure states that triggered the rescue as if they were intentional expert demonstrations. As section 5.8 establishes, the states visited by the learner right before a takeover supply training data for recovery policies, but autonomous commands from a failing interval require review rather than automatic admission as expert targets. Downstream learning algorithms, from Dataset Aggregation (DAgger) (Ross et al. 2011) to modern human-gated policy correction methods (section 14.8.3), depend on knowing which controller held authority over each logged timestep. To resolve this attribution, the architecture keeps an authority record (the twelfth record in the platform's record chain, specified in section 14.8), which retains the captured evidence preceding and following the takeover, with explicit gaps and timing bounds. Its per-tick entries timestamp every transition against the safety microcontroller's monotonic clock. An authority commit ends policy ownership, ensuring that autonomous exploration, the enforcer's transition blend, and verified human recovery remain distinct, auditable intervals.

Every shared-authority design begins by defining which named intervention may act upon which physical channel and establishing the maximum latency the machine can tolerate while awaiting human action. The protocol handshakes, setpoint blending algorithms, and authority records that follow all rest upon this initial grant of authority.

14.2 Human Authority, Reaction Time, and Clearance

An assistant guiding the arm can move the chassis if its credential also permits base-drive commands. A command admitted under that permission performs mechanical work on the plant before software

can revoke it. Authority must therefore identify the physical channels a person may affect, rather than grant unrestricted access through a generic operator role.

The remote assistant who clears a blocked aisle and the coworker who takes an item from the gripper act on the same machine, and neither should hold the other's authority. Each grant therefore names an operation together with its timing budget, physical degrees of freedom, and preemption rule. The permission path keeps these grants in an explicit **capability matrix**, a permissions table mapping individual operations (such as an emergency power cutoff, a velocity trim adjustment, a trajectory path veto, or manual drive of the base and arm) to authenticated roles. The design reflects classic taxonomies of human supervisory control[2] (Sheridan 1992) and multi-level automation (Parasuraman et al. 2000). Each entry in this matrix defines the exact actuator channels the operation governs, the preemption tier it carries over the learned policy, and the maximum propagation latency permitted from physical input to actuator response.

Sheridan also describes the supervisor's work as five steps in sequence: plan the task off-line, teach the plan to the computer, monitor the automatic action, intervene when it fails or the goal changes, and learn from the episode (Sheridan 2021). Intervening in flight and learning from the episode require finer granularity than a single autonomy level assigned to the whole task. The mobile manipulator needs an authority assignment per channel and per instant: during a takeover, the arm can sit near the manual end of the scale while the base still runs at the automatic end, and the enforcer holds the final admission gate on every channel throughout because it checks the operator's commands just as it checks the policy's. Levels that differ across channels are what a supervisor can lose track of, the mode confusion of section 14.6, so a channel left out of a transfer keeps its autonomous owner only while the console announces that it does, and otherwise holds. Each entry in the capability matrix therefore names the exact operation and channel it governs.

Naming the operations separates intervention from **safety enforcement**, two mechanisms that system architectures routinely conflate. Enforcement withholds permission from a candidate action proposed by a learned model, modifying, clamping, or projecting the setpoint while leaving the machine under autonomous control. Intervention transfers authority away from the model to an external entity, terminating autonomous operation and giving the supervisor the right to propose, while every command still passes the permission path. An **enforcement filter** sits in the fast inner control loop (1 kHz / $\leq$ 1 ms) to prevent the policy from demanding an over-current maneuver or violating a barrier certificate (Ames et al. 2019) during nominal tracking. An intervention mechanism strips the policy of its proposal token when an operational boundary is breached or an operator demands control. A system equipped with enforcement but lacking intervention cannot be redirected when human intent changes or external conditions fall outside the policy design envelope, leading to conservative deadlock when barrier constraints collapse the feasible control set. Conversely, a system equipped with intervention but lacking enforcement permits a lagging operator to drive the plant into structural failure during nominal manual operation. Table 14.1 sets the two mechanisms side by side, from trigger and authority holder to typical failure.

Table 14.1: Architectural boundaries of safety enforcement and supervisory intervention: Enforcement operates in-loop as an active constraint on proposed actions; intervention transitions authority between discrete proposers.

Dimension	Enforcement filter	Intervention state machine
Primary trigger	Invariant boundary approach ($\dot{h} + \gamma_{\text{cbf}} h < 0$) or torque limit	Human takeover assertion, monotonic lease timeout, or operational design domain (ODD) exit
Authority holder	Autonomous policy retains proposal rights; enforcer modifies setpoints	Authority transferred to external entity or fallback controller
Execution loop	Fast inner control loop (1 kHz / $\leq$ 1 ms)	Same permission tick; protocol exchange spans multiple ticks
Safety lease role	Enforces continuous barrier satisfaction on admitted commands	Lease expiry invokes the state-dependent validated fallback
Typical failure mode	Feasible set collapse; conservative deadlock or oscillation	Opposing commands cancel, mode confusion, or late human reaction

[2] **Supervisory Control Levels**: Sheridan and Verplank (1978) formulated a ten-level taxonomy of supervisory control, running from a human who performs the whole task without computer assistance to a computer that decides and acts while ignoring the human.

↩ The actuator current and thermal limits an enforcement filter must respect are established in section 2.1.

DRAFT

Definition 14.1: Supervisory intervention

Supervisory intervention is the transfer of the right to propose commands on named actuator channels between a learned policy and an authenticated person, committed on a control tick and bounded by a lease, while every command continues to pass the same permission check.

1. **Significance**: The transfer is a delay on a moving machine, so it is priced in the stopping budget $d_{\text{stop}} \leq D_{\text{clear}}$ rather than in the user interface, and the waiting before braking, not the braking itself, decides whether the machine stops in time.
2. **Distinction**: Enforcement changes a proposal and leaves the proposer in place; intervention changes the proposer and leaves the check in place. A machine needs both, because neither can do the other's job.
3. **Common pitfall**: A frequent misconception is that a takeover hands the operator the actuators. The operator gains only the right to propose, and the machine still needs a local stop that does not wait for the operator to act.

14.2.1 Capability matrices and the intervention-enforcement split

On the warehouse mobile manipulator, a coworker taking a mug from the gripper at the packing station would be at risk if their station credential also allowed them to command the arm's joints or drive the base. The capability matrix prevents that cross-channel hazard by letting the remote assistant redirect motion while denying any motion authority to the coworker accepting an item.

In that matrix, the remote assistant who supervises the mobile manipulator may hold a signed **trajectory veto** capability for the base's planner channel: role `remote_assistant`, operation `veto_path`, channel `planner_proposal`, preemption tier above the learned planner but below the local enforcer, authenticated session and nonce, and a clearance-derived acknowledgment deadline. The enforcer responds to a valid veto with a checked local hold or stop. The same session carries a second entry, `manual_drive`, on the base-velocity and arm-joint channels, which becomes active only through a handover that commits within the clearance-derived deadline, and lapses with the manual lease of section 14.3. Every command it carries still passes the permission check. A wheel drive-torque packet from that credential is denied, because neither entry grants the base's wheel drive-torque channel.

The coworker at the packing station holds a different entry, `accept_item`, which lets the coworker take from the gripper the mug the arm picked from the takeaway conveyor. That entry grants no motion authority. The item-handover channel of the enforcement record caps the arm's approach to the coworker's hand at 0.10 m/s, and no capability lifts that cap. The handover is a collaborative application in the sense of ISO 10218-2:2025 (International Organization for Standardization 2025b), and the body model of the hand that bounds it, with the contact force that model predicts, is set out once in section 12.7.2. ISO 10218-2 leaves out the hazards of mounting the arm on a mobile platform, which ANSI/A3 R15.08-2 addresses for the running machine (Association for Advancing Automation 2023).

The ceiling behind that cap comes from the contact-force model (equation 12.13). For a free hand, which recoils, the selected 50 N criterion admits up to 0.24 m/s, and the cap sits under that ceiling. A hand clamped against a rack upright or the arm itself cannot recoil, and the same criterion then admits only 0.053 m/s, below the cap. The cap therefore holds only if the handover geometry excludes clamping, a premise the release case must evidence. The ceiling is conditional on these inputs and does not by itself establish a pressure or injury limit for a particular contact geometry; the site's risk assessment qualifies the effective mass, the force criterion, and the contact geometry before the cap is qualified.

↪ The release criterion that holds the handover's contact force under its assessed limit is developed in section 16.2.

Each capability entry binds actor, operation, channel, deadline, authentication, preemption tier, and fallback; a valid signature alone grants no motion authority. Physical clearance sets the tolerable deadline; the operator's response time determines whether a human can meet it.

14.2.2 Human reaction time and travel before braking

The remote assistant must notice the blocked aisle, decide how to recover, move the controls, and deliver a checked request. Summed in sequence, the total supervisory takeover latency T_{Σ} is:

$$T_{\Sigma} = T_{\text{sensory}} + T_{\text{cognitive}} + T_{\text{motor}} + T_{\text{comm}} \tag{14.1}$$

The first three terms belong to the person and depend on engagement and expectation; the last belongs to the console and the link. Human response times are distributions with long right tails, so a stopping budget needs a value that nearly every request meets, not the typical one. The calculation below compares a continuously engaged operator with an out-of-loop assistant. Its communication term includes transport and the protocol exchange, so that exchange must not be charged again.

Waiting consumes distance before the selected stop begins. The finished stopping budget from section 12.3.1 supplies the machine delay, resident stop, and fixed allowances. Adding the human waiting interval exposes whether remote rescue can fit at the current speed; it does not authorize waiting when the local stop is already required.

The budgets that follow are illustrative design comparisons, not measured takeover performance. Each of them must also pay for the dispatch-to-admission interval Δ_{da}, which section 13.6.2 allocated but has not yet measured. A takeover does not remove that interval. The policy must still infer on the frame that shows the blocked aisle before it can request help, and its request, like any proposal, reaches the arbiter only through the safety microcontroller, so the base keeps rolling through Δ_{da} before the human response even begins. This chapter calls a budget without the interval the *partial budget* and a budget with it the *complete budget*. The stops and overruns below use the complete budget. The speed ceilings and deadlines give the partial value first and then the charged one, because the gap between the two is itself a design lesson.

The stopping budget of table 12.1 shows what equation 14.1 costs on the mobile manipulator. At the 1.3 m/s aisle speed it leaves 131.0 mm of the 1.10 m rack-end clear distance before dispatch-to-admission travel, and 48.7 mm once the 82.3 mm of travel during Δ_{da} is charged. A takeover delay adds to the machine's own pre-brake delay τ_{delay}, and every millisecond of it becomes travel at the aisle speed:

1. **Mode 1: Continuous in-loop teleoperation**: An attending operator with hands on the controls of a synchronized leader arm or a real-time console, responding to the stimulus the task has led them to expect, makes a simple reaction. The Model Human Processor[3] (Card et al. 1983) prices that reaction as one perceptual, one cognitive, and one motor cycle (Jastrzembski and Charness 2007). At the slow end of each cycle's range, $T_{\text{sensory}} = 200$ ms, $T_{\text{cognitive}} = 170$ ms, and $T_{\text{motor}} = 100$ ms. The console adds $T_{\text{comm}} = 135$ ms: the scene reaches the operator after a video glass-to-glass latency[4] of 104 ms, measured for a wired teleoperation link (Schimpe et al. 2022), and the request returns through a 31 ms protocol exchange, the four-phase handshake that section 14.3.3 builds and budgets phase by phase. By equation 14.1, $T_{\Sigma,1} = 605$ ms. The machine travels 786.5 mm during that delay, several times the spare margin. Solving the complete budget for speed, with $T_{\Sigma,1}$ and Δ_{da} added to τ_{delay}, bounds the machine to 0.797 m/s. The value holds only for the expected stimulus. A driver who is waiting for a brake signal needs up to 0.75 s to detect it and reach the pedal, and a surprise raises that to about 1.5 s (Green 2000). Section 14.2.3 prices those cases.
2. **Mode 2: Passive out-of-the-loop supervisory takeover**: An assistant who monitors the telemetry of several machines passively does not make a simple reaction, and its stages cannot be priced separately. Driver take-over studies measure the whole interval, from the take-over request to the first control input. Across 520 experimental conditions in 129 studies, the mean take-over time averaged 2.72 s, and the distribution of those condition means is skewed to the right (Zhang et al. 2019). For this illustrative comparison, the selected design value is the 90th percentile of the condition means, 4.33 s, computed from the study's published data. With the same 135 ms console term, the takeover delay is $T_{\Sigma,2} = 4.5$ s, during which the machine covers 5.80 m, more than five times the clear distance, before any brake command. The same solution bounds the machine to 0.189 m/s.

In Mode 2 at the aisle speed, the machine would reach a static obstacle at the rack end at full speed, because contact occurs before braking ever begins. Stronger braking can raise a finite stopping-speed

[3] **Model Human Processor**: Card et al. (1983) modeled a person responding to a stimulus as three processors in series, perceptual, cognitive, and motor, and gave each cycle time a typical value and a range rather than a single number. The range is the design input. A budget built on the typical cycles admits a speed that a slower but still normal operator overruns, so this chapter's design row takes the slow end of every range.

[4] **Glass-to-Glass Latency**: The interval from light entering the remote camera's lens to the matching image leaving the operator's display, covering exposure, encoding, transport, decoding, and display refresh. It is the only video delay the operator experiences, and every stage of that path contributes to it, so a value measured on a wired link does not carry over to a warehouse wireless link. The site must measure its own link before the value enters the takeover budget.

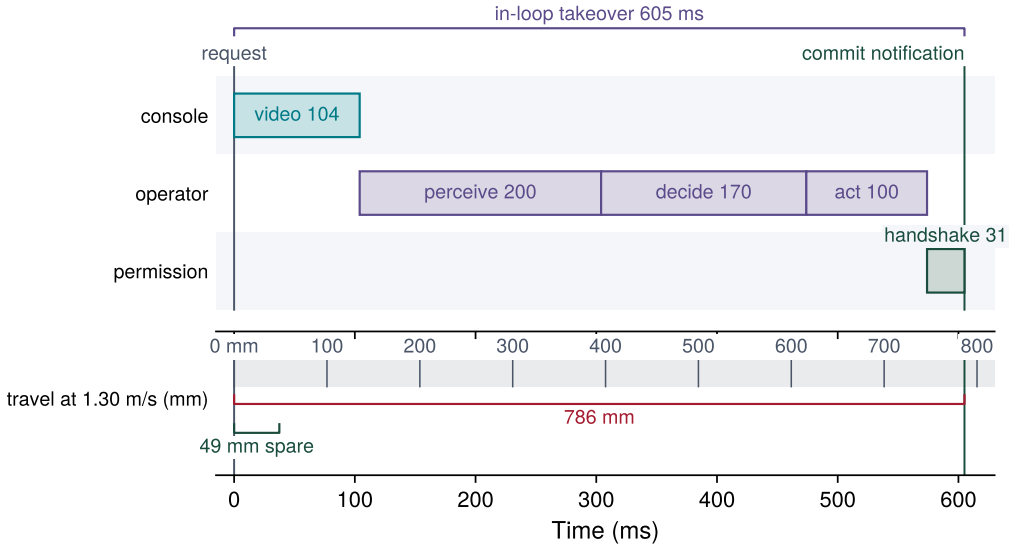

Figure 14.2: Where an in-loop takeover spends its time: The 605 ms in-loop takeover drawn to scale from the request, stage by stage: video transport to the console, the operator's perceptual, cognitive, and motor cycles at the slow end of the Model Human Processor, and the four-phase handshake through commit notification. Local commit starts the enforcer-owned blend before notification; the full exchange remains the conservative waiting allocation. The distance row converts the same axis into travel at the 1.3 m/s aisle speed; the bracket at its left marks the 48.7 mm spare of the complete budget, which the machine exhausts within the video stage.

ceiling, but cannot recover distance already spent waiting. As braking distance tends toward zero, reaction travel still sets a limiting ceiling. A percentile of condition means also understates the tail an individual operator can produce, because each condition's own spread grows with its mean; the site must measure its operators, console, and task load before any of these values admits a speed. Road regulation sizes the same interval generously for a vehicle that can keep driving while it waits. For an unanswered transition demand in the cited 2021 version of UN Regulation No. 157, an automated lane-keeping system begins its minimum risk manoeuvre no earlier than 10 s after it issues the demand (United Nations Economic Commission for Europe 2021), 2.2× the design takeover here. Severe system or vehicle failures permit an immediate minimum risk manoeuvre, and an obstacle can require an emergency response during the transition phase. The vehicle can afford that wait because it stays in its lane under automated control throughout. At the aisle speed the same wait would carry the mobile manipulator 13 m, so the machine cannot borrow the road's interval, only its structure of a demand, a bounded wait, and an automatic fallback. Section 14.2.4 turns the two design values into the speeds at which the machine may request each kind of takeover.

Drawn to scale, the Mode 1 budget shows where the clearance goes (figure 14.2). The 48.7 mm spare of the complete budget corresponds to 37.5 ms at the 1.3 m/s aisle speed, so the machine has spent it long before the 104 ms video stage ends and before the operator has perceived anything. The perceptual, cognitive, and motor cycles and the handshake that follow are all travel the budget cannot absorb, 786.5 mm in total.

Napkin Math 14.1: The takeover tax

Problem: At the 1.3 m/s aisle speed, does the finished stopping budget still fit the rack-end clear distance once an in-loop or an out-of-loop takeover delay is inserted before braking, and by how much does each overrun it?

Variables:

- $v = 1.3$ m/s (Chosen) and $D_{\text{clear}} = 1.10$ m (Illustrative).

- $\tau_{\text{delay}} = 133.6$ ms, the machine's own pre-brake delay (Derived; table 12.1), which excludes the dispatch-to-admission interval, and $\Delta_{\text{da}} = 63.3$ ms, the allocation of section 13.6.2 (Illustrative), which a takeover still spends before braking.
- $d_{\text{suffix}}(v) = v^2/(2a_{\text{brake}}) + v\,a_{\text{brake}}/(2j_{\max})$, the jerk-limited resident stop of equation 11.17, with $a_{\text{brake}} = 2$ m/s² (Illustrative) and $j_{\max} = 7.11$ m/s³ (Derived).
- $\delta = \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} = 190$ mm (Illustrative and Chosen).
- $T_{\Sigma,1} = 605$ ms in-loop and $T_{\Sigma,2} = 4.5$ s out-of-loop (Derived, from the measured human and transport terms of Modes 1 and 2 plus the chosen handshake).

Math: Every term is in millimeters. The machine alone, charged with the dispatch-to-admission travel, leaves a 48.7 mm spare:

$$d_{\text{stop},0} = v\,\tau_{\text{delay}} + v\,\Delta_{\text{da}} + d_{\text{suffix}}(v) + \delta = 173.68 + 82.30 + 605.31 + 190 = 1051.30 \text{ mm}$$

Each takeover adds $v\,T_{\Sigma}$ before the same stop:

$$d_{\text{stop},1} = v\,\tau_{\text{delay}} + v\,\Delta_{\text{da}} + v\,T_{\Sigma,1} + d_{\text{suffix}}(v) + \delta = 173.68 + 82.30 + 786.5 + 605.31 + 190 = 1837.80 \text{ mm}$$

$$d_{\text{stop},2} = v\,\tau_{\text{delay}} + v\,\Delta_{\text{da}} + v\,T_{\Sigma,2} + d_{\text{suffix}}(v) + \delta = 173.68 + 82.30 + 5804.5 + 605.31 + 190 = 6855.80 \text{ mm}$$

Result: The in-loop takeover overruns the clear distance by 737.8 mm and the out-of-loop takeover by 5.76 m; the second stop is 3.7× the first.

Systems insight: The waiting term, not the braking term, decides the verdict. The in-loop takeover alone covers 16.1× the spare, so no stronger brake can make $d_{\text{stop}} \le D_{\text{clear}}$ hold at this speed; only a lower v or a stop before the request can. The delay, braking, and allowance terms follow the stopping-distance model of section C.13.

14.2.3 Takeover speed ceilings from available clearance

Because no braking force can recover distance spent waiting, the machine must bound its operating speed before an intervention is ever requested. One inequality sets both bounds that this section and the next derive. If the machine continues at speed v for a waiting duration T_{wait} while awaiting the operator's response, the finished stopping budget of section 12.3.1 gains one term, the travel during that wait. The pre-brake delay τ_{delay}, the jerk-limited resident stop $d_{\text{suffix}}(v)$ (equation 11.17), and the fixed allowances keep the meanings defined there, and the sum must still not exceed D_{clear} measured at the same reference event:

$$d_{\text{stop}}(T_{\text{wait}}) = v(T_{\text{wait}} + \tau_{\text{delay}}) + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} \le D_{\text{clear}}. \tag{14.2}$$

Setting $T_{\text{wait}} = T_{\Sigma}$ and solving for speed gives the takeover speed ceiling of this section. Fixing the speed and solving for T_{wait} gives the latest fallback deadline of section 14.2.4.

The three stops of notebook 14.1 differ only in how long the machine coasts before an identical jerk-limited resident stop begins (figure 14.3). Every trace ends with the same braking curve, so the whole difference between stopping 48.7 mm short of the clear distance and stopping at 6.86 m is coasting.

Table 14.2 prices each sourced response time. Every row adds the 135 ms console term to the human response, adds the total to τ_{delay}, and solves the finished stopping budget for the largest speed at which the machine still stops inside the rack-end clear distance. Before charging the missing admission delay, the ceiling falls from 1.01 m/s for an attending operator who meets the expected stimulus at the nominal pace to 0.12 m/s for the slowest percentile of takeover conditions. No row fits at the 1.3 m/s aisle speed. Two facts dominate the table. Expectation matters more than the console, because moving from an expected to a surprising stimulus costs more speed than the whole

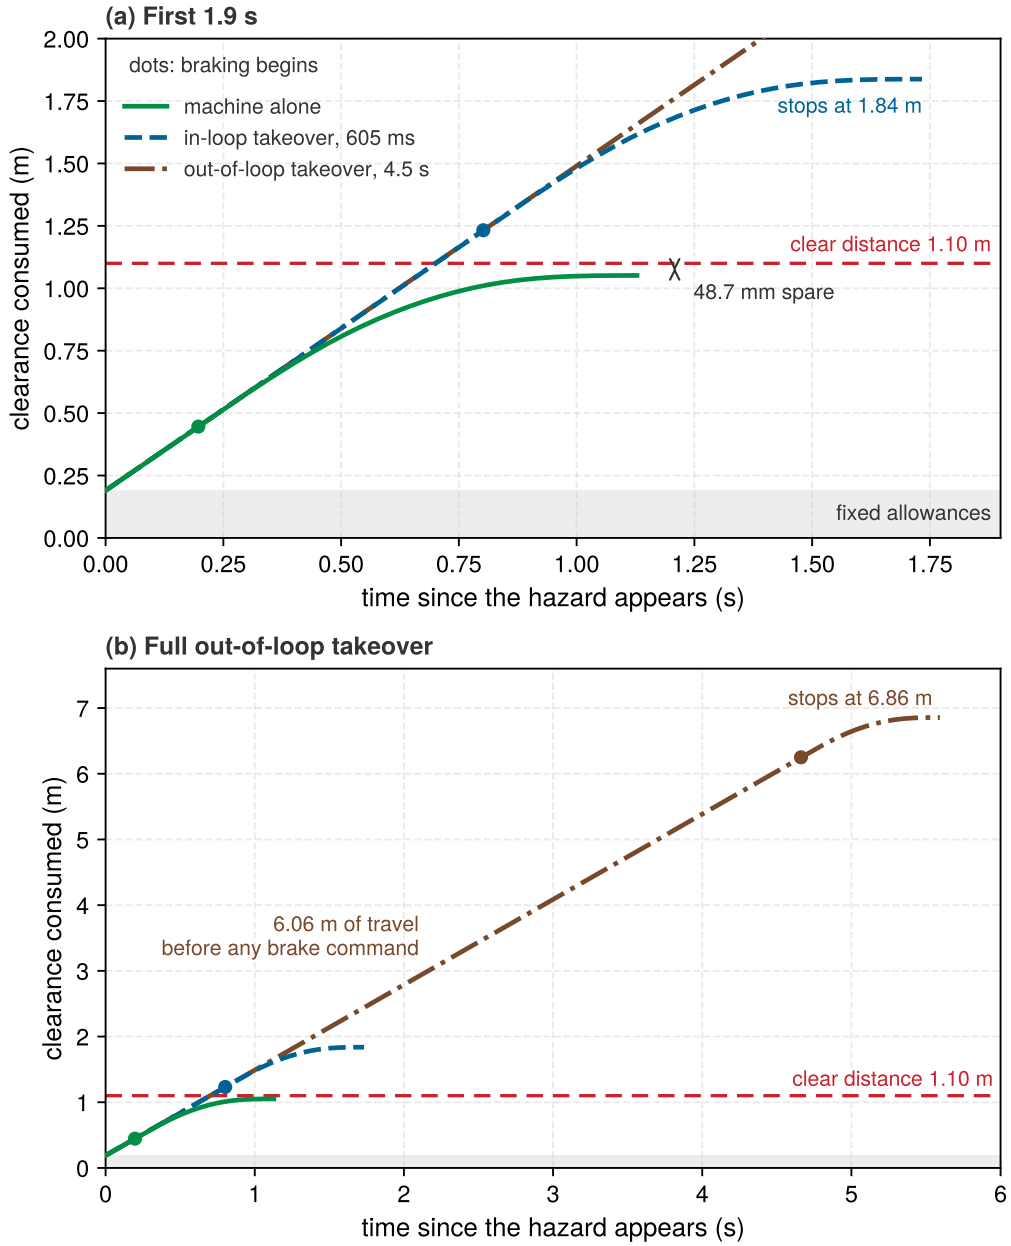

Figure 14.3: Two takeovers against one clear distance: Clearance consumed at the 1.3 m/s aisle speed, starting from the fixed allowances. Each trace coasts through its delay, including the dispatch-to-admission interval, and then follows the same jerk-limited resident stop. The machine alone stops 48.7 mm short of the 1.10 m clear distance. A 605 ms in-loop takeover inserted before braking carries the stop to 1.84 m, and a 4.5 s out-of-loop takeover carries it to 6.86 m. The waiting, not the braking, spends the clearance.

console term does. The tail matters more than the average, because a speed chosen for the mean take-over time is overrun by every condition slower than the mean.

A ceiling above the resident stop's transition speed $a_{\text{brake}}^2/j_{\max}$ is the positive root derived for the machine's own stop in equation 12.2, where the half jerk ramp acts as an added delay before full

braking (the rigid-stop form is equation 2.3). A takeover adds one more such interval, so setting $T_{\text{wait}} = T_{\Sigma}$ in equation 14.2 folds the human delay into the same root:

$$v_{\max}(T_{\Sigma}) = a_{\text{brake}} \left[\sqrt{b^2 + \frac{2\,(D_{\text{clear}} - \delta)}{a_{\text{brake}}}} - b \right], \qquad b = \tau_{\text{delay}} + T_{\Sigma} + \frac{a_{\text{brake}}}{2 j_{\max}}. \tag{14.3}$$

The term b collects every interval during which the machine still moves at v: its own delay, the human's, and the half jerk ramp before full braking. Below $a_{\text{brake}}^2 / j_{\max}$ the stop never reaches full deceleration and the cubic branch of equation 11.17 applies instead, which is why the table's slower rows come from the solver rather than from this root.

Napkin Math 14.2: The speed a human buys

Problem: What is the highest speed at which the mobile manipulator may request an in-loop takeover from an attending operator, and does any brake, however strong, admit the aisle speed?

Variables:

- $a_{\text{brake}} = 2$ m/s² (Illustrative) and $j_{\max} = 7.11$ m/s³ (Derived).
- $\tau_{\text{delay}} = 0.1336$ s (Derived) and $T_{\Sigma,1} = 0.605$ s (Derived, from the measured human and transport terms of Mode 1 plus the chosen handshake).
- $D_{\text{clear}} - \delta = 0.91$ m (Illustrative, less the fixed allowances).

Math: $b = 0.1336 + 0.605 + 2\,/(2\times 7.11) = 0.1336 + 0.605 + 0.1406 = 0.8792$ s. Then $b^2 + 2\times 0.91\ /\ 2 = 1.6830$ s², whose square root is 1.2973 s, so by equation 14.3 $v_{\max} = 2 \times (1.2973 - 0.8792)$. The root lies above $a_{\text{brake}}^2 / j_{\max} = 0.562$ m/s, so the quadratic branch was the right one. If both the deceleration and jerk bounds are removed so that the resident stopping distance tends to zero, the limiting ceiling is $(D_{\text{clear}} - \delta)/(\tau_{\text{delay}} + T_{\Sigma})$.

Result: $v_{\max} = 0.836$ m/s, the design in-loop row of table 14.2; instantaneous braking would raise it only to 1.23 m/s.

Systems insight: Even a perfect brake leaves the ceiling below the 1.3 m/s aisle speed, because the travel during $\tau_{\text{delay}} + T_{\Sigma}$ alone exceeds the clear distance at that speed. The waiting term of $d_{\text{stop}} \le D_{\text{clear}}$ sets the request speed, so faster brakes cannot buy back a slow human; adding the 63.3 ms admission allocation to b lowers the root to 0.797 m/s.

Table 14.2: Takeover speed ceiling against the sourced human response: The first two rows are Model Human Processor simple reactions, one perceptual, cognitive, and motor cycle at nominal and slow-bound cycle times (Jastrzembski and Charness 2007). The next three are driver perception-brake times for an expected, an unexpected, and a surprise signal (Green 2000). The last four are percentiles of the mean take-over time across 520 experimental conditions, computed from the published data of Zhang et al. (2019); they describe conditions, not individual operators, whose tail is longer. Each total adds the console term (video glass-to-glass latency (Schimpe et al. 2022) plus the four-phase exchange) and excludes the dispatch-to-admission interval, so every ceiling is optimistic; charging that allocation lowers the design in-loop ceiling to 0.797 m/s. Bold rows are the design values.

Operator state and response	Human response	With console term	Added travel at aisle speed	Speed ceiling
In-loop, expected stimulus, nominal pace	240 ms	375 ms	0.49 m	1.01 m/s
In-loop, expected stimulus, slow bound (design)	470 ms	605 ms	0.79 m	0.84 m/s
Expected brake signal	750 ms	885 ms	1.15 m	0.68 m/s
Unexpected but common signal	1,250 ms	1,385 ms	1.80 m	0.51 m/s
Surprise event	1,500 ms	1,635 ms	2.13 m	0.45 m/s
Out-of-loop takeover, median condition	2,370 ms	2,505 ms	3.26 m	0.32 m/s

Operator state and response	Human response	With console term	Added travel at aisle speed	Speed ceiling
Out-of-loop takeover, average condition	2,720 ms	2,855 ms	3.71 m	0.29 m/s
Out-of-loop takeover, 90th percentile (design)	4,330 ms	4,465 ms	5.80 m	0.19 m/s
Out-of-loop takeover, 99th percentile	7,000 ms	7,135 ms	9.28 m	0.12 m/s

The table also locates the other interfaces a site might offer. Continuous velocity guidance or supervisory waypoint dispatch places the operator somewhere between an expected-stimulus reaction and an out-of-loop takeover, and only a measured response distribution for that interface, console, and task says where. A hardwired protective input removes the console term but not the human response, so its operator still needs the local stop to hold the machine safe while that response runs.

14.2.4 Clearance-derived fallback deadlines

If a machine reaches the edge of its operating domain at speed and requests a takeover, an operator who is distracted, asleep, or incapacitated will fail to complete the handshake before the machine runs out of clearance. An autonomous policy's handover request can therefore never wait indefinitely, nor can its timeout be a fixed software constant: a single fixed window that is safe at a crawl will overrun the clearance at transport speed (section 14.9 prices such a window at both speeds). Safe timeouts must instead be derived at runtime from the machine's current speed, line-of-sight clearance, and braking deceleration.

The deadline is the second reading of the stopping inequality. The speed ceiling fixed the wait and solved for speed; the deadline fixes the current speed and solves for the wait. Setting equality in equation 14.2 ($d_{\text{stop}}(T_{\text{wait}}) = D_{\text{clear}}$) and solving for the maximum permissible waiting time yields the latest fallback deadline $T_{\text{deadline,fallback}}$:

$$T_{\text{deadline,fallback}} = \frac{D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - \epsilon_{\text{track}} - d_{\text{suffix}}(v)}{v} - \tau_{\text{delay}}, \qquad T_{\text{timeout}} = \max\Big(0, \min(T_{\text{config}}, T_{\text{deadline,fallback}})\Big). \tag{14.4}$$

For a live check, the safety microcontroller dispatches fallback **no later than** the last permission tick before the resulting deadline. A nonpositive $T_{\text{deadline,fallback}}$ calls for immediate fallback and may mean stopping is already infeasible. The configured protocol ceiling cannot extend that physical deadline or the expiry of active permission.

Napkin Math 14.3: The waiting allowance

Problem: How long may the mobile manipulator wait after a handover request before it must dispatch its own stop, at the 1.3 m/s aisle speed and at the 0.75 m/s slow-down, and does the 605 ms in-loop takeover fit either allowance?

Variables:

- $D_{\text{clear}} - \delta = 0.91$ m (Illustrative) and $\tau_{\text{delay}} = 0.1336$ s (Derived).
- $d_{\text{suffix}}(v) = v^2/(2a_{\text{brake}}) + v\,a_{\text{brake}}/(2j_{\max})$ (Derived; equation 11.17): 0.6053 m at 1.3 m/s and 0.2461 m at 0.75 m/s.
- $T_{\Sigma,1} = 605$ ms (Derived, measured human and transport terms plus the chosen handshake) and $\Delta_{\text{da}} = 63.3$ ms (Illustrative; the unmeasured allocation of section 13.6.2).

Math: By equation 14.4, $T_{\text{deadline,fallback}} = (0.91 - 0.6053)/1.3 - 0.1336 = 0.1008$ s at the aisle speed, and $(0.91 - 0.2461)/0.75 - 0.1336 = 0.7516$ s at the slow-down. Reserving the takeover leaves 751.6 ms − 605 ms = 146.6 ms, and charging Δ_{da} leaves 83.3 ms.

Result: At the aisle speed the takeover overruns a 100.8 ms allowance; at the slow-down it fits with 83.3 ms to spare on the complete budget.

Systems insight: Slowing from 1.3 to 0.75 m/s multiplies the waiting allowance 7.5×, because both the stop term and the travel per millisecond of $d_{\text{stop}} \le D_{\text{clear}}$ shrink with speed. The deadline is a function of the current state, so no single configured timeout can be correct at both speeds.

At the aisle speed, the 100.8 ms of notebook 14.3, or 131.0 mm of travel, is the unallocated timing allowance of the stopping subtotal in section 12.3.1, and it is a partial-budget value. Charging the 63.3 ms dispatch-to-admission allocation of section 13.6.2 completes the budget. At speed v the charge costs $v\Delta_{\text{da}}$ of travel, so at the aisle speed only 37.5 ms of waiting survives it. Wherever the rest of the chapter reports a waiting allowance, it gives the partial value and then the charged one, and the charged value is the one a design must meet. Rounded down to whole permission ticks, the partial aisle-speed allowance of 100.8 ms becomes 100 ms, which illustrates tick rounding rather than an absolute fallback time. The 500 ms configured ceiling is only an outer protocol limit, because the clearance deadline binds first.

Both readings of the stopping inequality also need a clock origin, and the chapter uses the two that table 14.3 sets side by side. The design budget behind every displayed number counts from the observation's capture. A live check on the safety microcontroller counts from now.

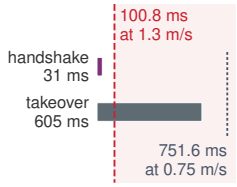

Table 14.3: Two clock origins for one stopping inequality: Either column is correct on its own. Mixing a cell from one column with a cell from the other charges elapsed travel twice or not at all.

	Design budget (capture origin)	Live check (now origin)
Where it is used	Every number this chapter displays	The safety microcontroller, at each permission tick of a pending request
Clear distance	D_{clear} measured at the observation's capture event	The current tick's remaining clearance, already reduced for the motion since capture
Delay before braking	$\tau_{\text{delay}} + \Delta_{\text{da}}$, from capture to the onset of the physical response	Only the delay still ahead: dispatch to response onset plus any unpaid processing, never a fresh full lease
Meaning of the wait	T_{wait} is additional delay inserted into that budget, with any overlap with its processing, lease, or transport intervals removed	The time left before the last permission tick at which a stop still fits

The two ways to mix them fail in opposite directions. A live check that takes the current clearance, which already reflects the travel since capture, and then also subtracts the capture-origin delay pays for the elapsed part of that delay twice and dispatches its fallback early, which costs availability. The reverse mix, the capture-time clearance with a delay counted only from now, never pays for the travel since capture and dispatches its fallback late, which costs clearance.

The 31 ms protocol exchange fits the aisle-speed allowance on both budgets. The sourced 605 ms in-loop response does not. It exceeds the aisle-speed allowance several times over, so an in-loop request needs a slower machine, and the human response time, not the machine, sets how much slower. Assuming a faster human gives the wrong answer. A slow-down to 1.2 m/s would suit an operator who responds in a small fraction of a second; there the budget leaves 184.1 ms, and the sourced response overruns it by 420.9 ms. Such a design passes every check that uses an optimistic human and fails the first operator who needs the time the literature measures.

The design slows to 0.75 m/s before requesting an in-loop takeover. That speed comes from solving the budget with both the sourced response and Δ_{da} added to τ_{delay}, which gives a complete-budget ceiling of 0.797 m/s, rounded down to the next 0.05 m/s step. At that speed the capture-origin budget leaves 563.7 mm, or 751.6 ms of additional delay. Reserving the response leaves 146.6 ms, and charging Δ_{da} still leaves 83.3 ms. That is a conservative design allocation, not a claim that every request at that speed receives the same live timeout, and it holds only while the operator meets the expected stimulus. An unexpected hazard moves the operator to the slower rows of table 14.2, whose ceilings the slow-down exceeds.

The handshake fits the aisle-speed allowance; the whole takeover needs the slow-down.

DRAFT

Solving with both intervals matters. The partial-budget ceiling, with the response alone added, is 0.84 m/s, and a designer who stopped there might choose 0.8 m/s, which sits under it. At that speed the response leaves 58.3 ms, less than the 63.3 ms allocation, so once the omitted interval is charged the slow-down misses its deadline by 5.0 ms. A budget that leaves out one interval of a few tens of milliseconds admits a speed that the complete budget rejects.

The out-of-loop takeover forces a larger change. Its 4.5 s design response caps the request speed at 0.19 m/s, so the crawl before an out-of-loop request is 0.15 m/s, where the budget leaves 5.79 s and the design response leaves 1.32 s of it unspent. The crawl survives the Δ_{da} charge, which lowers its ceiling only to 0.189 m/s. It still fails the 99th-percentile condition, whose 7.1 s response admits only 0.12 m/s, and an individual operator's tail is longer than any condition mean. A crawl slow enough for every operator is no longer motion worth keeping. The robust design therefore stops the machine automatically before handing over. The local stop runs first, and the out-of-loop takeover begins from standstill, where waiting costs time but no clearance. Both moving candidates still require qualified admission delay, current clearance, and a feasible stopping continuation. The hidden pallet leaves no room for an anticipatory slow-down at all, so the machine answers it with its own local stop and requests the takeover from standstill. A planned slow-down or crawl can prepare an anticipated request; neither permits waiting at aisle speed for a newly discovered obstacle.

Every one of these designs rests on two properties the chapter has so far assumed. Authority, once granted, must not outlive a proposer that falls silent, and it must move between proposers on a single tick without two of them ever commanding the same channel. Section 14.3 builds both.

Checkpoint 14.1: Takeover budgets and speed ceilings

A takeover is a delay inserted before braking, so every question about it is a question about the stopping budget.

- ☐ **Waiting vs. braking**: Can you explain, from the limiting case of equation 14.3, why no brake however strong admits an in-loop takeover at the aisle speed?
- ☐ **Ceiling estimate**: An operator who waits for an expected brake signal responds in 750 ms, plus the 135 ms console term. Using the givens of notebook 14.2, can you estimate the speed at which that operator may be asked to take over, and check it against table 14.2?
- ☐ **Clock origins**: Can you explain why a live check that measures clearance from now must not also charge the delay measured from capture?

14.3 Authority Transitions

When a remote assistant takes manual control of the arm after the mobile base has slowed or stopped for a blocked aisle, authority must move between proposers on a single permission tick without two of them ever commanding the same channel, and it must not outlive a proposer that falls silent. The transfer names each actuator channel and assigns it to a single owner; linear blending of two competing proposers is no substitute for choosing who is in charge. The local enforcer remains the sole writer to the physical actuator bus, generating a checked transition profile only after an ownership change has committed on a control tick boundary.

Discrete handover is not the only way to share control. Shared autonomy systems keep both proposers active and blend their actions continuously. In standard policy-blending methods, the robot infers the operator's intended goal and arbitrates between automated assistance and manual control; user studies show that this arbitration works only while the robot predicts the human's goal with high confidence (Dragan and Srinivasa 2013). That confidence breaks down when there is more than one path around an obstacle. When an operator steers left around a pallet while the autonomous policy steers right, a convex combination of two sensible commands produces a third trajectory that hits the obstacle. In those cases, a qualified arbiter must select or construct one admissible proposal; the permission path here selects a single source deterministically at each tick. Continuous blending works well when the task has a single clear goal and every intermediate blend is admissible, as when an operator makes fine adjustments to an end-effector pose. Even in purely manual operation, the safety enforcer acts as an invariant filter rather than a proposer, projecting

every human command onto the admissible control set regardless of who holds the channel. Before ownership can move between sources, however, each source's hold on a channel must be bounded in time so that a proposer that falls silent loses authority instead of leaving its last command in force.

14.3.1 Execution leases and three-position enabling hardware

A stalled policy and a disconnected teleoperator leave the same immediate problem, because in both cases the moving machine still holds a previously admitted command. An inference stall, lost wireless link, or incapacitated operator must not leave that command active indefinitely. Expiring the proposer's authority must also select a local response that brakes the machine or holds the load.

The permission path bounds autonomous chunks and manual sessions with **execution leases**, enforced on the safety microcontroller's clock. The autonomous lease is the running 60 ms chunk lease. The manual lease is a separate value, chosen in section 14.3.4 and checked against the remaining clearance in section 14.4.6. An authenticated renewal must also carry valid state and evidence, because a heartbeat alone cannot refresh old observations. A wireless console that carries these renewals is a cableless control system in the sense of IEC 62745, which specifies the functions and interfaces of radio and infrared links between operator control stations, including portable ones, and a machine's control system (International Electrotechnical Commission 2017). Formally, let t_{refresh} denote the local hardware timestamp of the most recent renewal accepted after authentication, freshness, state, and evidence validation. At physical time t, the lease-age condition is:

$$t - t_{\text{refresh}} < T_{\text{lease}} \text{ (autonomous)}, \qquad t - t_{\text{refresh}} < T_{\text{lease,man}} \text{ (manual)}. \tag{14.5}$$

The clock advances toward expiry even when packets stop arriving. At expiry, the microcontroller revokes the affected proposal rights and selects the validated response from the current physical state. Authority can return only through the declared recovery and fresh-admission procedure; packet resumption alone cannot restore it.

Electromechanical **enabling devices** provide an additional physical condition for manual motion, one that holds even when every network packet is valid. The industrial teach pendant in figure 14.4 is the familiar carrier: a technician standing beside a robot uses it to jog the arm by hand, with a display, a jogging joystick, and a latched emergency-stop button on its face and an enabling grip on its rear handle. On the running machine, an enabling device belongs to a person beside the machine, such as the maintenance technician who jogs one arm joint from a pendant. The remote assistant's console need not carry such a grip, because authenticated heartbeats maintain the manual lease, with presence assessed by the console's chosen checks, which do not establish cognitive engagement (section 14.3.4). A site may add an enabling grip to the console as a second condition. The grip that matters is a three-position one.[5] A startled or distressed operator may release a grip or squeeze it harder, and a two-position device that enables whenever pressed does not detect the latter response. By contrast, a three-position grip enables motion only in its intermediate position (Position 2). Releasing it (Position 1) or squeezing beyond the center detent (Position 3) withdraws the enabling signal; the configured safety circuit determines the resulting stop. These dual-channel contacts request the stop selected by the machine's safety circuit, independently of the Linux application processor and its scheduler. Where that response includes Safe Torque Off (STO, IEC 61800-5-2), STO disables torque generation; the configured braking or holding mechanism must still establish the required plant response. The enabling circuit must also prevent a return through Position 2 after an over-squeeze from automatically restoring motion.

The pendant's red mushroom button is a different device with different semantics. Under ISO 13850, the emergency stop is a complementary protective measure, not a substitute for safeguarding or for the stop the risk assessment selects. It takes priority over every other function in every operating mode, it latches until an operator deliberately resets it at the device, and that reset must not restart the machine (International Organization for Standardization 2015b). Which physical response the stop invokes is a stop-category choice that table 12.3 maps to its evidence. The latch and the reset rule matter for supervisory control because they make a human stop sticky in exactly the way a network command is not. A remote packet can request a stop and a lease can lapse into one, but only the local reset of a latched device, followed by the fresh admission this chapter requires, returns the machine to motion.

↩ The minimal-intervention principle, which keeps an admissible proposal and applies the smallest feasible correction otherwise, is established in section 12.7.

5 **Manual Reduced Speed**: ISO 10218-1:2025 limits the tool speed of an industrial robot in manual reduced-speed mode to 250 mm/s (International Organization for Standardization 2025a), the mode in which the pendant of figure 14.4 couples motion to a three-position grip. Releasing or over-squeezing the grip only requests a stop from the safety circuit, and the performance level that circuit must reach, graded from PL a to PL e, is set by the machine's risk assessment under ISO 13849-1 (International Organization for Standardization 2023a). The grip therefore bounds how fast the machine may be moving when a startled operator lets go, not which stop follows.

Figure 14.4: Industrial teach pendant with three-position enabling grip: Front view of an ABB teach pendant showing the touch display, manual jogging joystick, emergency-stop mushroom button, and industrial fieldbus cable. The three-position enabling grip described in the text sits on the rear handle, out of view. (Credit: Auledas, Wikimedia Commons, CC BY-SA 4.0.)

Even while an operator holds an active lease and maintains Position 2 on the deadman grip, the deterministic enforcer evaluates human setpoints against the same barrier certificates, current limits, and kinematic envelopes applied to the learned neural policy. If an operator panics and commands a high-speed steering angle that would induce dynamic chassis rollover, or requests a joint torque that would shear harmonic drive gear teeth, the enforcer clamps or rejects the command. A human command therefore remains a proposal, and the third law, proposal is not permission (principle 3), binds human supervisors and neural models alike. Intervention transfers the right to propose away from the learned policy, while the right to admit stays with the permission path. With every owner's authority bounded by a lease, what remains to design is how the right to propose changes hands, at which control tick it commits, and what the machine does when a network handover stalls.

14.3.2 Authority states and single-writer actuator ownership

If the autonomous policy and the remote console both write to a motor drive while a handover is in flight, the drive receives alternating setpoints on consecutive ticks. To prevent two sources from commanding an actuator at once, the arbiter resolves authority over each channel at every discrete time tick t to a single, mutually exclusive state:

$$S_t \in \{\text{Autonomous}, \text{Handover-Pending}, \text{Blend}, \text{Human-Manual}, \text{Fallback}, \text{Protective}\}.$$

These states separate proposer identity from actuator access. Each carries a short code name, used in the per-tick record and in figure 14.5, and each names who holds the proposal token on the channel:

- `Autonomous` (`AUTO`): The learned model holds the proposal token and proposes setpoints, while the local enforcer verifies barrier certificates ($h(\mathbf{x}) \geq 0$) on every control cycle before dispatching commands.
- `Handover-Pending` (`PEND`): A takeover handshake is negotiating across the network; the policy keeps the token and continues proposing commands under a strict clearance-derived countdown timer T_{timeout}. Active lease and evidence expiry run concurrently with that timer, so the arbiter dispatches fallback at the earliest of the protocol, lease, evidence, and clearance deadlines.

- `Blend` (`BLEND`, enforcer-owned bridge): No proposer holds the token. The enforcer assumes exclusive bus ownership, driving a smooth, C^2-continuous quintic interpolation between the latched autonomous setpoint and the validated human target setpoint.
- `Human-Manual` (`MAN`): The authenticated teleoperator holds the proposal token, streaming commands that pass through enforcer barrier checks under an active manual lease ($T_{\text{lease,man}}$).
- `Fallback` (`FALLBACK`): Entered when an active lease expires, communication drops, or no admissible continuation remains. No proposer holds the token; the arbiter selects the validated HOLD or STOP rung for the measured state without waiting for remote commands. An ordinary least-change correction, by contrast, is enforcement within the current state and leaves the token with the current proposer.
- `Protective` (`PROTECTIVE`): Entered directly from an independent hardwired protective input or a critical silicon fault. No proposer holds the token. The safety circuit selects the validated protective stop; Safe Torque Off (STO) disables torque generation, and any required load-holding mechanism must be qualified for the current state and surviving resources.

At no point do two software masters write to an actuator simultaneously. Even during the `Blend` state, the enforcer alone owns the actuator channel, executing a precomputed profile between the latched references and validating dynamic constraints against the current state on each tick. Each edge in table 14.4 therefore names its guard and deadline, its single actuator owner, and the fallback taken when the guard fails or an active lease lapses.

Table 14.4: Authority state machine transition matrix: Each row names the single actuator owner and the state-dependent fallback. The example uses a 1 ms permission tick. The `BLEND` state interpolates only latched, checked endpoints, under enforcer ownership.

From → to	Guard and deadline	Actuator owner / command	Failure response
Autonomous → Handover-Pending	Policy requests supervision; deadline computed from clearance	Enforcer admits policy proposals while feasible	Validated fallback if deadline reached
Autonomous or Handover-Pending → Blend	Authenticated operator ACK, fresh state, feasible target and stopping reserve; commit on a control tick	At commit, revoke the policy's proposal token, latch last approved command and checked manual target; **enforcer alone** writes actuator	Deny invalid target; retain valid active mode or fall back
Blend → Human-Manual	Profile completes and manual lease remains valid	Enforcer admits live human proposals within physical limits	Validated fallback on lease or enabling-device loss
Handover-Pending, Blend, or Human-Manual → Fallback	Timeout, stale lease, or invalid state	The permission path executes the validated HOLD or STOP rung and records it	Re-arm only after validated recovery procedure
Any state → Protective	Independent protective input or qualified critical fault	Safety circuit/controller selects plant-specific protective stop	Validated brake or hold, not torque removal alone

14.3.3 The four-phase takeover handshake

If a single network packet could switch a channel directly from `Autonomous` to `Human-Manual`, a delayed request could hand the actuators to an operator whose view of the aisle is already stale. With the same single packet, a dropped reply could leave the operator and the machine disagreeing on who is driving. Moving a channel between states instead takes a deterministic **four-phase takeover protocol** (`Request` → `Acknowledge` → `Commit` → `Confirm`) run by the safety microcontroller. This four-stage exchange separates the local hardware commit from the physical blend and from the final release of manual proposal rights, checks cryptographic freshness so replayed frames cannot trigger a switch, and changes ownership on a single tick boundary:

1. **Notice (`Request` phase)**: Either the human supervisor notices policy drift and requests an override (for example, by pressing an enabling button or moving a joystick past its calibrated deadband), or the autonomous policy hits an epistemic uncertainty spike and requests teleoperation assistance. Upon receipt, the arbiter initializes the clearance-derived countdown timer $T_{\text{timeout}} = \max(0, \min(T_{\text{config}}, T_{\text{deadline,fallback}}))$ of equation 14.4.

2. **Declutch (`Acknowledge` phase)**: The enforcer validates target prerequisites across the system. It verifies that sensor telemetry is fresh, network links are live, and the current plant state $\mathbf{x}(t)$ retains sufficient stopping reserve to brake safely if the transfer aborts. It then captures a synchronous state snapshot before preparing to revoke the autonomous policy's proposal authority.
3. **Transition (`Commit` phase)**: At the next synchronous control tick boundary, the enforcer executes the state transition. It revokes the policy's proposal token on the committed channels, latches the last approved policy setpoint alongside the checked manual target setpoint, and assigns sole write authority to the enforcer in the `Blend` state. The enforcer drives the C^2-continuous transition profile, continuously checking that the trajectory remains feasible under measured plant dynamics.
4. **Notification (`Confirm` phase)**: The permission path broadcasts confirmation of the committed owner and the active `Blend` state to the operator console. A dropped confirmation packet alarms the operator interface, but does not undo or stall the local commit on the robot. After the physical profile completes under valid state, sufficient stopping reserve, and an active manual lease, the arbiter separately grants the proposal token on the committed channels to the operator and transitions to `Human-Manual`. This release timing is dictated by physical profile completion rather than the network notification round trip.

Each phase in table 14.5 carries a strictly budgeted bound, an explicit guard and owner, and deterministic failure handling. The transaction rejects spoofed override attempts and applies the failure response assigned to its current phase. Lost confirmation does not reverse a committed transfer; lease expiry or a failed physical guard invokes the validated state-dependent fallback.

Table 14.5: Four-phase takeover timing: The phase budgets sum to 31 ms. This sum budgets the exchange through commit notification, not physical blending or release of manual proposal rights. The blend begins at commit and may continue after notification.

Phase / takeover stage	Budgeted bound	Guard and owner	Failure handling
1. Request (Notice)	10 ms	Authenticated role, checked nonce, and fresh clock-converted timestamp; no owner change	Reject invalid packet; keep current qualified mode
2. Acknowledge (Declutch)	5 ms	Check state, manual target, and full stop reserve; isolate write path	Reject request; invoke fallback if current mode cannot continue
3. Commit (Transition)	1 ms tick	Revoke the policy's proposal token, latch both checked endpoints, assign **enforcer** sole actuator write path	No partial commit within the requested channel mask; fallback on failed guard
4. Confirm (notification)	15 ms	Announce committed `BLEND`; later announce `MAN` after profile and lease check	Lost notice alarms operator but does not undo commit

14.3.4 Arbiter execution and manual-lease heartbeats

Once a channel reaches Human-Manual, a dropped wireless link or a distracted assistant who leaves the console would let the last manual command keep running unless the machine checks that the operator is still present. The safety microcontroller bounds that risk with a hardware-timed **manual lease**. Depending on the console, presence detection may use a capacitive grip sensor, eye tracking, or continuous joystick deflection past a deadband, chosen for their sensor coverage and false-drop rates. Manual authority is sustained exclusively through authenticated keep-alive heartbeats streamed from the operator console to the safety microcontroller. The manual lease $T_{\text{lease,man}}$ of section 14.3.1 is the longest silence the microcontroller tolerates between them. Two bounds set its length. From below, the lease must outlast the heartbeat period plus the link's jitter and at least one lost packet, or ordinary wireless loss would drop a healthy operator into fallback. That floor is why the heartbeats must run at a rate several times the lease's inverse. From above, the lease replaces the chunk lease inside τ_{delay} while the operator holds `MAN`, so the travel it adds over the chunk lease, $v(T_{\text{lease,man}} - T_{\text{lease}})$, must fit the clearance left after the takeover. The reference implementation chooses 100 ms. Section 14.4.6 checks that value against the upper bound at the in-loop request speed, and only the site's measured heartbeat loss can show that it clears the lower one.

Each heartbeat packet carries a strictly increasing 64-bit sequence counter k, a monotonic hardware timestamp t_k^{hb}, an authenticated operator credential, and a keyed message authentication code (AES-128 CMAC, evaluated in section 14.5). In the age calculation below, t_k^{hb} represents the sender's timestamp translated into the local clock domain. The receiver tracks the bounded clock-synchronization uncertainty interval and computes freshness relative to the oldest plausible timestamp; an unqualified clock mapping cannot safely establish packet freshness. The nominal local-clock age is:

$$\Delta t_{\text{heartbeat}} = t_{\text{local}} - t_k^{\text{hb}}.$$

These fields combine communication checks used in black-channel safety architectures (International Electrotechnical Commission 2021) with cryptographic security over an untrusted wireless link. The sequence counter detects transmission loss and replay attacks. The timestamp and bounded lease act as a communication watchdog against excessive latency. The cryptographic tag authenticates the claimed credential. The safety communication checks and the security mechanism require separate qualification.

A heartbeat packet may renew authority only while its conservative age falls within the configured freshness window. The active manual lease expires deterministically on the local hardware clock at its committed deadline; stale or out-of-order network traffic cannot extend that horizon. Similarly, an autonomous action chunk expires strictly according to its admitted local deadline. A packet that fails cryptographic verification is immediately discarded. It cannot renew the lease, but it does not revoke currently valid authority either; the existing timer runs down on its own. Upon lease expiration, the microcontroller automatically revokes the operator's proposal token, drops into `Fallback`, and executes a pre-validated holding or stopping trajectory. Once a lease lapses, the state machine prohibits any immediate return to Autonomous or Human-Manual. The robot must satisfy strict recovery conditions: it must come to a complete mechanical standstill, resolve and acknowledge the relevant faults without erasing their evidence, and undergo an authenticated four-phase re-admission handshake initiated from rest.

↩ The proposal header that applies the same black-channel safeguards to every learned proposal is established in section 4.4.1.

When multiple control sources propose concurrent commands, the permission path resolves candidate selection through a fixed priority hierarchy evaluated deterministically every 1 ms control cycle below the proposal boundary. This mechanism adopts the layered priority structure of subsumption architectures (Brooks 1986), but applies it strictly to input source selection rather than behavioral synthesis. The independent enforcer then admits, modifies, or rejects the winning candidate to ensure compliance with configured physical limits. In the Human-Manual state with a valid lease, the human proposal takes precedence over learned model proposals, while remaining bounded by barrier certificates and actuator limits. In Autonomous, the learned policy generates candidate actions for safety screening. Because fixed-state arbitration requires bounded work per tick ($\mathcal{O}(1)$ computational complexity), it eliminates runtime negotiation or dynamic bargaining between software proposers.

Two properties of the protocol show only when the states and handshake are drawn together (figure 14.5). Every active state has an edge to `Fallback`, so no failure of the network or the operator can leave a channel without a defined owner, and the only edge out of `Fallback` is a reset from standstill. The hardwired `Protective` input sits outside the protocol entirely and preempts every state.

↩ The proposal boundary, above which a learned component may only propose and below which the permission path alone admits commands, is established in section 1.7.

Here the state machine decouples physical bus ownership from protocol progress. An acknowledgment prepares the transition. The local hardware commit (`REVOKE_PROPOSAL_TOKEN()`) strips the autonomous policy of its proposal token on the committed channels and grants the enforcer sole ownership of the blend. The enforcer admits live manual proposals only after the interpolation profile completes under an active manual lease. An unconfirmed transition therefore leaves only the console uncertain, as the `Confirm` phase states. A delayed handover request or a dropped heartbeat, in contrast, runs down its local timer and invokes the validated fallback without waiting for network consensus.

Assigning a single writer resolves authority unambiguously at each control tick, but an instantaneous switch can still produce hazardous dynamic transients. If the autonomous policy's last admitted joint torque diverges significantly from the operator's initial target, directly swapping setpoints across a single tick boundary requests an unachievable step change in torque, risking mechanical shock or actuator saturation. The enforcer avoids this discontinuity by using the latched

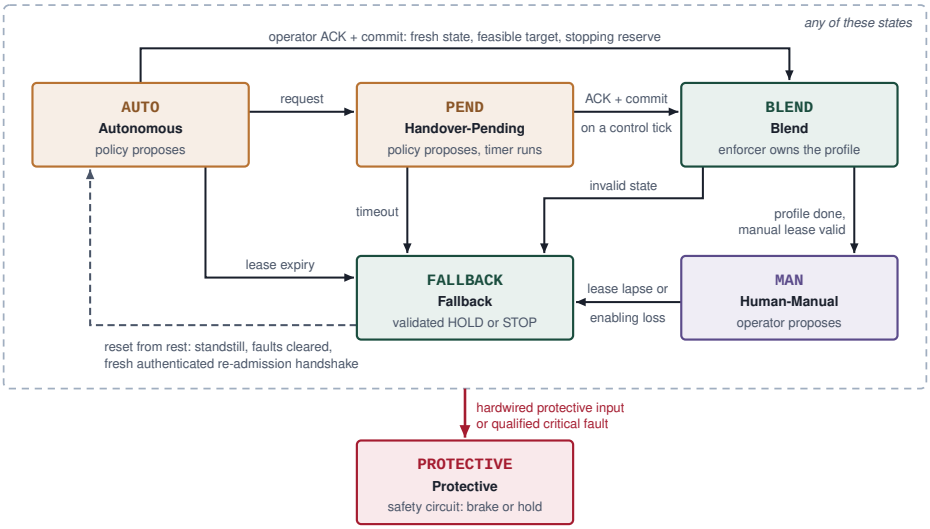

Figure 14.5: Authority states and their guards: Each box is one value of the per-channel authority state, with its code name above its plain name. A handover runs from request through acknowledgment to a commit on a control tick; from then on the enforcer owns the blend between latched endpoints, and manual proposals begin only when the profile completes with a live manual lease. Timeout, lease lapse, or an invalid state leads to the validated fallback, whose only exit is a reset from rest with a fresh re-admission. The hardwired protective input preempts every state.

boundary conditions to generate a dynamically feasible interpolation profile that preserves stopping margins throughout the transition.

Checkpoint 14.2: Authority transitions and timeout bounds

Before moving from who owns each channel to how its command changes value, verify your understanding of leases, transition state machines, and timeout dynamics:

- ☐ **State-dependent fallback**: Can you explain why the moving base and the loaded arm need different validated responses when a lease lapses, and why Safe Torque Off alone provides neither?
- ☐ **Finite-state transition semantics**: Can you trace the deterministic progression among the Autonomous, Handover-Pending, Blend, Human-Manual, and Fallback states, and name the guard and the single actuator owner on each edge?
- ☐ **Timeout bound**: At the aisle speed the configured protocol ceiling is 500 ms and the clearance-derived deadline after charging the dispatch-to-admission allocation is 37.5 ms. Can you state which one sets T_{timeout}, by how many milliseconds it is the tighter, and how many whole 1 ms permission ticks the arbiter may wait before it dispatches fallback?
- ☐ **Asymmetric preemption hierarchy**: Can you explain why the qualified local protection path must meet its measured deadline, while restoring autonomous authority requires a fresh admission handshake?
- ☐ **Fallback on a lapsed handover**: Can you explain why a lapsed or unacknowledged handover goes to the validated stop rung rather than back to the degraded policy that requested it?

If any transition paths permit unhandled timeouts or undefined intermediate states, the authority protocol is vulnerable to mode confusion and runaway actuation. Review this section before proceeding to smooth command blending.

14.4 Transfer Without Discontinuity

At commit time t_0, the enforcer latches the last admitted policy command $\mathbf{u}_0$ and a checked human target $\mathbf{u}_1$. Switching them in one permission tick may exceed the channel's allowed command rate. In classical process control, bumpless transfer between manual and automatic modes is achieved by making the inactive controller track the active one's output, so its internal state, including its integrator, already agrees at the switch (Åström and Hägglund 2006). Section 14.4.3 applies that tracking to the console-side controller that turns operator input into a command. Here **bumpless transfer** also names a second mechanism layered on top, which spreads the remaining command change across a finite window while matching the required endpoint derivatives. The quintic seam bridges of section 11.4.4 provide the construction; takeover adds a new admission decision because waiting for the operator has already consumed some clearance.

14.4.1 Command steps and mechanical drivetrain shock

A step change in torque or acceleration excites torsional resonances and snaps gearboxes across their backlash, while a slower blend lowers the command rate at the cost of stopping reserve. Because the $L_{\text{bus}}\, dI/dt$ coupling to the DC supply also turns a current step into a voltage sag on the shared rail, the command transition must satisfy the drive's rate limits while leaving enough clearance for fallback. A smooth profile therefore needs both a rate bound and a check against the remaining physical envelope.

↩ The $L_{\text{bus}}\, dI/dt$ coupling through which a current step sags the shared DC bus is established in section 2.6.1.

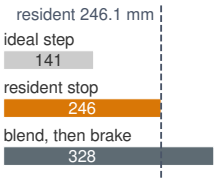
> **Definition 14.2: C² bumpless authority transfer ramp**
>
> C^2 ***bumpless authority transfer ramp*** is the enforcer-owned command profile between two checked, latched references $\mathbf{u}_0$ and $\mathbf{u}_1$. It is parameterized by a monotonic weighting function $\alpha(t) \in [0,1]$ with vanishing first and second boundary derivatives ($\dot{\alpha} = \ddot{\alpha} = 0$) over a finite blending window τ_{blend}. The profile keeps that command and its first two derivatives continuous across the fixed-endpoint handoff. When the command is acceleration, its first derivative is commanded jerk; when it is torque, the first derivative is torque rate.
>
> 1. **Significance**: A setpoint step has an unbounded ideal derivative. A C^2 command profile removes that discontinuity; measured actuator tracking and plant limits still decide physical feasibility.
> 2. **Distinction**: Unlike a linear interpolation ramp whose derivative jumps at both endpoints, a C^2 quintic spline enforces vanishing first and second derivatives ($\dot{\alpha} = \ddot{\alpha} = 0$) at entry and exit, making the interpolated command and its first two derivatives continuous for stationary endpoint derivatives. The physical meaning of those derivatives depends on the command channel.
> 3. **Common pitfall**: Choosing a window shorter than the rate limit allows for a fixed acceleration-command change (the bound equation 14.7 derives below) breaches the stated command-jerk limit even though the profile is smooth. Resonance, slip, and stopping distance require plant tests.

14.4.2 Sizing the blend window and the stopping-distance cost

Smoothing an acceleration command from cruising speed to emergency braking delays the onset of maximum deceleration, so bumpless transfer consumes clearance. It trades stopping reserve for lower mechanical stress, and sizing the blend window means balancing the actuator's jerk limit against the clearance that remains.

The enforcer blends with the quintic smoothstep. For normalized progress $\hat{t} = (t - t_{\text{start}})/\tau_{\text{blend}} \in [0,1]$, the polynomial weighting function is:

$$\alpha(\hat{t}) = 10\hat{t}^3 - 15\hat{t}^4 + 6\hat{t}^5. \tag{14.6}$$



The polynomial in equation 14.6 is the fixed-endpoint result derived in section B.5. Its derivative $\alpha'(\hat{t}) = 30\hat{t}^2(1-\hat{t})^2$ peaks at $\hat{t} = 1/2$ with value $30/16 = 1.875$, so the profile's peak slope is $1.875/\tau_{\text{blend}}$ and an acceleration change must satisfy:

$$\tau_{\text{blend}} \geq \frac{1.875\|\Delta\mathbf{u}\|}{j_{\max}}. \tag{14.7}$$

For a torque command, replace the acceleration difference and jerk ceiling with the torque difference and torque-rate ceiling. The illustrative 15 N·m joint-torque change under a 750 N·m/s ceiling therefore requires 37.5 ms, rounded up to 38 ms on the permission clock. These bounds assume stationary endpoint derivatives; a transfer from a moving ramp must match its boundary state explicitly.[6]

Increasing τ_{blend} reduces the profile's peak commanded jerk, but delays the full human target and can lengthen the stopping trajectory. Consider the remote assistant's takeover of the mobile manipulator's base, committed while the machine cruises at the $v = 0.75$ m/s it slowed to before requesting it (section 14.2.4). Suppose the assistant commands a stop at the scenario's braking deceleration, a fixed step of $|\Delta a| = 2$ m/s² from the latched cruise command. The enforcer holds the blend to $j_{\max} = 7.11$ m/s³, the jerk bound of the resident jerk-limited stop. That bound is a stipulated property of the loaded base, not of its speed, so the blend window does not depend on the speed at which the takeover commits. Measured load response still requires qualification. The smoothstep bound then sets a minimum blending window of 527.34 ms, longer than the 281.25 ms the resident stop spends ramping its deceleration at the same jerk bound, because the smoothstep reaches its peak slope only at mid-window. The smoothstep weight averages one half over the window, so the base would leave the blend at 0.22 m/s after traveling 316.1 mm. Integrating the smoothstep weight a first time subtracts one half of $|\Delta a|\,\tau_{\text{blend}}$ from the entry speed v, whereas integrating that speed profile across the window subtracts only one seventh of $|\Delta a|\,\tau_{\text{blend}}^2$ from the unbraked travel $v\,\tau_{\text{blend}}$ because most of the deceleration occurs in the second half of the ramp. Braking from there at the full target would take another 12.4 mm, for 328.4 mm to zero speed in this partial model. It holds full deceleration until rest, then switches acceleration to zero instantaneously. The value is therefore a lower-bound comparison for the ramp followed by ideal braking, not a complete smooth stopping trajectory. A feasible terminal transition needs its own distance and boundary-state check.

An instantaneous step takeover would stop in 140.6 mm, so even this partial ramp-and-brake model adds 187.8 mm of travel. The partial model is also 82.4 mm longer than the 246.1 mm resident stop from the same speed. For the one-dimensional model starting at zero acceleration and ending at rest with zero acceleration, the resident profile is a minimum-distance stop under the stated deceleration and jerk bounds (section 11.5.2), so a different complete transition into braking must be checked against that baseline. The partial comparison above lacks the required terminal transition and is not itself a competing complete profile. For a braking command the resident stop is already the bumpless transfer. The base's blend window therefore governs base command changes that do not stop the machine, such as the first manual command after an automatic stop, where the blend starts from rest and the enforcer still checks the resident stop from every blended state. An idealized step stop is mathematically shorter. Executing an unblended emergency stop, however, risks wheel lockup, dynamic rollover, or load shedding (such as throwing a loaded tote off the manipulator rack), which can increase the actual physical stopping distance beyond the ideal theoretical rigid-body stop. Command smoothing limits the requested rate; physical stability and sufficient clearance still require qualification. The enforcer admits each blended tick only while the resident stop from the resulting state still fits. Where no blend fits, the base receives the resident stop itself, the suffix the fallback ladder's stop rung executes. Bypassing the blend window by applying the acceleration step within a single 1 ms permission tick would instead request a command jerk of about 2,000 m/s³ over that tick. The idealized step is only a comparison baseline.

Under the stated stopping model, the blend adds travel beyond the resident stop.

14.4.3 Initial condition matching and integrator pre-biasing

Command blending removes the chosen output discontinuity, but it cannot remove one that a controller upstream of the blend produces. On the remote assistant's side that controller is the console-side tracking loop, the software that turns joystick deflection, or a measured guiding force (the force-guided input that section 14.4.4 describes next), into a velocity target for the channel.

[6] **Nonzero Boundary Derivatives**: The $1.875/\tau_{\text{blend}}$ peak derivative factor assumes stationary endpoint derivatives. A general quintic can match the command value, first derivative, and second derivative at both endpoints, including nonzero values (section 11.4.4). Its interior rate extrema must then be checked; the fixed-endpoint smoothstep factor does not automatically apply.

DRAFT

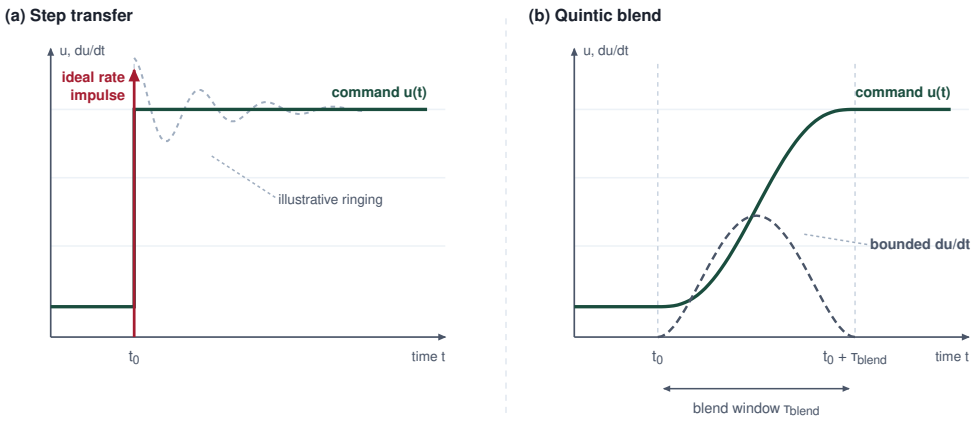


Figure 14.6: Step vs. quintic command transfer: A step and fixed-endpoint quintic blend are compared. The solid line is the command. The step's ideal derivative is a red impulse, the quintic's bounded derivative is dashed slate, and the gray ringing is schematic. The profile bounds the commanded rate for the assumed endpoints.

While the policy still owns the channel, that loop runs against a plant it does not drive, and its integrator accumulates the difference between its target and a motion that never follows. At commit it would emit that accumulated correction as a jump in the manual target, a step the blend window was never sized to absorb. **Initial condition matching** pre-biases that loop against the measured state before commit, so its internal controller state matches the output required at transfer rather than releasing accumulated error. It does not force the deliberate human target to equal the last policy command. The enforcer latches both endpoints, sizes the blend for their actual difference, and checks the resulting command and stopping reserve throughout transfer.[7]

To verify a transfer, record the command profile, motor current, encoder motion, and chassis inertial response on a shared timebase with bounded alignment error. In the ideal model, a step command has an infinite derivative at the switch, which excites high jerk, unmodeled compliance, and drivetrain ringing in physical hardware. A fixed-endpoint quintic polynomial removes the command discontinuity by zeroing the boundary derivatives, so its command rate stays bounded across the whole window τ_{blend} instead of concentrating in one impulse (figure 14.6). The measured plant response, not the command profile, establishes whether the handover met its physical limits.

The two panels distinguish the command's mathematical continuity from the plant's measured response. Removing the step bounds the requested rate under the stated endpoint assumptions; it does not establish that the drive tracks the command or that the load remains stable. Those measurements decide whether the selected blend window is acceptable.

The enforcer's 1 kHz loop gathers the four-phase handshake, integrator pre-biasing, and the C^2 quintic blend into one protocol on the safety microcontroller. Each tick it samples plant state, stopping reserve, protective inputs, and the active execution lease. It commits an ownership change only on the qualified commit tick that follows a verified acknowledgment, blends only between latched endpoints and checks every blended candidate before dispatch, and falls back on a lapsed lease or a failed clearance check.

14.4.4 Mapping operator input to arm motion

Once the operator holds the arm channel, commanding a rigid position target into a bin wall or rack upright builds contact force until the enforcer trips, whereas guiding the arm through measured contact force lets the wrist comply. Position streaming supplies kinematic targets directly; force guiding uses measured contact force to generate a motion target through an admittance controller[8] (Hogan 1985). Either mapping remains subject to the arm's qualified limits. The choice also changes the logged learning target, so the record must retain whether a sample is a requested pose, a force measurement, or an admitted command.

7 **Mid-Blend Re-Intervention Abort**: If an operator commands a secondary protective stop while a bumpless transfer blend is actively underway ($0 < \hat{t} < 1$), the enforcer does not wait for τ_{blend} to complete. It uses the measured plant position, velocity, and acceleration, together with the active command and their uncertainty, to select a qualified state-matched fallback. A new polynomial seeded only from the intermediate command does not establish that the physical plant can execute it.

↪ **Protocol:** The enforcer's cadence, memory and write invariants, and per-state execution steps are given in section C.15.7.

8 **Admittance and Impedance Control**: Hogan (1985) framed interaction control as programming the relation between force and motion at the contact. An impedance controller answers imposed motion with a commanded force; an admittance controller is its dual, turning a measured force into commanded motion, which suits stiff, highly geared arms whose position loops are accurate but which cannot render force directly. On such an arm a force-guided target is still a motion command, so it passes the same enforcer checks as a streamed pose.

14.4.5 Bilateral teleoperation and haptic feedback passivity

A force-reflecting console adds an actuated device at the operator's hands. Delayed feedback[9] can destabilize that coupled loop even when authority ownership is correct (Anderson and Spong 1989). Such a console therefore needs a separate interaction-energy argument, including its port conventions, controller sampling, delay and loss assumptions, and actuator saturation. The energy-storage condition and wave-variable construction are developed in section B.10; they do not replace the clearance or force limits. The basic warehouse takeover does not require bilateral force reflection. If a site adds it, pre-biasing and ramping the console's force output must prevent a command step at the operator's hand within its own measured limits, because the arm's accepted blend duration does not automatically qualify the console. Whichever input mapping and console a site chooses, the session that carries them must still fit the clearance left after the operator's response.

[9] **Delayed Teleoperation**: Ferrell (1965) found that operators working through a transmission delay fall back on a move-and-wait strategy, so task time grows with the delay. Force reflection through the same delay proved unstable until Anderson and Spong (1989) used scattering theory to make the communication channel passive, a construction that Niemeyer and Slotine (1991) recast as wave variables. For a force-reflecting console the delay budget is therefore a stability term as well as a latency term.

14.4.6 Admitting the remote-assistant session

Every interval priced so far in this chapter now draws from the same finite stopping reserve when a remote session begins. Admitting the remote assistant requires bounding four timing parameters against the machine's limits: the operator reaction budget (the takeover latency T_{Σ} of equation 14.1 for the takeover mode in use), the **handshake protocol latency** $T_{\text{handshake}}$, the manual lease $T_{\text{lease,man}}$, and the minimum blending window τ_{blend}. Table 14.6 states them for the machine's two command channels, the base and the arm, which one remote-assistant session commands together.

↪ How many machines one remote assistant can serve before requests wait minutes for a person is developed in section 17.3.2.

Table 14.6: Blending windows on the mobile manipulator: One remote-assistant session commands both channels, and each window is rounded up to whole 1 ms permission ticks. The rate ceiling r bounds the derivative of each *command*. The base window is the same at every speed, because the jerk bound belongs to the loaded base. At the in-loop request speed a braking blend does not fit the clearance that remains, so the base receives the resident stop and its window applies only to non-braking changes. Every lease and pending deadline must fit the state-dependent stopping reserve.

Machine channel	Command change and chosen rate ceiling	Smoothstep window $\tau_{\text{blend}} \geq 1.875\lvert\Delta u\rvert/r$, whole ticks	Human / protocol time	Fallback contract
Base acceleration command	Zero to 2 m/s²; $r = 7.11$ m/s³, the resident stop's jerk bound	528 ms	605 ms / 31 ms	100 ms manual lease; 500 ms pending ceiling shortened by clearance
Arm joint torque command	15 N·m; torque rate $r = 750$ N·m/s	38 ms	605 ms / 31 ms	The same manual lease; its loss invokes the arm's validated stop

Consider an illustrative remote-assistant in-loop takeover, requested after the mobile manipulator has slowed to 0.75 m/s with the assistant's `manual_drive` entry. The four parameters take the values already derived. The reaction budget T_{Σ} is the 605 ms in-loop takeover of section 14.2.2, which already includes transport and the 31 ms four-phase exchange of table 14.5, so the handshake is part of T_{Σ}, not an addition to it. The manual lease, the longest silence tolerated from the assistant before the permission path falls back, is 100 ms, and table 14.6 gives the blending window for each channel.

An in-loop session at 0.75 m/s closes its complete budget by only a few centimeters, and only because the base takes its resident stop rather than a braking blend. A session that begins at the 0.15 m/s crawl or from standstill has far more room, so those are the configurations worth qualifying. Table 14.7 charges the in-loop session's intervals one at a time against the clearance the finished budget leaves at that speed.

Table 14.7: Clearance budget for an in-loop remote-assistant session: Each row charges one interval at the 0.75 m/s request speed, in the capture-origin design budget, and the last column carries what remains. The first four rows close the complete budget by a few centimeters; the blend row would overrun it. These are screening values for an allocated, unmeasured Δ_{da}, not a qualified admission result.

Interval charged at the in-loop request speed	Travel	Clearance left
None (the finished budget's spare)		563.7 mm

Interval charged at the in-loop request speed	Travel	Clearance left
In-loop takeover T_{Σ}, handshake included	453.8 mm	110.0 mm
Dispatch-to-admission allocation Δ_{da}	47.5 mm	62.5 mm
Manual lease in place of the chunk lease in τ_{delay}	30 mm	32.5 mm
Base braking blend (reserve it would use)	up to 157.0 mm	Does not fit; the base takes its resident stop

Three rows of the table decide that verdict. The remainder after the takeover, the 146.6 ms by which the takeover beats $T_{\mathrm{deadline,fallback}}$ (section 14.2.4), bounds the transfer itself. Any further delay before a stop could begin while authority is changing hands must fit inside it, and the enforcer checks the resident stop against it at every tick of the transfer. The lease row exists because, once the assistant holds `MAN`, the manual lease replaces the 60 ms chunk lease inside τ_{delay}, so its extra length becomes travel. The row is the upper bound on the lease set out in section 14.3.4, and the chosen value passes it. The blend row fails. Blending the step to braking from 0.75 m/s grows the travel plus the resident stop from the blended state by up to 157.0 mm, well past the remainder, so in this session the base receives the resident stop and only the arm blends. This conservative per-tick check charges a fresh resident stop starting from zero deceleration at each blended speed rather than the partial model's 82.4 mm constant-deceleration tail, because any fallback triggered during the blend begins from the standard resident profile. The slow-down was derived with Δ_{da} charged, so the complete budget closes, but by centimeters, another reason the base should complete its stop before accepting continued manual motion.

At the crawl, after a 4.5 s out-of-loop takeover, 198.4 mm remains before the same charges, and the base's stop from the crawl is its resident stop, with no braking blend to reserve. The admission allocation and the lease extension cost travel in proportion to speed, so at the crawl they take only a small part of that remainder. Once the assistant holds `MAN`, the live check of table 14.3 uses the current remaining clearance, the measured speed, and only the unelapsed portions of those intervals; commit does not restore the distance spent waiting or blending. These figures screen the candidates. Qualification must still check the rounded executable profile and the state-matched fallback, including delay travel, over the full transition, against a measured Δ_{da}.

Every command in that session, whether a streamed pose, a force-guided target, or a heartbeat that renews the manual lease, must also come from the authenticated operator that the `manual_drive` entry names. A budget that closes by a few centimeters leaves no room for a forged or replayed packet, which makes identity and packet admission the next constraint.

14.5 Authenticating an Intervention

On a shared wireless link, a legitimate `veto_path` intervention packet and an unauthorized drive-torque packet can arrive within the very same control cycle. The permission architecture must prevent an adversary or malformed network frame from seizing kinetic authority, yet it must never obstruct an authorized operator from arresting the machine before a collision. Systems engineers reconcile the two demands by classifying intervention operations according to the mechanical work they produce. Stopping the machine by removing power or engaging a mechanical holding brake is not symmetrical with injecting active motion commands, so the two actions take different verification paths. A protective stop brings the machine to a controlled halt along a braking or holding rung of the fallback ladder rather than abruptly cutting actuator torque. Commanding base velocities, wheel torques, or joint trajectories, by contrast, injects fresh mechanical energy into the plant: a forged or corrupted trajectory command can drive a moving mass into an obstacle, whereas an authenticated out-of-band protective input only requests a plant-specific minimum-risk stop.

Authentication adds delay to the remote intervention path, so it is priced against the same deadline as every other latency source, the latest fallback deadline $T_{\mathrm{deadline,fallback}}$ of equation 14.4. At the warehouse aisle velocity of 1.3 m/s, the partial spare permits at most 100.8 ms of added delay before charging the admission latency Δ_{da}, which drops to 37.5 ms once the placement allocation is charged. Transferring published Cortex-M4 cycle counts to the reference microcontroller clock gives an illustrative estimate of 1.8 ms for one Ed25519 signature verification[10] (Owens et al. 2024),

[10] **Ed25519**: The Edwards-curve signature scheme of Bernstein et al. (2012) provides rapid verification alongside compact 32-byte public keys and 64-byte signatures. Constant-time implementations eliminate secret-dependent branches and memory lookups to protect against side-channel timing attacks. While that defense primarily shields the signing teleoperation console, the receiving safety microcontroller only verifies incoming frames. Well-formed invalid signatures can still require the expensive verification path, even when malformed inputs admit early rejection. The verifier's processing load therefore depends on admitted traffic and its verification paths, the vulnerability that the verifier-flooding analysis of section 14.9 prices.

which translates into 2.34 mm of physical travel and leaves 128.7 mm of spare displacement margin. The same cycle-count and clock-rate estimate for an AES-128 CMAC over one command frame is 5.0 µs (Dworkin 2005; Schwabe and Stoffelen 2017). Per packet, both estimates fit within the deadline; loaded measurements on the target must qualify them. The design problem is therefore not choosing an algorithm but meeting five requirements on the admission path that carries the packets:

1. **Protective stops never wait for verification.** The local hardware fallback timer and independently wired emergency inputs act unconditionally, regardless of whether cryptographic routines have completed or stalled. If a verification routine overruns its deadline, the permission subsystem marks remote assistance as unavailable and cedes control to the autonomous protection layer; it never postpones an emergency deceleration. As analyzed in the verifier-flooding pitfall of section 14.9, what causes a cryptographic verifier to miss real-time deadlines is rarely the algorithmic cost of an individual packet, but rather the ingress volume of hostile or unvetted network traffic saturating the execution queue.
2. **Takeover requests must be attributable to an individual.** Because a symmetric Message Authentication Code (MAC) relies on a shared key known to both endpoints, a valid tag proves frame integrity but cannot prove which endpoint originated the transmission. An asymmetric digital signature, however, cryptographically binds the takeover request to the teleoperator's private key, supporting attribution when credential enrollment, key custody, and compromise evidence also identify the operator. The architecture therefore mandates an asymmetric digital signature on the session-initiating `manual_drive` request, while subsequent streaming commands and periodic heartbeats rely on the lower-overhead symmetric MAC.
3. **Freshness represents a spatial displacement budget, not merely a clock tolerance.** In embodied systems, packet latency translates directly into unmodeled vehicle travel. A replayed or delayed motion packet arriving at the boundary of a 100 ms freshness acceptance window commands an action based on an obsolete vehicle pose. Over that interval the mobile base travels 130 mm, consuming nearly the entire safety margin and leaving only 1.0 mm of the 131.0 mm partial spare. Once the admission latency Δ_{da} is factored in, such a replay completely overruns the available spare, so the allowable freshness window must shrink below 37.5 ms. The receiver drops counters no newer than the last authenticated, accepted counter before spending processor cycles on cryptography. It advances that stored counter only after authentication and freshness checks pass, so an unauthenticated high counter cannot invalidate later legitimate traffic. Furthermore, if heartbeat packets cease for longer than the lease duration $T_{\mathrm{lease,man}}$, the controller immediately revokes manual authority and engages the certified local fallback ladder.
4. **Malformed traffic never alters control authority.** Any packet with a corrupted checksum, an out-of-order sequence counter, or an invalid authentication tag is immediately rejected and recorded according to Rule A4 of section 14.8. A corrupted packet neither modifies existing actuator channel assignments nor triggers a spurious emergency stop. Rejecting an isolated invalid packet preserves still-valid authority; interference or dropouts that prevent timely renewal still expire the lease and invoke the qualified fallback.
5. **Every actuator-write path must be accounted for.** All side channels capable of driving physical hardware, including diagnostic ports, hardware bootloaders, debug interfaces, and direct fieldbus wiring, must be gated by the hardware permission authority or guarded by dedicated interlocks. The intervention threat model explicitly accounts for unauthorized remote packets injected across wireless links, replay attacks traversing internal communication buses, and rogue commands originating from a compromised high-level application processor. Physical tampering, by contrast, enters the safety assurance case only when explicitly mandated by the operational threat model.

These authentication and transport latencies directly impact policy learning and sim-to-real transfer. An embodied simulator that provides instantaneous human takeover underprices the danger of visiting marginal states. If an autonomous policy learns that intervention occurs instantaneously, it will tolerate trajectories that are physically unrecoverable once realistic communication, cryptographic verification, and actuator fallback latencies are introduced. Training and hardware-

in-the-loop evaluation pipelines must therefore inject these bounded authentication, transport, and mechanical reaction delays.

Verifying an incoming packet authenticates its credential; the capability manifest separately determines its privileges. Cryptographic validity alone cannot guarantee dynamic stability during control transfer. When authority shifts while the chassis carries linear momentum and the manipulator actuators exert active joint torques, the permission path must commit one selected source per channel and announce that ownership to the operator. Local mutual exclusion and human mode awareness are separate requirements; a valid packet establishes neither by itself.

14.6 Authority Handover Failure Modes

When the warehouse mobile manipulator's perception policy meets an unmodeled specular reflection from wet shrink-wrap on a pallet, depth artifacts drop its confidence and the runtime asks a remote assistant to reposition the gripper. If the console grants manual joystick authority over the arm without locking the base channel or announcing that the base is still moving, an assistant focused on aligning the fingers assumes the chassis is stationary. Meanwhile the autonomous navigation thread keeps driving the wheels into a rack upright. Every individual hardware and software component in that handover operates within its specification. The collision comes from mode confusion, the failure class that Sarter and Woods identified in automated aircraft cockpits (Sarter and Woods 1995). Every operating mode added to a control loop multiplies the state a human supervisor must track. When an interface changes modes without unambiguous telemetry of which agent holds each channel, operators take actions that are right for their assumed mode and hazardous in the actual one (Sarter and Woods 1995). In embodied physical systems, the most dangerous form of this failure is **authority ambiguity**: a state in which the autonomous runtime assumes the human has taken over a physical degree of freedom, while the human assumes the automated controller still guides it.

Definition 14.3: Mode confusion

Mode confusion is a mismatch between the operational state a human supervisor believes an automated system occupies and its actual execution mode, leading the supervisor to take actions that would be correct for the presumed state but are hazardous in the real one.

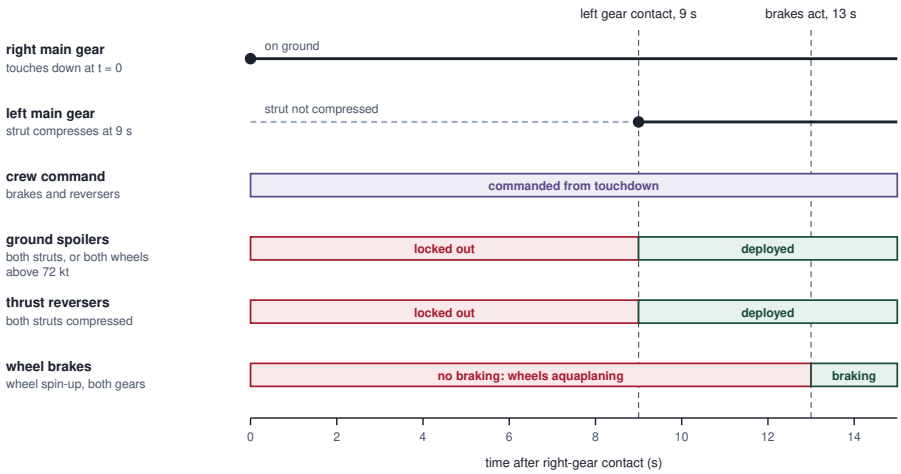
1. **Significance**: When control channels transfer authority independently, an operator's mental model of one channel can easily go stale while their attention is consumed by another. For example, an operator dedicates the 605 ms in-loop response window entirely to an arm alignment, under the false belief that the base is parked. The base, running under the autonomous policy at 1.3 m/s aisle speed, then travels 786.5 mm, which is 16.1× the 48.7 mm margin the complete budget leaves for $d_{\text{stop}} \leq D_{\text{clear}}$.
2. **Distinction**: Conflicting command streams between concurrent software modules represent an arbitration fault, which single-owner bus gating resolves by construction. Mode confusion, by contrast, resides within the supervisor's mental model of the machine. Resolving it requires committed channel masks and explicit per-channel status annunciation at the console, because deterministic ownership on the CAN bus or Ethernet backplane cannot correct a human's false assumptions.
3. **Common pitfall**: Telemetry confirming that an operator's gaze is directed at a primary task monitor does not guarantee the absence of mode confusion. Tracking an operator's visual focus onto an end-effector camera stream reveals nothing about whether that operator realizes the autonomous navigation stack still holds kinetic authority over the drive chassis.

On a machine with several axes, control authority splits naturally across distinct groups of joints, such as the mobile base's planar velocity $(\dot{x}, \dot{y}, \dot{\theta}_{\text{head}})$ and the manipulator arm's joint positions. In the wet-shrink-wrap collision, those channels transferred independently. Telemetry logs reveal the fault as disjointed control flags toggling asynchronously across execution threads. At the human-machine interface, however, the split state stays invisible until physical clearance is exhausted, because neither

the policy nor the human receives an immediate, unambiguous indicator of the other's partial withdrawal.

To prevent this desynchronization, handover protocols must enforce explicit, per-channel bitmasks across every phase of negotiation. Every `Request`, `Acknowledge`, and `Commit` message must declare the exact subset of degrees of freedom being transferred. The formal transition state machine of section 14.3 moves proposal tokens exclusively for those designated channels, and the subsequent `Confirm` phase explicitly annunciates active ownership on each channel back to the operator console. A channel left out of the bitmask may keep its autonomous owner, so the base can keep navigating while the operator takes the arm. This holds only while the console annunciates that the base is still moving under the policy and the operator's acknowledgment covered that state. Without that annunciation, the commit places the untransferred channel in a certified holding state, such as an active brake hold, rather than letting autonomous execution continue silently. The wet-shrink-wrap collision above is the second rule's case, an untransferred base left running without annunciation.

Explicit channel ownership protocols solve arbitration on the digital bus, but they cannot restore the situational awareness of an out-of-loop human. For this reason, the in-loop and out-of-loop takeovers of section 14.2.2 must be treated as distinct operational states with different timing budgets, the 605 ms and 4.5 s that set different request speeds. While gaze tracking can verify where an operator directs their eyes, it cannot verify cognitive comprehension or justify truncating the required takeover latency budget. Local stopping envelopes must remain continuously armed and active, even when the console reports an attentive supervisor. Two field incidents show what happens when either half of this two-layer protection is missing.



In the Tempe, Arizona collision, the National Transportation Safety Board (NTSB) determined that the safety driver was visually distracted by a personal smartphone, identifying operator complacency and inadequate monitoring policies as primary contributing factors (National Transportation Safety Board 2019). The vehicle architecture had disabled automatic emergency braking during testing and relied entirely on the human supervisor to perceive hazards and intervene. In the San Francisco Cruise incident, an autonomous vehicle executed an emergency stop after striking a pedestrian who had been thrown into its path by an adjacent human-driven car. The onboard planner, however, subsequently initiated an automated pull-over maneuver, dragging the pedestrian beneath the chassis (Quinn Emanuel Urquhart and Sullivan, LLP 2024). The Tempe disaster demonstrates why an operator-monitoring contract must always be backed by an autonomous, local stopping envelope capable of bringing the machine to a halt within the remaining sensor clearance, regardless of operator attentiveness. The Cruise incident demonstrates that unexpected physical contact, tactile sensor anomalies, or sudden external force spikes must immediately lock out all motion authority into a verified physical inspection hold, rather than allowing automated post-collision clearing routines to execute.

↩ The Tempe timeline, including the action suppression that withheld emergency braking, is established in section 1.8.

A human operator's manual command can oppose an active safety barrier without creating a multi-writer conflict on the actuator bus. When an operator commands a manipulator toward a prohibited obstacle, the downstream safety enforcer either projects the trajectory onto the safe half-space or rejects the command entirely, dispatching only the admitted control action to the motor drives. However, the supervisory console must make this active constraint immediately visible to the human. If the interface conceals why the robot has stopped responding, the operator will instinctively command higher control effort or larger joystick displacements, leading to severe command saturation and instability once the constraint clears. Furthermore, when the console incorporates bilateral teleoperation or force-feedback interfaces, system stability depends directly on the passivity-based energy bounds established in section 14.4.5; ownership tokens alone cannot prevent feedback oscillations across a physical-virtual coupled loop.

Authority ambiguity also corrupts downstream imitation learning. If the record cannot say who held each channel, interventions are mislabeled as autonomous behavior or the reverse, and a behavioral-cloning policy learns to reproduce the very errors that triggered the takeover. A low offline validation loss cannot catch this, because it only shows that the policy memorized the wrong labels. Causal intervention masking, developed in section 14.8.3, depends on ownership bits that the authority record stamps at commit time.

War Story 14.1: Ground-contact interlocks on flight 2904

Context: On Lufthansa Flight 2904 at Warsaw, the flight crew executed an approach based on outdated wind reports, encountering an unreported tailwind that caused the aircraft to touch down at high speed far down a waterlogged runway. Upon touchdown, the crew immediately commanded maximum manual braking and deployed thrust reversers, but the aircraft's automated flight-control logic refused to grant deceleration authority (Main Commission Aircraft Accident Investigation Warsaw and German Federal Bureau of Aircraft Accident Investigation 1994).

Mechanism: Crosswinds and runway hydroplaning delayed the left gear compression: the right main gear made contact 9 s before the left. The aircraft's deceleration interlocks were rigid. Ground spoiler deployment required weight-on-wheels shock-strut compression on both main gears **or** wheel spin-up above 72 knots. Thrust reversers required weight compression on both main struts. Mechanical wheel braking was locked out until the main wheels achieved synchronized spin-up. Because hydroplaning prevented wheel spin-up and an asymmetric roll angle kept the left strut uncompressed, the control logic determined the aircraft was still airborne. Consequently, the flight computer locked out spoilers and reversers for 9 s and inhibited wheel brakes for even longer.

Impact: Wheel braking was inhibited until 13 s after initial touchdown. With braking authority locked out across the primary deceleration zone, the aircraft could not dissipate its kinetic energy along the remaining wet runway. It overran the runway threshold at 72 knots, struck an airport embankment, and caught fire, resulting in two fatalities and total hull loss.

Response: Official accident investigators cited the ground-contact interlock logic as a critical contributing cause alongside crew decision-making and delayed meteorological updates. The crew could not override the spoiler and reverser lockouts. The report identifies those design constraints alongside crew actions and incomplete landing-distance guidance; it does not establish that a manual override alone would have prevented the overrun.

Systems lesson: Embodied robots share this exact failure topology whenever automated sensor preconditions, such as docking latch checks, wheel-slip traction observers, or ground-contact switches, gate emergency braking or reverse-torque commands issued by human supervisors. Unmodeled wheel slippage or uneven terrain can violate a sensor predicate precisely when deceleration is urgently required. Any control architecture that gates physical actuation behind automated preconditions must satisfy three rules. First, it must immediately annunciate unsatisfied interlocks across the operator console. Second, it must explicitly identify the unfulfilled sensor predicate. Third, it must provide a deterministic fallback mode for sensor disagreement. Rather than bypassing safety interlocks blindly, the supervisory architecture

must define a certified fallback deceleration path that executes based on conservative, physically verifiable stops.

The formal authority arbiter detailed in section 14.3 exists to prevent these failures. Safe embodied control architectures cannot rely on implicit authority handoffs, assumed human vigilance, or ad hoc torque summing on the actuator bus. Evaluating post-incident behavior requires a tamper-evident, channel-by-channel telemetry record captured at every control cycle, with explicit gaps and bounded event timing. The surviving record can help distinguish a safety boundary breach, an invalid token exchange, and electrical noise on a safety bus only to the extent that its independent measurements, capture coverage, and timing bounds separate those events. Its storage path must therefore survive unexpected power interruptions, kernel panics, and real-time scheduling stalls.

14.7 Trustworthy Operational Logs

Consider a robotic arm striking a warehouse racking upright during a supervisory takeover. If the operational log contains an unrecorded gap, investigators cannot determine whether the policy proposed the damaging trajectory, the enforcer admitted it, or the operator received authority too late to intervene. Rigorous incident reconstruction requires two foundational properties: declared loss handling and an operational record engineered to survive physical failure.

A trustworthy record must capture state on both sides of the causal boundary, paired with independent plant observations.[11] Motor phase currents, optical encoder positions, and wrist force-torque measurements provide physical observations distinct from software setpoints, subject to their calibration, bandwidth, and uncertainty bounds. Dispatched commands alone cannot prove delivered actuator torque or establish mechanical collision causality.

At every cycle, the 1 kHz deterministic control loop records a structured authority and action tuple under declared loss handling. The minimal **evidence tuple** takes the form:

$$\langle t_{\text{MCU}}, S_{\text{auth}}, \mathbf{x}, \mathbf{u}_{\text{nom}}, \mathbf{u}^*, \tau, \text{ID}_{\text{operator}}, T_{\text{lease,rem}} \rangle$$

This tuple records both sides of the proposal-permission boundary. Its command fields are the action taps of section 5.5.1 taken at intervention time: $\mathbf{u}_{\text{nom}}$ is the requested or mapped command (a_{req} or a_{cmd}, whichever the source emits), $\mathbf{u}^*$ is the enforced command a_{enf}, and the measured response a_{meas} lives in $\mathbf{x}$. The fields are:

- t_{MCU} is the monotonic event timestamp recorded in nanoseconds by the safety microcontroller hardware clock, mapped to other subsystem clocks through a qualified clock-conversion method with an explicit error bound. Expressing values in nanosecond units does not imply nanosecond-level inter-device synchronization accuracy.
- S_{auth} records the active discrete authority state (`AUTO`, `PEND`, `BLEND`, `MAN`, `FALLBACK`, or `PROTECTIVE`).
- $\mathbf{x}$ captures the instantaneous measured plant state, including joint angles, velocities, motor phase currents, and IMU linear accelerations.
- $\mathbf{u}_{\text{nom}}$ is the proposed plant control setpoint requested by the cognitive policy or human operator console.
- $\mathbf{u}^*$ is the control command admitted by the enforcer, including a feasible CBF-filtered proposal or the selected qualified fallback. Associated event metadata must distinguish admission, modification, and rejection; section 12.7.1 specifies the projection path.
- τ is the actuator torque command dispatched across the real-time fieldbus to the motor inverters. It is still a command; delivered motor torque can be estimated from the measured phase currents in $\mathbf{x}$ using a qualified motor model and explicit uncertainty bounds.
- $\text{ID}_{\text{operator}}$ identifies the authenticated cryptographic entity holding active proposal rights.
- $T_{\text{lease,rem}}$ records the remaining time on the active execution lease (T_{lease} or $T_{\text{lease,man}}$, minus the elapsed duration $t_{\text{MCU}} - t_{\text{refresh}}$).

Omitting any of these fields breaks post-incident reconstruction. Without the proposal $\mathbf{u}_{\text{nom}}$, a dispatched torque τ cannot show whether the policy or operator asked for an erratic action. Without the enforcer output $\mathbf{u}^*$, the log cannot show whether the safety barrier modified that

11 **Event Data Recorder Baseline**: A passenger-vehicle event data recorder captures 5 s of pre-crash data at 2 Hz (phasing in from September 2028 to 20 s at 10 Hz), which even under the modernized rule yields only one sample per 100 ms across 100 permission ticks (National Highway Traffic Safety Administration 2024a). Similarly, the data storage system mandated for automated lane-keeping systems under UN Regulation No. 157 logs system activations, overrides, and transition demands to establish driver attribution, but its timestamps require accuracy only within 1 s, or 1,000 permission ticks (United Nations Economic Commission for Europe 2021). Because neither regulatory standard provides the time resolution needed to order an intervention against physical contact within a single control cycle, the autonomous machine must maintain its own deterministic, per-tick operational record.

↩ A record of what was proposed, evaluated, dispatched, and measured is the third demand on the permission path established in section 1.9.

DRAFT

request. Without $T_{\text{lease,rem}}$, it cannot show whether authority had already lapsed into a fallback mode when the command was evaluated. Chained with cryptographic integrity proofs and clock-synchronization metadata, these tuples form the per-tick half of the authority record that section 14.8 specifies.

Three architectural requirements ensure that logged tuples serve as reliable forensic evidence. First, timestamps must date physical events rather than software handling. A software interrupt handler that samples the clock only after being scheduled records its own execution delay rather than the event time. Under variable scheduling jitter and interrupt latency, this delay can easily invert the apparent chronological order of an intervention command and a mechanical contact. Protective inputs and fieldbus ingress packets must therefore be timestamped directly at the hardware boundary through timer edge capture and network controller hardware counters. When clock-conversion error, sensor exposure windows, and sampling intervals overlap between two events, the log must explicitly record their relative order as indistinguishable rather than asserting an unverified sequence.

Second, the storage pipeline must be strictly tiered by guarantee level. Minimal evidence tuples stream to a bounded ring buffer in non-volatile memory on the safety microcontroller. The serialized tuple size multiplied by the control tick rate sets a continuous write bandwidth that hardware qualification tests must prove the device sustains under all operating regimes, with buffer overflows explicitly flagged rather than silently dropped. High-bandwidth perception streams, including camera frames, point clouds, and policy internal activations, flow to a best-effort buffer on the primary host. This high-volume traffic is never permitted to contend for the safety microcontroller's memory or bus bandwidth.

↩ The multi-camera ingestion rate that this best-effort buffer must absorb is established in section 5.6.2.

Third, loss must be declared explicitly. When buffer exhaustion or bus stalls occur, the logger must record a missing entry or overwritten frame as a declared gap in the evidence, never as an implied safe pass. A declared gap alerts both post-incident auditors and downstream training pipelines that the trajectory continuity was broken, whereas a silent drop makes two separated ticks appear contiguous in time.

Upon receiving an intervention trigger, such as an operator takeover command, an emergency stop assertion, or an enforcer barrier violation, the logger freezes a configured **pre-trigger window** ($T_{\text{pre}} = 5$ s) and transitions to recording a dedicated post-trigger segment. The pre-trigger duration matches the 4.5 s design out-of-loop takeover latency characterized in section 14.2.2, rounded up to whole seconds. This window preserves the design takeover interval, but policy divergence may begin before the operator notices it, so its duration alone does not establish that the complete causal chain remains in the log. Operational sites that measure longer takeover tails must lengthen T_{pre} accordingly. Overwritten frames or dropped samples within this interval remain declared gaps in the evidence. Section 5.8 uses this same window as its lookback horizon, searching it for the divergence point t_{div} and detailing why learner-visited states during drift are essential for offline policy training. The authority record provides the cryptographic ownership stamps that allow the training pipeline to distinguish unprivileged policy proposals from enforcer interventions and operator overrides.

Finally, the operational record must reveal any subsequent tampering or truncation. Each entry carries a keyed cryptographic link over its predecessor,[12] while periodic authenticated anchors are written to replay-protected storage located outside the logger's primary write path. Rewritable non-volatile storage with authenticated writes satisfies this requirement, avoiding the need for dedicated write-once media. Under this design, investigators can determine exactly which log prefix each anchor authenticates, verify that cryptographic keys and anchors remained in trusted custody, and flag any unanchored tail or missing block as a declared gap. Hardware-level tamper resistance and loss declaration protect record integrity and expose missing evidence; they do not establish that a sensor reading is accurate. To serve post-incident reconstruction and downstream policy training, however, these raw evidence streams must be bound into a formal, machine-checkable artifact: the authority record.

[12] **Linked Hash Chains:** Haber and Stornetta (1991) proposed linking each timestamp to the cryptographic hash of its predecessor, ensuring that no historical record can be backdated or inserted without invalidating every subsequent link. The authority record inherits both this tamper-evident property and its limit, since an adversary possessing the signing keys and complete control over the storage device can recompute the entire chain. To protect against retroactive tampering, commitment anchors must be mirrored to an independent, replay-protected storage domain outside the logger's mutable write path.

14.8 The Authority Record

When an incident investigator asks, weeks after an abrupt blocked-aisle takeover, which entity drove the mobile base as it neared the rack end, the machine's recorded telemetry provides evidence bounded by its capture coverage, clock alignment, independent plant measurements, and trusted

custody. The **authority record** bridges real-time supervisory arbitration with downstream verification and release claims. To establish this audit trail, the authority record consumes two upstream contracts. From the enforcement record of section 12.11, it ingests the rungs of the fallback ladder so that every logged fallback explicitly identifies the rung executed by the permission path. From the placement record of section 13.8, it incorporates the permission path's declared timing bounds and bus arbitration settings, which every operator command also crosses, together with the placement record's loaded-test field, which stays empty until verification fills it. The record shows who held each channel at each tick; it does not show who decided the speed, the staffing, or the operating domain that put the machine there.

↪ The record of who decided that the machine could be in that situation at all, with a named owner for each decision, is developed in section 17.9.

To these upstream contracts, the authority record adds two deliverables of its own. The static authority manifest translates the capability matrix of section 14.2 into a machine-checkable contract. It binds every actuator channel to its authorized actors, operational preconditions, preemption tiers, and transition deadlines, and the safety microcontroller verifies and seals this manifest before the actuator drivers energize. Complementing the manifest, the record's per-tick log forms an independent stream that records, for every control cycle, which entity held kinetic authority alongside the commands proposed, admitted, and dispatched, paired with independently measured physical response. In this stream, a missing cycle registers as an explicit communication or capture gap rather than an implied pass. The static manifest establishes the legal rules of interaction, while the per-tick log supports checking recorded runtime adherence under the capture, synchronization, custody, and declared-gap assumptions of section 14.7.

14.8.1 The static authority manifest and capability binding

If an operator's permissions or a channel's rate limits can be edited in software while the machine runs, a post-incident log cannot prove which rules the arbiter was supposed to enforce at the moment of a takeover. The static authority manifest fixes those rules before the actuators energize: loading and cryptographically sealing the manifest during system initialization binds every subsequent event to the permissions and physical limits in force at boot. It specifies every permitted interaction as a verifiable contract between the physical platform and potential command sources. Each entry delineates a distinct physical authority domain using a hardware actuator mask, an authorized entity class (such as a local physical operator, a remote teleoperation console, an autonomous trajectory policy, or an emergency stop loop), and an integer **preemption tier**. Before any command vector enters the actuation pipeline, the permission path verifies the sender's cryptographic role credentials against this manifest. Over the network, an operator's command arrives as an `OPERATOR` payload under the same proposal header, carrying the operator's role, the requested channel mask, the command vector, a monotonically increasing nonce, and a keyed authentication tag.

In addition to credential validation, each manifest entry enforces four operational invariants on its assigned channel:

1. *Single-writer mutual exclusion*: Hardware access controls guarantee that exactly one entity writes to an actuator channel at any given instant.
2. *Execution lease duration ($T_{lease,man}$)*: For human operators, the lease defines the maximum tolerable silence before the enforcer revokes authority and triggers a state-dependent fallback.
3. *Command rate ceiling (r)*: A hardware slew limit caps how rapidly a requested command vector may change between successive cycles, preventing abrupt step inputs.
4. *Bumpless blending duration (τ_{blend})*: A transition window enforces a C^2 continuous authority transfer ramp that preserves the kinodynamic feasibility bounds established in section 11.4, requiring a qualified executable profile and a feasible state-matched fallback at every transition state if communication severs. The fallback depends on surviving sensing, controller, and energy premises; duration and continuity alone do not establish it.

14.8.2 Per-tick evidence tuples and the fault injection suite

A general telemetry tuple that records only a single machine-wide mode cannot show which channels were mid-blend, which fallback rung fired, or why a higher-tier source preempted a lower one. Every entry in the authority record's per-tick log therefore expands the evidence tuple of section 14.7 with further fields. A field names the specific actuator channels governed by the arbitration decision.

DRAFT

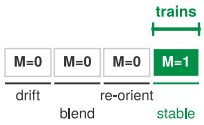
Another gives the ladder rung of any active `FALLBACK`. Others give the root cause of any preemption and the instantaneous blend factor $\alpha(t)$ of the enforcer-managed profile. The last is a cryptographic hash link to the preceding log block, authenticated through the platform's protected anchoring scheme. The versioned static manifest supplies the decoding context, specifying physical units, field serialization order, clock synchronization mappings with their associated error bounds, credential validation rules, and hardware access control masks.

Verification draws its test inputs from the static manifest and its evidence from the event schema. The manifest's `authority_claims` field hands section 15.6.2 four authority rules by identifier, each of which becomes a hardware-in-the-loop fault case on the machine:

↪ **Byte layout:** The operator payload's and the authority record's fields, types, and offsets are given in section C.15.6.

- **A1.** Exactly one qualified enforcer output path writes each actuator channel. Source arbitration and hardware access controls prevent a second sender from bypassing that path while the policy and remote assistant both propose commands; successful bus arbitration alone does not satisfy this claim.
- **A2.** No lower-tier source bypasses an active higher-tier source or the independent permission check. An autonomous policy proposal during `MAN` is ignored, and an assistant command that opposes the enforcer's admitted barrier limit is clamped or rejected.
- **A3.** An unacknowledged handover or stalled manual lease decays authority by T_{timeout} of section 14.2.4, initiating controlled fallback by the earlier of the configured lease ceiling and the clearance-derived deadline of equation 14.4. This clearance deadline has a partial-budget upper bound of 751.6 ms at the 0.75 m/s slow-down before an in-loop takeover, and 100.8 ms for a handover requested by the policy at the 1.3 m/s aisle speed. Both values represent additional-delay allocations in the capture-origin budget. The runtime deadline evaluates the actual event history and future delay budgets without double-charging for elapsed capture-to-admission transit.
- **A4.** The enforcer rejects replayed `veto_path`, `manual_drive`, or `accept_item` packets, and packets with invalid authentication tags or expired sequence counters, without modifying still-valid channel authority. It logs each rejection in the evidence tuple while allowing the active lease to age normally.

These authority rules turn the event log into a checkable contract. The same synchronized hardware timestamps also mark which controller generated each segment of an intervention trajectory, and that separation must exist before any segment can serve as a training target for imitation learning.



14.8.3 Causal masking and recovery eligibility

If a training pipeline feeds an entire rescued episode into behavioral cloning without filtering, the policy learns to imitate the autonomous drift that caused the near-miss, the enforcer's synthetic blend spline, and the operator's initial startled oscillations. The curation rules of section 5.8 prevent that contamination by deciding which logged samples may train a policy: drift commands are quarantined, drift states are relabeled only by an automated expert, and only stabilized, reviewed recovery is admitted. Each rule keys on a timestamp that the authority record supplies, so a logging system that records intervention episodes for downstream policy retraining must preserve controller ownership, target meaning, and declared sample eligibility. This chapter's conservative direct-imitation policy applies **causal intervention masking** to that record. Its optimization objective over recorded trajectories is formulated as:

$$\mathcal{L}_{\text{imitation}}(\theta) = \mathbb{E}_{(\mathbf{x},\mathbf{u}_{\text{target}},\mathcal{M})\sim\mathcal{D}_{\text{train}}}\left[\sum_{k=0}^{S}\mathcal{M}(k)\cdot\ell\left(\pi_\theta(\mathbf{x}_k),\mathbf{u}_{\text{target}}(k)\right)\right] \tag{14.8}$$

where $\ell(\pi_\theta(\mathbf{x}_k),\mathbf{u}_{\text{target}}(k))$ denotes the policy prediction loss (such as mean squared error across action chunks or score-matching denoising loss for diffusion policies), $\mathcal{M}(k)\in\{0,1\}$ is a binary causal mask, and $\mathbf{u}_{\text{target}}(k)$ is the supervised training target. Each sample's mask and target are evaluated at that sample's logged hardware timestamp. The target carries its own symbol because it is not the admitted command $\mathbf{u}^*$ of the evidence tuple; in each interval it is chosen from the logged fields, or supplied by an expert, as the interval list below states. Constructing the training dataset $\mathcal{D}_{\text{train}}$ requires selective transformation rather than wholesale ingestion of raw telemetry. While

every logged state preserves its chronological position in the trajectory, its supervision target $\mathbf{u}_{\text{target}}(t)$ and mask $\mathcal{M}(t)$ depend on the physical regime of the recording interval. As a result, the command dispatched to the hardware is not necessarily the training target. Deterministic authority transitions stamped by the safety microcontroller establish controller ownership. Empirical stabilization criteria, task validity checks, and the availability of expert labels, in turn, determine which samples receive $\mathcal{M}(t) = 1$.

One intervention, four intervals; only validated, stabilized recovery trains directly as a human demonstration.

A supervisory intervention does not occur as a single monolithic demonstration. Instead, it spans four distinct physical intervals along the execution timeline:

1. **Compounding policy drift ($t_{\text{div}} \le t < t_{\text{commit}}$)**: The autonomous policy π_θ drifts away from the expert state distribution, accumulating compounding errors while the human supervisor perceives the anomaly, orients, and decides to intervene (the pre-commit latency modeled in equation 14.1).
   - *Masking policy*: The autonomous proposals $\mathbf{u}_{\text{nom}}(t)$ executed during this drift are quarantined from training targets. Without an external expert label, the system sets $\mathcal{M}(t) = 0$.
   - *Relabeling*: The *learner-visited states* $\mathbf{x}(t)$ remain in the log for the corrective aggregation of section 5.8, whose relabeling rule accepts only an automated expert's labels. A drift state therefore enters training with $\mathcal{M}(t) = 1$ and target $\mathbf{u}_{\text{target}}(t) = \pi^*(\mathbf{x}_t)$ only when such an expert, for example an omniscient trajectory planner with privileged simulation state, supplies the correction.

2. **Atomic handover and enforcer blend ($t_{\text{commit}} \le t < t_{\text{commit}} + \tau_{\text{blend}}$)**: The safety microcontroller latches the channel endpoints and computes a C^2 continuous smoothstep trajectory between controllers.
   - *Masking policy*: The system sets $\mathcal{M}(t) = 0$ unconditionally. Dispatched setpoints $\mathbf{u}(t)$ during this window are synthetic interpolation splines generated by the enforcer's deterministic quintic polynomial profile. Because they reflect neither learned neural policy intent nor human cognitive demonstration, training on this interval would condition the network to emit open-loop kinematic ramps detached from environmental feedback.

3. **Operator re-orientation and hunting ($t_{\text{commit}} + \tau_{\text{blend}} \le t < t_{\text{stabilize}}$)**: Upon receiving the active manual lease ($T_{\text{lease,man}}$), the operator experiences neuromuscular latency, visual parallax, and control re-orientation, producing high-jerk, oscillatory corrections while regaining situational awareness.
   - *Masking policy*: The system enforces $\mathcal{M}(t) = 0$. Bainbridge documented this control hunting directly. An operator whose active manual skill has lapsed during passive monitoring makes abrupt step corrections, oscillating around the setpoint before settling into smooth tracking (Bainbridge 1983). Control stabilization often takes significantly longer than the physical handover itself. In driving simulator studies, operators resuming control from automated systems required approximately 35–40 s before their lateral steering stabilized (Merat et al. 2014), at least 7× the length of the machine's 5 s pre-trigger window. Consequently, post-trigger masking cannot rely on a fixed time constant; logging systems must evaluate empirical stabilization criteria. Discarding these initial frames prevents hesitation and oscillatory hunting from corrupting the imitation buffer. This exclusion involves an engineering trade-off, because interval 3 also contains the operator's initial corrective inputs, which certain human-gated methods retain (table 14.8). The enforcer marks the stabilization boundary $t_{\text{stabilize}}$ only after tracking error and command slew have remained within calibrated limits for a declared dwell interval. Later violations mask the affected samples again. The limits are:

$$\|\mathbf{e}_{\text{track}}(t)\| \le \epsilon_{\text{stable}} \quad \text{and} \quad \|\dot{\mathbf{u}}_{\text{human}}(t)\| \le j_{\text{stable}}.$$

     Here, $\mathbf{e}_{\text{track}}(t)$ is the difference between the admitted manual setpoint and the measured plant response, $\dot{\mathbf{u}}_{\text{human}}(t)$ is the time derivative of the operator's command, and the parameter j_{stable} denotes a channel-specific slew ceiling, representing an acceleration derivative (jerk) only when the underlying command vector represents acceleration. Both

DRAFT

thresholds must hold continuously across the dwell window before the logger lifts the mask.

4. **Stabilized expert recovery ($t \geq t_{\text{stabilize}}$)**: The operator executes coherent, task-directed recovery maneuvers once measured control metrics stabilize. Smooth motion alone does not validate a recovery; the episode must also satisfy formal task-completion criteria before its samples qualify as expert targets.
    - *Masking policy*: The system sets $\mathcal{M}(t) = 1$ with imitation target $\mathbf{u}_{\text{target}}(t) = \mathbf{u}_{\text{human}}(t)$ exclusively for stabilized segments that pass task-validity review. All other telemetry frames remain masked from direct imitation, so this interval is the only post-takeover segment the curation rules admit as expert recovery data.

Feeding unsegmented telemetry directly into behavioral cloning or diffusion policies injects synthetic enforcer ramps and operator control transients into the training distribution. The causal mask $\mathcal{M}(t)$ and target vector $\mathbf{u}_{\text{target}}(t)$ use the commit and state timestamps recorded by the safety microcontroller to enforce controller ownership boundaries, bounded by hardware clock synchronization and sampling limits.

The binary causal mask represents the most conservative member of a broader algorithmic spectrum. Contemporary human-in-the-loop learning methods treat interventions in fundamentally different ways: as direct state labels, as importance weights over surrounding trajectories, or as negative reinforcement signals indicating policy failure. Table 14.8 maps five representative paradigms onto these four operational intervals. For instance, Human-Gated DAgger (HG-DAgger) grants the human supervisor full authority upon takeover and aggregates only the human's executed commands, leaving interval 1 unmasked but unlabeled (Kelly et al. 2019). Sirius generalizes $\mathcal{M}(t)$ by assigning categorical importance weights across sample classes; it assigns zero weight to a fixed pre-intervention window while upweighting human recovery trajectories (H. Liu et al. 2023). Specifically, Sirius sizes its pre-intervention window to 15 robot actions (approximately 2 s), derived from observed human reaction times. While Sirius fixes this window a priori, the authority record timestamps the commit and supports reconstruction of the drift interval once t_{div} is identified from the retained evidence, a duration that the out-of-loop takeover budget of section 14.2.2 shows can be 2.2× longer. Meanwhile, Reinforcement Learning from Intervention Feedback (RLIF) eliminates the assumption of human optimality altogether, treating the intervention event as a negative reward penalty within an off-policy reinforcement learning framework (J. Luo et al. 2024). Similarly, Human-in-the-Loop Sample-Efficient Robot Learning (HIL-SERL) incorporates human interventions as targeted correction buffers for real-world reinforcement learning (Luo et al. 2025). Finally, RECAP, which trains the $\pi^*_{0.6}$ vision-language-action model, blends autonomous rollouts, teleoperated interventions, and demonstrations using advantage conditioning, explicitly labeling human takeover corrections as positive-advantage actions (Physical Intelligence et al. 2025).

Table 14.8: Human-in-the-loop learning methods as of 2026, placed on the four intervals: Every method needs the ownership boundary the authority record holds; they differ in what the intervention becomes and in which intervals they train on. None trains on the enforcer's blend as a demonstration. Entries summarize each method's published design (Kelly et al. 2019; H. Liu et al. 2023; J. Luo et al. 2024; Luo et al. 2025; Physical Intelligence et al. 2025); a later edition should refresh the list.

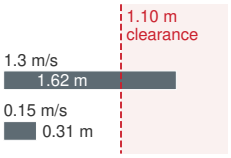
Method (year)	What the intervention becomes	Interval 1 (policy drift)	Interval 3 (re-orientation)	Needs from the authority record
Causal mask (this chapter)	Boundary between owners	Excluded unless an automated expert labels it	Excluded until measured stabilization	Commit, blend end, stabilization times
HG-DAgger (2019)	Label: human commands while in control	Not labeled	Kept with the human's commands	Owner per sample
Sirius (2023)	Weight per sample class	Fixed pre-intervention window, weight zero	Kept, upweighted	Commit time; window measured to it
RLIF (2024)	Reward: the takeover itself is a penalty	Kept; the takeover penalizes it	Human samples added to the data	Commit time as the reward event
HIL-SERL (2025)	Correction data for a reinforcement learner	Kept as the learner's own experience	Kept as correction data	Owner per sample

Method (year)	What the intervention becomes	Interval 1 (policy drift)	Interval 3 (re-orientation)	Needs from the authority record
RECAP, $\pi^*_{0.6}$ (2025)	Correction marked as a positive-advantage action	Kept; a value function scores it	Kept, marked positive	Owner per sample; episode outcome

Individual learning algorithms change, but every one of them must answer the same three systems questions: who held write authority over each sample, whether the takeover serves as a supervised label, an importance weight, or a reward penalty, and which physical intervals enter the training set. Downstream training pipelines cannot recover those ownership boundaries from trajectory kinematics alone. Recording the commit, blend-end, and stabilization timestamps on the safety microcontroller's clock grounds dataset curation and fleet-level intervention rates directly in hardware measurements.

When an engineering team assembles the safety case for release (section 16.3.3), the authority record also supplies the primary evidence that runtime handovers obey rules A1 through A4 (claim C6 in table 16.2). That release dossier pairs the static authority manifest with the loaded stopping and blending measurements from section 14.4 and hardware-in-the-loop traces that verify an unbroken audit chain. Because a handover that looks clean on the communication bus can still slip a wheel on a wet floor or jolt a loaded tote rack, the dossier always checks bus timestamps against independent plant sensors. It treats measured preemption times as empirical percentiles rather than analytical worst-case bounds.

↩ The distinction between an empirical latency percentile and a response-time bound is established in section 4.5.



Checkpoint 14.3: Authority evidence and causal masks

The authority record is useful twice, once to an investigator and once to a learner, and both uses depend on the same ownership timestamps.

- ☐ **Evidence tuple**: Can you name the incident question that becomes unanswerable when the log drops $\mathbf{u}_{\text{nom}}$, when it drops $\mathbf{u}^*$, and when it drops $T_{\text{lease,rem}}$?
- ☐ **Interval masks**: For one takeover, can you assign $\mathcal{M}(t)$ and $\mathbf{u}_{\text{target}}(t)$ to each of the four intervals and name the logged event that bounds each?
- ☐ **Sample count estimate**: An out-of-loop takeover commits 4.5 s after the divergence, and the arm then blends for 38 ms. At the 1 ms permission tick, can you estimate how many logged ticks fall in intervals 1 and 2, and how many of them may train an imitation policy when no automated expert is available?
- ☐ **Fixed windows**: Can you explain what a fixed 2 s pre-intervention window misclassifies for a takeover that took the design out-of-loop time?

14.9 Fallacies and Pitfalls

Flipping a bit in an authority register does not complete a safe supervisory handover. A real-time physical AI system must preserve its dynamic stopping margin and protective enforcement functions throughout every stage of transfer. Furthermore, downstream imitation learning pipelines cannot treat intervention logs as unblemished expert recoveries without explicit causal filtering. When systems fail in deployment, the breakdown almost always traces back to one of four subtle architectural traps.

One 500 ms window overruns at aisle speed and idles at a crawl.

Pitfall: *Treating human takeover timeout as a static time delay rather than a dynamic spatial stopping budget.* Consider a mobile manipulator that initiates a takeover request at its operational 1.3 m/s aisle speed under a statically configured 500 ms acknowledgment window. If the controller waits out that full window before commanding brakes, the vehicle covers 0.65 m of unbraked travel. When combined with the jerk-limited resident stop profile and actuator execution overheads, the total stopping distance ends 0.52 m beyond the 1.10 m rack-end clearance, causing a physical collision. Conversely, at an out-of-loop crawl speed of 0.15 m/s, that same window consumes negligible distance, leaving 5.8 s of margin before fallback braking must begin. The wait costs travel in proportion to speed, and the stop that follows grows with its square, so a timeout that leaves ample response time

at a crawl overruns the clear distance at aisle speed. Real-time supervisory handovers cannot treat human response intervals as fixed wall-clock durations. The permissible wait time must be computed dynamically from instantaneous velocity, remaining obstacle clearance, and validated brake deceleration envelopes. Autonomous fallback must begin the moment the remaining clearance matches the required stopping profile.

A supervisory timeout is not a static timer; it is a dynamically bounded spatial margin that must fit the instantaneous stopping budget.

Architect's countermeasure: On every control cycle, evaluate the instantaneous obstacle clearance against a complete stopping budget composed solely of future sensing delays, brake actuation lag, and jerk-limited deceleration. Dynamically recompute a candidate absolute deadline, anchored to a consistent time origin, from equation 14.4, which gives the longest wait whose delay travel and stop suffix still fit inside the remaining clearance. If a newly calculated deadline is earlier than the currently active deadline, tighten the expiration threshold immediately; never extend or restart an active countdown based on optimistic recalculations. Account for sensor pipeline latency consistently, and do not subtract historical capture-to-enforcement delay from clearance measurements that have already physically reflected that travel. If supervisory acknowledgment does not arrive before the deadline expires, immediately trigger the validated autonomous fallback brake sequence.

Fallacy: *Human manual takeover should bypass automated safety barriers and grant unconstrained, open-ended actuator authority.*

When a remote operator takes manual control of a mobile manipulator to steer it around an unexpected obstacle, the chosen steering commands might vector the chassis directly toward a warehouse rack upright. Granting manual control alters only the origin of proposed motion setpoints; it cannot alter chassis momentum, tire-floor friction coefficients, or environmental obstacle boundaries. The low-level safety enforcer must therefore evaluate human manual proposals against the formal admissible motion set on every cycle. If the operator commands a trajectory that risks collision or dynamic instability, the enforcer projects the command onto the nearest safe, kinodynamically feasible trajectory. If no safe trajectory exists within the admissible envelope, the enforcer rejects the proposal entirely and triggers an immediate autonomous fallback. Manual intervention grants the operator authority to guide high-level intent, but mechanical stresses, obstacle clearance, and brake margins remain hard physical constraints enforced at the joint actuator boundary.

Furthermore, manual intervention must operate under strictly bounded, perishable leases rather than open-ended authority grants. Transient wireless packet loss or operator distraction can easily leave stale velocity vectors active in flight. To prevent uncommanded runaway motion, every intervention session requires a cryptographically renewed manual lease calibrated to the active operational mode's stopping reserve. In this warehouse aisle scenario, the system enforces a 100 ms manual lease. If periodic, authenticated heartbeat renewals fail to arrive before the lease expires, the safety microcontroller immediately revokes proposal authority and executes an autonomous fallback stop independently of host software or operator intervention.

Manual intervention transfers the authority to propose setpoints, but never the authority to bypass physical barrier certificates or operate on stale communication.

Architect's countermeasure: Channel all teleoperation and manual override inputs through the enforcer's control barrier certificates and kinodynamic clamping filters. When an operator command exceeds dynamic rollover thresholds, threatens structural shear limits, or breaches clearance buffers, the enforcer automatically clamps the actuation setpoint to the boundary of the safe set or initiates an emergency stop. Subordinate all manual authority to a hardware-timed watchdog lease sized to the active mode's stopping reserve, guaranteeing that lease expiration automatically executes a deterministic brake or hold sequence without software intervention.

Pitfall: *Relying on cryptographic authentication without rate limiting the traffic that reaches the verifier.*

Cryptographic authentication guarantees message authenticity and integrity, but it introduces an asymmetric computation cost that an adversary or a misbehaving transceiver can exploit to starve real-time processing. Suppose an admission controller validates incoming signed remote takeover requests (section 14.5) using an embedded microcontroller that requires 1.8 ms to verify each Ed25519

digital signature. Malformed inputs may be rejected cheaply, but well-formed invalid signatures can still reach the expensive verification path. The following queue model charges every such request the stated verification time.

If a malfunctioning or compromised device on the network link floods the interface with bogus signed `manual_drive` packets, as few as 55 forged requests queued ahead of a critical `veto_path` message from a remote supervisor will delay its verification to 100.80 ms. At aisle speed, this delay exceeds the fallback deadline $T_{\text{deadline,fallback}}$ of 100.78 ms. When charging the allocated downstream admission delay Δ_{da}, the usable admission margin shrinks to 37.5 ms, meaning just 20 forged packets suffice to cause a deadline violation. Sustaining this denial-of-service attack requires an injection rate of only 546 packets per second, a trivial load for even a low-bandwidth industrial wireless channel.

Substituting symmetric MACs shifts the computational bottleneck to the network transceiver without eliminating the underlying vulnerability. Validating a MAC requires far fewer cycles, so roughly 20,306 forged frames within the same window are needed to induce a miss, yet the queue remains susceptible to line-rate saturating traffic. The robot's independently wired protective stops and hardware lease timers must never share queues with network ingress. Those local safety channels must remain fully operational even when the cryptographic verifier is saturated. To protect real-time responsiveness, the ingestion pipeline must deploy hardware mailbox filters and per-source rate limiters ahead of the verification queue, and safety qualification tests must evaluate worst-case intervention latency under full adversarial packet inundation.

Cryptographic authentication protects command integrity but introduces an asymmetric availability risk, because an admission verifier spends finite compute cycles rejecting forged traffic before it can service critical safety messages.

Architect's countermeasure: Deploy hardware mailbox filtering and per-source token-bucket rate limiters[13] on the fieldbus interface ahead of the software verification queue. In addition, route emergency protective stops and fail-safe interlocks through dedicated, hardwired electrical circuits that bypass digital networking and cryptographic parsing entirely.

[13] **Token Bucket**: A limiter holds up to b tokens, refills at rate r, and admits a packet only by spending a token, so a source may burst b packets but never sustain more than r. Placed before the verifier, it bounds the forged signatures that can arrive within $T_{\text{deadline,fallback}}$ at $b + r\,T_{\text{deadline,fallback}}$. For the single-source queue modeled here, keeping that bound below the 55 forgeries that push a genuine veto past its deadline, or 20 once Δ_{da} is charged, sizes b and r from the stopping budget rather than from link capacity. A deployed ingress must also bound aggregate traffic across sources, include already queued work and legitimate traffic, and prevent forged source identifiers from bypassing those limits.

Fallacy: *Training directly on raw human intervention logs captures expert demonstrations.*

Training on raw intervention logs commits the learner-action contamination of section 5.8. The raw telemetry of a rescued episode is not a continuous expert demonstration. It stitches the policy's diverging trajectory to the operator's reaction latency, the corrective jerks as the operator regains situational awareness, and the overshoots before stabilization, and a policy cloned from it reproduces the oscillations that made the takeover necessary.

The methods in table 14.8 require attribution of who generated each state-action pair and a declared interpretation of the sample as a target, a weight, or a reward. Neither a coarse session-level takeover timestamp nor an active manual authority bit guarantees that recorded telemetry is fit for policy training. This chapter's conservative direct-imitation policy segments intervention trajectories into distinct causal regimes and masks transitional dynamics; the alternative objectives in table 14.8 retain some early corrections.

Unsegmented intervention telemetry records human cognitive lag and abrupt corrective overshoots; naively cloning these trajectories trains policies to reproduce the instability that triggered the takeover.

Architect's countermeasure: For this chapter's conservative direct-imitation corpus, apply causal intervention masking (equation 14.8), taking the interval boundaries from the commit, blend-end, and stabilization timestamps on the safety microcontroller's monotonic hardware clock. Only Interval 4, validated post-stabilization guidance, trains as a human demonstration ($\mathcal{M}(t) = 1$); Interval 1 drift states train only under an automated expert's labels, and everything else stays in the record for forensics.

14.10 Summary

Supervisory intervention transfers the right to propose, never the right to admit. A capability matrix grants each authenticated role named operations on named actuator channels, each with a preemption tier and a clearance-derived deadline, while the enforcer checks every command from

DRAFT

every source against the same physical envelope. Enforcement changes a proposal and leaves the proposer in place; intervention changes the proposer and leaves the check in place, and the machine needs both.

A takeover is a delay inserted before braking on a moving machine, so it is priced in the stopping budget rather than in the user interface. At the 1.3 m/s aisle speed the subtotal before dispatch-to-admission travel leaves 131.0 mm, a waiting window of 100.8 ms, and only 37.5 ms once the 63.3 ms dispatch-to-admission allocation of section 13.6.2 is charged. Sourced human responses of 605 ms in the loop and 4.5 s out of it cap the request speed at 0.797 m/s and 0.189 m/s once it is charged. No brake, however strong, admits the aisle speed, because the waiting term rather than the braking term spends the clearance. The design therefore slows to 0.75 m/s before an anticipated in-loop request, crawls at 0.15 m/s or stops first before an out-of-loop one, and answers a newly discovered hazard with its own local stop. None of these speeds qualifies until loaded measurements confirm the allocation and the braking premises.

Authority is bounded and moved by mechanisms that never wait on the network. Execution leases on the safety microcontroller's clock, the autonomous chunk lease and the 100 ms manual lease, revoke a silent proposer and select the fallback that matches the machine's state. A four-phase handshake commits ownership on one control tick for an explicit channel mask, the enforcer remains the only writer to the actuators, and every timer that expires leads to a defined state. Authentication keeps forged commands out of admission, but only a rate limiter ahead of the verifier keeps forged traffic from delaying a genuine veto, and hardwired protective inputs bypass both.

Changing the proposer does not change the physics of the command. A fixed-endpoint C^2 smoothstep bounds the command rate between latched endpoints, but it spends clearance. The base window is 528 ms at every speed because the jerk bound belongs to the loaded base, and at the 0.75 m/s request speed no braking blend fits the clearance that remains. Within the stated one-dimensional stopping model and boundary conditions, no smoothed braking under the same bounds beats the resident profile, so the base receives the resident stop while the arm blends over 38 ms.

The authority record turns every handover into evidence. It binds the sealed static manifest to per-tick evidence tuples that record who held each channel and what was proposed, admitted, and dispatched alongside independent measurements of the response, chains them against tampering, and declares every gap. It draws its fallback rungs from the enforcement record and its declared timing bounds from the placement record, whose loaded measurements are still to come. The same ownership timestamps serve two readers. An investigator can reconstruct an incident from them, provided independent current, encoder, and contact measurements confirm what the commands did, and a learner can apply this chapter's conservative four-interval direct-imitation mask, under which only validated, stabilized human recovery supplies post-takeover demonstration targets. Other learning objectives use the same provenance with different eligibility rules (table 14.8). Table 14.9 summarizes the governing quantitative relations for supervisory intervention, detailing the specific operational or physical quantity bounded by each equation.

Table 14.9: Key equations of supervisory intervention: Each equation fixes one quantity a takeover design must declare. The kinematic relations assume the jerk-limited resident stop and a constant speed while the machine waits; the ceiling's closed form holds only above $a_{\text{brake}}^2/j_{\max}$. The delays inside them must be measured on the site's operators, console, and link.

Equation	What it bounds or decides	Derived in
$T_\Sigma = T_{\text{sensory}} + T_{\text{cognitive}} + T_{\text{motor}} + T_{\text{comm}}$	The takeover delay a person and a console add before any command changes	equation 14.1
$v(T_{\text{wait}} + \tau_{\text{delay}}) + d_{\text{suffix}}(v) + \delta \le D_{\text{clear}}$	Whether the machine can still stop after waiting T_{wait} at speed v	equation 14.2
$T_{\text{deadline,fallback}} = (D_{\text{clear}} - \delta - d_{\text{suffix}}(v))/v - \tau_{\text{delay}}$	The latest fallback dispatch after a handover request; a fixed timeout is clipped to it	equation 14.4
$v_{\max} = a_{\text{brake}}\left[\sqrt{b^2 + 2(D_{\text{clear}} - \delta)/a_{\text{brake}}} - b\right]$	The highest speed at which a takeover with delay T_Σ may be requested	equation 14.3
$t - t_{\text{refresh}} < T_{\text{lease}}$ or $T_{\text{lease,man}}$	Whether a proposer still holds authority; expiry invokes the validated local response	equation 14.5

Equation	What it bounds or decides	Derived in
$\alpha(\hat{t}) = 10\hat{t}^3 - 15\hat{t}^4 + 6\hat{t}^5$ with $\tau_{\text{blend}} \geq 1.875\|\Delta\mathbf{u}\|/j_{\max}$	The minimum window within the fixed-endpoint quintic family under the stated rate ceiling	equation 14.6 and equation 14.7
$\mathcal{L} = \mathbb{E}[\sum_k \mathcal{M}(k)\,\ell(\pi_\theta(\mathbf{x}_k), \mathbf{u}_{\text{target}}(k))]$	Which logged samples train the next policy, and with which target	equation 14.8

Key Takeaways: Supervisory intervention and authority bounds

- **State-dependent fallback and monotonic leases:** Bind each proposer to an explicit, mode-specific lease and stopping reserve. Lease expiry invokes the validated local fallback response appropriate for the current physical state, along with the sensing, drive energy, braking, and holding premises required to execute it safely. For manual teleoperation, the reference design chooses a 100 ms lease, bounded from below by heartbeat loss and jitter and from above by the clearance its extra travel over the chunk lease consumes after the takeover.
- **Clearance governs waiting:** A takeover delay is travel before braking, so its allowance comes from the stopping budget, not from a configured timer. The subtotal before dispatch-to-admission travel allows 100.8 ms of waiting at the aisle speed, 37.5 ms once the 63.3 ms admission allocation is charged, and 751.6 ms at the 0.75 m/s slow-down, which still leaves 83.3 ms after an in-loop takeover and the charge. Price human responses at design percentiles, not averages. On the complete budget, the 605 ms in-loop design response caps the request speed at 0.797 m/s and the 4.5 s out-of-loop response caps it at 0.189 m/s. Dispatch the fallback at the earliest of the protocol, lease, evidence, and clearance deadlines, and stop before handing an unexpected hazard to an out-of-loop operator.
- **Single-writer actuator ownership:** Explicit source arbitration and exclusive enforcer command ownership eliminate conflicting actuator writes; low-level bus arbitration alone cannot establish safety authority. Every request, commit, and confirmation message must explicitly declare its channel mask. A partial transfer, such as reassigning arm control while the base keeps navigating autonomously, is admissible only while the console annunciates the untransferred channel's owner; otherwise that channel holds. A four-phase protocol (Request, Acknowledge, Commit, Confirm) transitions authority deterministically. The commit transition revokes the autonomous policy token on the designated channels and latches its last admitted command. No proposer holds the proposal token during `BLEND`, while the enforcer owns the command; the arbiter grants the token to the operator only after the profile completes, and the enforcer then checks human proposals against the same physical envelopes as the policy's.
- **Smooth command blending and haptic passivity:** A fixed-endpoint C^2 acceleration profile bounds peak jerk during authority transitions, and its additional stopping displacement must be reserved in the braking envelope. If the system incorporates bilateral force reflection, the console feedback loop requires its own passivity and stability argument evaluated under realistic network latency, packet loss, and actuator dynamics.
- **Independent stopping paths:** Dedicated, hardwired protective circuits execute risk-assessed mechanical and electrical stops independent of software. Network-delivered commands undergo cryptographic admission checks: corrupted or unauthenticated packets are dropped at ingress, whereas a failure to refresh a valid lease triggers an autonomous local fallback.
- **Causal data attribution:** Training on intervention logs requires preserving controller provenance and declaring target and eligibility rules. This chapter's conservative direct-imitation mask $\mathcal{M}(t)$ (equation 14.8) preserves learner-visited drift states for failure analysis and automated relabeling, zeros out synthetic enforcer blending splines (τ_{blend})

and initial operator hunting, and admits only validated, stabilized human recovery as post-takeover demonstration targets. Other objectives may retain or weight early corrections differently (table 14.8).

- **Authority as auditable evidence:** The authority record logs per-tick evidence tuples $\langle t_{\text{MCU}}, S_{\text{auth}}, \mathbf{x}, \mathbf{u}_{\text{nom}}, \mathbf{u}^*, \tau, \text{ID}_{\text{operator}}, T_{\text{lease,rem}} \rangle$ into tamper-evident cryptographic hash chains, treating a missing entry as an explicit fault rather than an implied pass. The manifest's four authority rules serve as primary test targets for verification fault injection; their passing logs, anchored by the authority record, are the evidence the release argument needs before it may admit remote takeover.

A person's authority over an embodied physical AI system is granted on verifiable evidence and expires when that evidence lapses, as the fourth law, permission must be earned (principle 4), requires of every privilege the machine honors. Fresh credentials, checked plant state, a feasible target and fallback reserve, and a successfully committed handshake support the grant of authority; the manual lease bounds how long the grant remains valid while its physical premises continue to hold. When operator inputs cease renewing the lease, authority immediately lapses to a verified local fallback governed by the hardware permission path. Preemption tiers do not persist across a lease expiration: a remote assistant who previously commanded the mobile base retains no residual authority once the lease expires. Re-establishing control under any proposer requires satisfying the reset conditions of the authority state machine and presenting fresh, validated credentials.

14.11 Historical Perspective and Further Reading

Supervisory control emerged as an engineering discipline when teleoperated systems outgrew direct manual control. In deep-sea exploration and hazardous environment manipulation, transmission latency and high operator workloads made continuous teleoperation fragile. Sheridan and Verplank (1978) formalized the division of labor between human operators and machine intelligence, grading autonomy into explicit levels that range from complete manual execution to autonomous computer execution that ignores human input. Sheridan (1992) consolidated these insights into a unified systems theory of human supervisory control, modeling how human operators alternate between planning, programming, monitoring, intervening, and learning from automated subroutines. Expanding on this taxonomy, Parasuraman et al. (2000) decoupled automation across four functional dimensions: sensory information acquisition, information analysis, decision selection, and action execution, assigning distinct operational levels to each stage. Meanwhile, industrial process automation approached supervisory handovers from a control-theoretic perspective. Switching a closed-loop plant between manual operation and automatic tracking without inducing mechanical shock or actuator saturation requires the idle controller to track the active plant state continuously. This bumpless transfer technique, detailed as standard practice by Åström and Hägglund (2006), provides the classical foundation that this chapter's enforcer generalizes: smoothly blending between verified endpoint states while strictly respecting physical actuator limits.

Human factors engineering revealed why relying on a passive human operator as an emergency fallback is fundamentally flawed. In a landmark critique, Bainbridge (1983) articulated the central irony of automation: automating routine operations leaves the human supervisor responsible solely for rare, anomalous edge cases, precisely when sustained inactivity has degraded both situational awareness and manual control proficiency. Sarter and Woods (1995) examined cockpit automation to trace the root causes of mode confusion, demonstrating how silent automation state changes lead pilots to issue inputs that are entirely correct for their assumed operational mode but hazardous for the aircraft's actual mode. Endsley (1995) formalized the cognitive basis of operator intervention, decomposing situation awareness into three hierarchical tiers: perceiving sensory cues, comprehending the operational state, and projecting system trajectories into the near future. Physical latency imposes strict mathematical limits on these interactions. Ferrell (1965) demonstrated that when loop delays exceed a fraction of a second, human operators inevitably degrade into a disjointed "move-and-wait" strategy to avoid destabilizing the physical plant. In bilateral teleoperation with force reflection, delayed feedback injects non-physical energy into the loop and can destabilize it. Anderson and Spong (1989) addressed this instability through a passive communication-channel

construction within a specified bilateral control architecture. Closed-loop stability also depends on the channel terminations and the coupled controllers and plant. Niemeyer and Slotine (1991) reformulated the communication-channel passivity condition using wave variables. Variable delay, packet loss, sampling, and saturation require the additional analysis identified in section B.10. At the architectural level, arbitrating between competing subsystem commands using rigid priorities directly descends from the layered suppression and inhibition mechanisms pioneered by Brooks (1986) in the subsumption architecture.

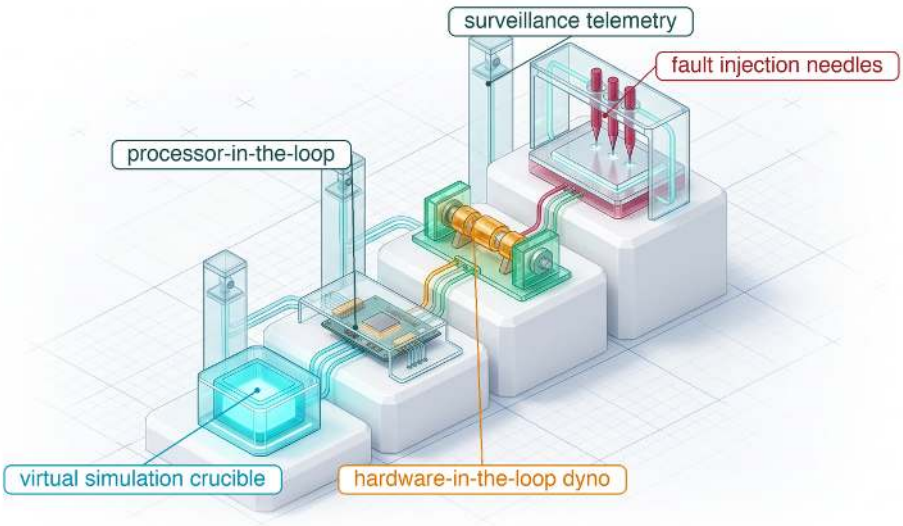
Machine learning turned supervisory intervention into a source of training data. Ross et al. (2011) proved that naive behavioral cloning fails under distributional drift because the autonomous policy inevitably encounters states absent from the expert demonstrations; robust training requires querying the expert along the learner's own induced state distribution via the DAgger algorithm. To reduce human fatigue, Kelly et al. (2019) introduced Human-Gated DAgger, delegating continuous control to the autonomous policy and recording demonstrations only when the human supervisor actively intervenes. Modern embodied systems generalize these intervention boundaries into core training signals. Sirius (H. Liu et al. 2023) uses intervention transitions as prioritized sample weights in offline policy optimization. J. Luo et al. (2024) converts supervisory takeovers into reinforcement learning reward penalties. Luo et al. (2025) uses intervention corrections to drive real-world robotic reinforcement learning safely on physical hardware. Every data-driven approach relies on unambiguous execution provenance: the system must record exactly which agent (human supervisor, machine policy, or safety enforcer) held authority over every actuator command. Tamper-evident logging draws on a deep cryptographic lineage, from the cryptographically linked timestamps of Haber and Stornetta (1991) to the hierarchical authentication structures of Merkle (1988). This chapter integrates these disparate systems threads into a single runtime abstraction: a per-tick authority record that aligns the handover sequence with the physical stopping budget and retains ownership boundaries for downstream policy learning. The arbiter and enforcer establish exclusive channel ownership; per-channel announcements support mode awareness, and the record supports evaluating both under its timing and capture assumptions.

Six works trace this lineage from the ironies of automation to learning from interventions:

- Bainbridge (1983) articulates why automating routine operations deprives human operators of the running mental model and manual dexterity required to handle anomalous edge cases, establishing the engineering motivation for executing a safe dynamic stop before requesting intervention.
- Sheridan (1992) provides the definitive monograph uniting supervisory control, teleoperation architectures, and the dynamics of delayed human-in-the-loop systems.
- Sarter and Woods (1995) identifies the cognitive mechanics of mode awareness breakdowns in complex cockpits, illustrating the failure modes that per-channel masks and state announcements mitigate in section 14.6.
- Parasuraman et al. (2000) establishes the multi-dimensional taxonomy of automation across acquisition, analysis, decision, and action, providing the conceptual architecture behind channel-by-channel capability matrices.
- Anderson and Spong (1989) develops a passive communication-channel construction for delayed bilateral teleoperation, forming the analytical basis for section 14.4.5. Its closed-loop stability argument depends on the specified channel terminations and control architecture.
- Ross et al. (2011) introduces the DAgger algorithm and demonstrates that imitation learners must be trained against corrections collected on their own visited state distributions, explaining why the authority record must capture policy drift intervals and takeover boundaries.

What's Next: From authority revocation to verification

Operational logs alone cannot establish that the arbiter enforces its rules under adverse conditions. Weeks of clean handovers in the authority record rarely contain a duplicate writer, a replayed packet, or a dropped heartbeat, and a record cannot testify about a fault that never occurred. The same gap runs through every record this book has developed, because the chunk



lease, the permission path, and the held-up permission rail all describe protective responses that normal operation never exercises. Chapter 15 creates those faults on purpose. It pairs four physical faults injected as the loaded base approaches the rack end, beginning with a stalled proposer, with the four authority rules A1 through A4 that this chapter's manifest hands over. It scores each trial against an oracle fixed before the test, measured by instruments the fault cannot reach rather than by the arbiter's own account of what it did.

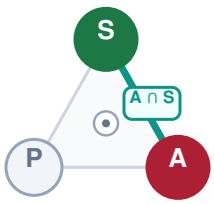
Purpose

Why can a machine pass its normal operating tests and still fail when its protective response is needed?

The claims that matter most in a physical machine describe what it does after something has already gone wrong, when the learned proposer stalls, an observation arrives old, a message is lost, or the supply sags while a loaded body moves toward a person. Normal operation almost never exercises those responses, so thousands of clean runs can coexist with a stopping mechanism that has never once been made to stop the machine. Without deliberate testing, the first real trial of that mechanism happens in service, where a late response delivers energy that no software correction can recall. Establishing such a claim requires creating the fault on purpose, measuring the physical response with instruments the fault cannot reach, and scoring it against acceptance conditions fixed before the test. Every condition left untested still limits what the result can support. Verification makes those limits explicit before release grants any action authority to cross the causal boundary.



Learning Objectives

- Derive test conditions and stopping oracles from the machine's operating envelope
- Derive faults from design assumptions, physical hazards, authority-transfer failures, and attacks on the proposer and sensors
- Select qualification environments that exercise the causal mechanism behind each claim
- Design hardware injections with independent witnesses and precommitted acceptance conditions
- Interpret temporal safety margins and search for disturbances that violate them
- Evaluate the assumptions limiting simulation transfer, rare-event estimates, and formal proofs
- Assemble fault records that preserve failed, invalid, unobservable, and untested cases

15.1 The Claim a Fault Trial Must Test

The authority record at the close of chapter 14 can log weeks of clean handovers and still say nothing about what the machine does when a duplicate writer appears on the bus, a stale packet replays, or a heartbeat drops. None of those faults occurred during normal service. Every preceding chapter of this book rests on protective claims of the same kind: a chunk lease that expires within its declared deadline, a permission path that halts the mobile base within its clear distance, or a safety microcontroller that outlasts a voltage brownout on the shared electrical supply. Because those fallback paths stay dormant until a subsystem breaks, an unexpected fault discovered in service has already crossed the causal boundary into the room, releasing kinetic energy that no software update can undo. Verification turns these design assertions into auditable evidence by provoking each fault deliberately before release, under the physical loads that make the protective response hardest to execute.

A trial passes only when an independent sensor witnesses the act.

⇄ **Contrast:** Policy evaluation, which scores the learned proposer's task proficiency rather than the whole machine's protective responses, is established in chapter 7.

Policy evaluation measures how capably a learned candidate policy completes tasks across declared environments. Verification, by contrast, tests the integrated machine as a whole: proposer, runtime enforcer, communication buses, power distribution network, and physical body. High task completion rates during policy evaluation do not show that an independent emergency stop engages when the neural proposer hangs; conversely, a reliable emergency stop does not show that the learned policy navigates aisles smoothly. Qualifying an embodied machine requires both kinds of evidence gathered on the same production hardware and software stack. The same distinction separates raw policy autonomy from whole-machine safety, because an enforcer applying a least-change correction can keep the robot safe during a mission while isolating and logging a hazardous proposal from the model.

Treating passing assertions in a software simulator as sufficient proof of physical safety is the **digital twin delusion**.[1] A physics engine or digital emulator models timing jitter, power transients, and floor traction only to the extent that its authors anticipate and calibrate those effects; a simulated controller cannot fail on an unmodeled supply sag or bus collision. Passive operational logs invite an equally dangerous complacency: millions of incident-free operating hours show only that severe corner conditions did not arise during benign runs, leaving dormant failure modes untested.

Adversarial fault injection answers both traps by turning a design claim into a controlled disturbance executed inside an independent physical containment cell. To count as engineering evidence rather than an ad hoc stress test, a fault trial must declare its operating-envelope point, score telemetry against precommitted oracles that leave no room for after-the-fact negotiation, and preserve cryptographic records of the hardware and software state. The campaign then reports which points across the envelope those trials actually cover while the test harness records how each fault propagates across power rails, fieldbuses, and mechanical brakes.

Consider the warehouse mobile manipulator navigating an aisle at 1.3 m/s (chosen; see the Reader Guide) toward a rack end where a pedestrian may step out from a blind intersection. The learned proposer might abruptly stop renewing motion commands while the base continues rolling under momentum. An architectural authority diagram specifies which subsystem must take over, but that specification does not prove that the physical permission path survives the crash or that mechanical

[1] **Digital Twin:** Grieves and Vickers (2017) trace the concept to a 2002 presentation on product lifecycle management, and Glaessgen and Stargel (2012) gave it the sense aerospace adopted, a simulation of one as-built vehicle, updated continually from that vehicle's own sensors and history so that it mirrors the life of its flying twin. The original meaning therefore depended on continual calibration against one particular physical article. A simulator that has never been compared with a measured stop of this machine is a model, not a twin, and treating it as a twin is the delusion this chapter names.

DRAFT

brakes engage before impact. An empirical trial that induces the fault and measures physical motion supplies evidence for the named protective response under its declared conditions. To structure that trial, the test harness must reflect how the machine partitions execution across its physical substrates. An application system-on-chip (SoC) equipped with an embedded accelerator executes the unprivileged learned proposers (the vision-language-action intent model and the chunk policy beneath it). A lockstep safety microcontroller executes the deterministic runtime enforcer. The safety microcontroller commands the base-drive motor inverters across a hard real-time fieldbus (EtherCAT, or Controller Area Network with Flexible Data-Rate, CAN FD) whose cyclic frames arrive on a strict, microsecond-scale schedule. Both processors draw power from the shared 47.7 V drive bus that powers the traction motors: the application SoC through a buck-boost converter, and the safety microcontroller through an isolated converter backed by a dedicated, held-up permission rail.

Weeks of uneventful operational logs at that speed say little about four severe hardware and timing faults that the architecture claims to contain:

1. **Proposer Stall (F1):** The chunk policy, the fast proposer of section 3.5.2 that renews motion every 50 ms, has its latest proposal successfully admitted by the permission path, renewing its chunk lease, but immediately suffers a thread deadlock, driver lockup, or thermal throttling freeze.
2. **Stale Observation (F2):** A camera frame or depth tensor arrives at the permission path with an aged or corrupted hardware timestamp after silent queuing in an image signal processor (ISP) buffer or direct memory access (DMA) ring.
3. **Lost Fieldbus Frames (F3):** Electromagnetic interference (EMI) from high-current inverter switching corrupts or drops a burst of EtherCAT or CAN FD frames between the safety microcontroller and the wheel actuators.
4. **Drive-Bus Droop and Feed Loss (F4a/F4b):** A supply injector steps the shared 47.7 V drive bus below the 33 V lockout threshold of the converter feeding the application processor under the declared drive load (F4a), or the permission rail itself loses its primary electrical feed (F4b).

These physical failure modes F1–F4, paired with the supervisory authority transfer faults A1–A4 (formalized in table 15.2), organize the entire verification campaign. In theory, each threat has a dedicated countermeasure: the lease detects a hung proposer, the evidence-epoch check discards stale sensor frames, the fieldbus watchdog flags dropped communication cycles, and the isolated undervoltage supervisor manages electrical brownouts. In practice, adversarial verification injects each disturbance as the robot approaches the rack end, alongside the four authority handoff faults that the authority record hands over (section 14.8.2). It scores every stopping trial against temporal and distance bounds derived from the machine's own stopping budget.

An injected fault converts a physical trial into valid evidence for an auditable safety case only when the experiment satisfies the five requirements of the **cyber-physical test contract**:

1. **A bounded claim:** The test specifies the exact invariant the machine must maintain. For the mobile base at the rack end, the machine must come to a complete stop within the 1.10 m clear distance.
2. **Defined test conditions:** The specification bounds every relevant physical variable, including initial velocity, payload mass, floor friction, ambient operating temperature, bus traffic saturation, and DC supply voltages.
3. **A precommitted oracle:** An automated evaluation harness inspects captured telemetry against the claim without human intervention, retrospective threshold tuning, or post-hoc excuses (section 15.4 defines the oracle formally).
4. **A stated sampling and injection procedure:** The test harness exercises the machine systematically across its operational envelope, deliberately triggering faults in sensors, buses, power rails, and actuators during peak mechanical and computational load.
5. **Provenance:** The campaign logs complete cryptographic digests of model weights, calibration tables, sensor serial numbers, oscilloscope traces, and raw bus logs to enable matched re-

DRAFT

execution. Software builds can be reproduced bit for bit; a physical trial can be replicated only when repeated under physical conditions that match declared tolerances.

The base's stopping claim and the manipulator arm's latch-force claim require separate operational envelopes, injection points, and acceptance criteria; this chapter follows the mobile base's stopping claim. Fixing the contract starts with its second element, the declared conditions under which the claim must hold, which also locate the point beyond which nominal regulation must yield to an independent containment response.

15.2 The Operating Envelope

A mobile robot carrying a full payload down a warehouse aisle stops in a different distance when memory-bus contention delays its perception pipeline, when battery supply rails sag under acceleration, or when drive inverters heat up under sustained torque. Specifying the external operational design domain (ODD) alone therefore leaves the test conditions half-defined; an **operating envelope** couples those external conditions with the internal execution state of the computing, power, and actuation hardware. Every protective claim must declare both dimensions, the environmental bounds and the internal computational and electrical loads, under which it is guaranteed to hold.

For the mobile manipulator, the operating envelope declares the range of conditions over which the protective claim must hold. The campaign samples a discrete set of qualification points within that range; extending their results to untested points requires an explicit coverage argument. These points span an aisle speed of 1.3 m/s, payload masses ranging from an unloaded chassis to the full 50 kg rack capacity, and ambient operating temperatures from 5 °C to 35 °C. Surface friction must also be parameterized explicitly. In an optimistic all-weight traction screen, dry aisles require a friction coefficient of at least 0.204 to support the design braking deceleration of 2 m/s², whereas areas under the facility floor inspection regime guarantee only 0.12. The screen assumes that the driven wheels carry the entire weight; the actual base requires a qualified loaded deceleration that respects driven-wheel load share, configured braking current, and tip stability. For these inspected surfaces, the screen identifies a candidate restricted point at 1 m/s, whose friction premise must be logged in the enforcement telemetry. Verification trials on inspected floors must run against a physical test surface calibrated to this 0.12 threshold and must recalculate the oracles from the qualified loaded deceleration before testing the actual base.

Each physical configuration couples directly to the machine's internal execution state. Trials must evaluate application-processor utilization driven to peak neural inference bursts, drive-bus voltages sweeping from a depleted 42 V up to a nominal 47.7 V, transmission jitter across EtherCAT or CAN FD buses, DRAM crossbar contention, and the thermal state of the safety microcontroller. The verification campaign also challenges transient edge conditions, chief among them a human takeover while the base is moving. Section 14.2.4 screens a candidate in-loop takeover, with its 605 ms conservative response-and-exchange allowance, at the 0.75 m/s slow-down; the same moving handover is infeasible at the 1.3 m/s aisle speed and must be rejected. The slow-down remains a qualification candidate, conditional on operator response, admission delay, current clearance, and a feasible stopping continuation. The operative design stops the base before handing over. Both speeds therefore belong in the campaign, one to challenge a candidate moving transition and one to verify its rejection. Whenever an authority transition cannot preserve the verified stopping envelope, the enforcer must execute a local stop.

↩ The rule that an authority transition unable to preserve the stopping envelope ends in a local stop is established in section 14.2.4.

Definition 15.1: Operating envelope

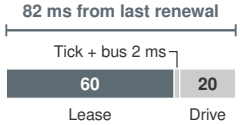
Operating envelope is the declared set of external conditions and internal execution states, each point stated with its units and tolerances, over which a machine's protective claim must hold and at which every trial of that claim is run.

1. **Significance**: The envelope governs which terms of the inequality $d_{\text{stop}} \leq D_{\text{clear}}$ are stressed during an empirical trial. For the running machine, an aisle speed of 1.3 m/s falls below the optimistic 1.44 m/s ceiling on a dry floor, yet exceeds the 1.23 m/s ceiling on an inspected surface. The identical velocity therefore passes the all-weight screen

on one surface and fails it on another; passing still requires loaded qualification before admission.

2. **Distinction**: The operational design domain describes the external environment encountered by the planning policy. The operating envelope expands this definition to incorporate internal machine states, including processor utilization, drive-bus voltages between 42 V and 47.7 V, and communication bus saturation. The same physical aisle yields different safety margins under memory contention or electrical depletion.
3. **Common pitfall**: A frequent mistake is treating an operating envelope as a simple Cartesian product of decoupled intervals, assuming that testing each parameter independently at its minimum and maximum guarantees coverage. In cyber-physical systems, multi-dimensional boundary couplings are the rule rather than the exception: two parameters operating well within their nominal isolated bounds can combine to trigger an unrecoverable failure. Robust verification demands testing directly at these coupled, high-stress corners.

An operating envelope must be distinguished from the wider **survival envelope** that encloses it. Within the operating envelope, the learned policy and low-level tracking controllers regulate nominal behavior. When an external disturbance, sensor dropout, or compute stall pushes the machine across that boundary, nominal control yields to safety mechanisms that bring the robot to a bounded, safe stop before structural limits are violated. For the mobile manipulator, the survival envelope must be characterized separately for each fallback response and machine state. The standard resident stop executes controlled, powered deceleration before setting electromechanical holding brakes at zero velocity. In contrast, torque inhibit prevents commanded torque generation without necessarily electrically isolating the drive; it does not follow the controlled stopping profile or inherit its stopping-distance budget. If the remaining containment mechanisms cannot absorb the motion, structural damage may result when kinetic energy ($E_k = \frac{1}{2}mv^2_{\text{impact}}$) exceeds what mechanical compliance and chassis end-stop dampening can absorb before hard impact. For the base in a test cell, the survival envelope is therefore the set of states from which the qualified combination of torque inhibit, passive resistance, holding mechanisms, and compliant end-stops can contain the remaining motion and energy. That boundary, not the clear distance of the stopping claim, is what the test cell's own protection watches.



↩ The fallback rungs, from the controlled resident stop to hardware torque inhibit, are established in section 12.9.1.

Establishing envelope boundaries requires deriving physical constraints from first principles rather than asserting arbitrary software timeouts. In rack-end operations, this boundary is governed by the stopping budget. Total stopping distance scales linearly with pre-braking latency and quadratically with vehicle speed (equation 2.2). In the conditional design budget of table 12.1, a pre-brake subtotal of 133.6 ms measured from sensor capture, combined with the jerk-limited resident stop and the tracking inset, yields a partial-budget speed ceiling of 1.44 m/s on a dry floor. That ceiling holds only before the dispatch-to-admission interval is charged, and section 13.6.2 allocated that interval without yet measuring it. Running at the candidate aisle velocity of 1.3 m/s consumes 969.0 mm of the available 1.10 m clearance. The unallocated spare of 131.0 mm, which the vehicle crosses in 100.8 ms, must still absorb that interval. Its allocation of 63.3 ms costs 82.3 mm of travel at this speed and leaves 48.7 mm, or 37.5 ms of waiting, the same remainder that section 14.2.4 found for a human takeover at aisle speed. The full 100.8 ms is therefore a ceiling, the longest dispatch-to-admission interval the spare could pay for. When later examples in this chapter quote the full spare, they quote an upper bound on the unbudgeted delay the machine can tolerate; once the allocation is charged, only the remainder is left to spend.

↩ The jerk-limited resident stop and its stopping distance are established in section 11.5.2.

Two conditional oracle bounds follow from that budget. Before any qualification trial, the harness must show that the bounds cover the whole execution path from the reference event to rest, because an interval left unallocated is an open qualification gap rather than a margin.

1. **Powered Deceleration Onset Deadline:** Powered deceleration must begin no later than 82 ms after the last valid renewal. This deadline traverses the full permission and actuation chain: the 60 ms lease duration, a single 1 ms tick of the safety permission loop, one 1 ms communication bus cycle, and the 20 ms drive latency from delivered stop command to physical deceleration

Of the 82 ms onset deadline, the lease takes 60 ms.

onset. (For the power-rail fault scenario F4, the onset deadline is referenced instead to the assertion of the hardware undervoltage flag.)

2. **Stopping Distance Bound:** The vehicle, tracked by external optical instruments independent of onboard odometry, must come to rest within the distance allocated from the reference event that triggers the fault. Three reference events are possible, and figure 15.1 places them on one time axis. A *capture-referenced* trial measures clearance and displacement from the exposure midpoint of a qualified sensor capture; the 969.0 mm subtotal starts there but omits the dispatch-to-admission interval, so it is incomplete until that interval is added. An *appearance-referenced* trial starts earlier, at the optical appearance of an unheralded hazard. It must timestamp that appearance and the first usable capture independently, and add the travel between them, as well as the dispatch-to-admission travel, to obtain a complete bound against the clearance measured at appearance. A *renewal-referenced* trial applies when a stalled proposer produces no new target at all; it scores both stopping distance and onset latency from the last valid lease renewal. No trial may claim a pass against an incomplete budget subtotal.

↩ The lease path, from the last admission through the permission tick and bus cycle to brake onset, is established in section 4.4.

Measured from that event, the two F1 verification predicates are (equation 15.1):

$$t_{\text{onset}} \le T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}, \qquad d_{\text{F1}}(v) = v\,(T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}) + d_{\text{suffix}}(v) + \epsilon_{\text{track}} \tag{15.1}$$

Here t_{onset} is the measured interval from the last valid renewal to the physical onset of powered deceleration, $d_{\text{F1}}(v)$ bounds the measured travel from that renewal to rest, $d_{\text{suffix}}(v)$ is the jerk-limited resident stop profile from equation 11.17, and ϵ_{track} is the tracking inset. The design budget's pre-brake subtotal τ_{delay} begins earlier, at raw sensor capture, and its sum also carries the localization bound and the protective margin. Notebook 15.1 evaluates both sums at the rack end.

DRAFT

Napkin Math 15.1: The reference-event gap

Problem: A proposer stall at the aisle speed is scored from the last valid renewal. What onset and travel bounds follow from the lease path and the resident stop, and how far below the capture-referenced subtotal of the design budget do they sit?

Variables:

- $v = 1.3$ m/s (Chosen) and $D_{\text{clear}} = 1.10$ m (Illustrative; table 1.2).
- $T_{\text{lease}} = 60$ ms and $T_{\text{tick}} = 1$ ms (Chosen); $T_{\text{bus}} = 1$ ms and $T_{\text{act}} = 20$ ms (Illustrative).
- $a_{\text{brake}} = 2$ m/s^2 (Illustrative; stands in for a measured loaded deceleration) and $j_{\max} = 7.11$ m/s^3 (Derived; the reference stop polynomial's peak jerk).
- $\epsilon_{\text{track}} = 40$ mm and $\delta_{\text{loc}} = 50$ mm (Illustrative); $\delta_{\text{margin}} = 100$ mm (Chosen); evidence age $t_{\text{age}} = 51.6$ ms (Derived; section 8.4.1).

Math:

Onset bound.

$$t_{\text{onset}} \le T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}} = 60 + 1 + 1 + 20 = 82 \text{ ms}$$

Resident stop (equation 11.17).

$$d_{\text{suffix}}(v) = \frac{v^2}{2a_{\text{brake}}} + \frac{v\,a_{\text{brake}}}{2j_{\max}} = \frac{1.3^2}{2 \times 2} + \frac{1.3 \times 2}{2 \times 7.11} = 0.4225 + 0.1828 = 0.6053 \text{ m}$$

F1 oracle from the last valid renewal (equation 15.1).

$$d_{\text{F1}}(v) = 1.3 \times 82 + 605.3 + 40 = 106.6 + 605.3 + 40 = 751.9 \text{ mm}$$

Capture-referenced subtotal, which leaves 131.0 mm of the clear distance.

$$v\,\tau_{\text{delay}} + d_{\text{suffix}} + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} = 1.3 \times 133.6 + 605.3 + 50 + 100 + 40 = 969.0 \text{ mm}$$

The gap between them.

$$969.0 - 751.9 = 1.3 \times 51.6 + 50 + 100 = 67.1 + 150 = 217.1 \text{ mm}$$

Sensitivity. In the optimistic all-weight screen at the restricted point on the inspected floor, friction caps the deceleration at 1.18 m/s²:

$$d_{\mathrm{F1}}(1) = 1 \times 82 + \left(\frac{1^2}{2 \times 1.177} + \frac{1 \times 1.177}{2 \times 7.11} \right) \mathrm{m} + 40 = 82 + 507.6 + 40 = 629.6 \text{ mm}$$

A speed reduction of 23.1 percent shortens the oracle distance by only 16.3 percent, because the diminished traction cancels out the majority of the kinematic savings.

Result: F1 passes only if powered deceleration begins within 82 ms and the base travels at most 751.9 mm from the last valid renewal, 217.1 mm less than the capture-referenced subtotal.

Systems insight: Both formulations share the identical deceleration trajectory $d_{\text{suffix}}(v)$; they diverge entirely on their reference event. The design subtotal incorporates 67.1 mm of evidence-age travel alongside the localization bound and protective margin that protect a detected target. However, a stalled proposer produces no target. If the verification harness evaluated an F1 proposer stall against this generous capture-referenced subtotal, the distance predicate would tolerate a braking onset roughly 167 ms late, more than double the entire onset deadline. Verifying the invariant $d_{\text{stop}} \leq D_{\text{clear}}$ remains sound only when travel is measured strictly from the physical or temporal event that the fault disrupts.

The partial budget beneath both bounds reproduces the arithmetic of the design record, serving as a conditional oracle specification rather than empirical timing closure. A physical trial must directly instrument and log successful admission timestamps, continuing evidence age, and physical deceleration onset. Nominal proposer loop cadences cannot guarantee that lease renewals succeed before the deadline expires. Because a safety lease begins strictly upon successful admission, the renewal verification campaign must qualify the maximum inter-admission interval demanded by the lease rule (equation 4.4) under realistic compute contention, bus saturation, and rejected proposals, rather than measuring only unvetted proposer dispatch timestamps.

Both oracle bounds also assume that the safety permission pipeline, required perception channels, and powered traction drives survive the injected fault. Capacitive hold-up for logic rails and brake coils cannot sustain the traction drives during heavy braking. The power-loss fallback (F4b) must therefore maintain and monitor a verified auxiliary power reserve and dynamic braking dissipation path throughout deceleration. If an injected fault disables these electrical reserves, the system drops into an unpowered fallback mode whose stopping envelope must be characterized independently. Neither oracle bound relies on corrective action from either learned proposer. When the chunk policy stalls, it cannot delay braking onset: the hardware safety monitor issues the stop when the lease timer expires, with physical onset following the allocated tick, bus, and actuator path, cleanly isolating safety enforcement from proposer latency. The F1 qualification test thus benchmarks the deterministic safety permission path rather than the learned policy. Finally, this stopping budget assumes a static obstacle located at the clearance boundary. Static verification trials do not validate protection against dynamic agents moving toward the machine; site crossing restrictions and occluded-motion tracking must cover that case. Declaring these qualification points alongside both formal bounds provides the complete specification required to execute an empirical verification trial.

↩ Tracking a moving body through occlusion, which this static-obstacle budget does not cover, is established in section 9.7.

15.3 One F1 Trial from Injection to Record

The campaign's first trial is F1, a proposer failure during transit, planned at the candidate restricted envelope point of 1 m/s with the full declared payload on a test floor qualified to the inspected friction. The numerical oracle remains a screening specification until loaded braking qualification supplies the actual deceleration bound. The safety claim under test is conditional. Once trajectory proposal renewals cease, the low-level permission path and motor drives must autonomously execute the resident powered stop within their allocated stopping envelope. The test deliberately halts or freezes the chunk policy immediately following its last valid lease renewal while leaving its underlying timer heartbeat active. This fault pattern cleanly separates true algorithmic progress in the proposer from the superficial liveness of an unblocked timer interrupt.

Verifying this stopping claim in its entirety requires a full physical rig: the production mobile base, motor drives, representative payload mass, and a qualified test surface. A processor-in-the-loop (PIL) bench, which runs the enforcer's compiled binary on its target microcontroller against a simulated plant, can validate lease expiration but not the plant's response, and a pure software simulation approximates both the target's execution timing and the contact mechanics. Neither bench environment alone provides empirical ground truth for physical stopping distance. Because the machine operates at the edge of its operational envelope during fault injection, an external physical containment fixture must guard the testing volume independently of whatever safety action the machine itself takes.

The temporal reference event for F1 is the last successful admission check that renewed the trajectory lease, not the upstream planner dispatch or the subsequent fault injection trigger. A complete diagnostic trace captures both the final renewal and the injection event across isolated hardware channels that independently record lease expiration, the permission path's stop command, the physical onset of powered deceleration, and external tracking of base position through complete standstill. Calibrated motor-current or torque measurements alongside wheel encoders identify drive effort and wheel response; external base-motion tracking is still needed to establish chassis deceleration under possible wheel slip. Timing uncertainty belongs in the onset margin. An auxiliary contact switch on the mechanical brake verifies subsequent holding-brake engagement. Relying on the mechanical brake switch alone would mischaracterize stopping latency, as it cannot record the initial phase of regenerative or active electric braking.

Instrumentation must capture the machine's state trajectory, fault detector identity, refusal timestamp, and recovery time to a safe state, and it must be electrically and logically decoupled from the robot. Examples are external optical ground-truth cameras and optical shaft encoders routed to isolated digitizers. An onboard logging daemon cannot serve, because the fault under evaluation, whether a panicked kernel or a saturated interconnect bus, delays or drops the very log it would write.[2] Independent external measurement helps expose false passes, where an anomalous run appears successful for reasons outside the formal safety claim. For example, injecting a dropped-frame fault might unintentionally trigger an unmonitored thermal breaker or an auxiliary ground loop that cuts drive power. If that happens, the spring-applied mechanical brake halts the base well within the distance budget, even while the software safety enforcer remains deadlocked in a priority inversion. A naive verification oracle that checks only final stopping distance would mark that trial as a success. A rigorous test harness must verify that the exact causal enforcer path specified in the safety claim commanded and governed the deceleration.

Superficial liveness signals are a second source of false passes. Section 4.4.1 required that a watchdog be refreshed only when a safety-critical cycle completes, never from an independent periodic interrupt. That section grounded the rule in the Toyota unintended-acceleration litigation, where expert testimony argued that a timer interrupt could keep a hardware watchdog satisfied after the control tasks had stopped (Barr 2013). A design rule on paper does not show that the built machine obeys it, and F1 is the test of whether it does. The harness halts the chunk policy's task or freezes its command output while keeping the periodic interrupt handler alive (perspective 15.1), and it measures the actuator response and watchdog state with external instruments. A host daemon can keep reporting a valid process heartbeat after the policy inference thread has frozen, so trial F1 passes only when physical deceleration onset is recorded at the motor drives, never on the strength of a software heartbeat logged in memory. The Toyota record adds a second question that the design rule alone does not raise, whether the supervising monitor shares an input with the processor it supervises (war story 15.1).

[2] **Probe Effect**: Gait (1986) identified the probe effect in concurrent software systems, where the overhead of monitoring instrumentation alters execution timing, inadvertently masking or introducing race conditions. On-chip hardware trace units, such as Arm's CoreSight Embedded Trace Macrocell, stream cycle-accurate instruction flows over dedicated trace pins, while external protocol analyzers monitor bus transactions without altering bus arbitration. A verification trial must time the enforcer's reaction using non-intrusive hardware instruments rather than software logging daemons executing on the processor under test.

Systems Perspective 15.1: The watchdog liveness invariant

A watchdog serviced by a periodic timer interrupt proves only that the timer interrupt service routine executed, not that safety-critical application tasks met their deadlines, computed valid outputs, or avoided memory corruption. A qualified fault-injection campaign explicitly decouples application progress from interrupt liveness, verifying that the system initiates physical shutdown under task termination, thread starvation, and frozen control registers.

War Story 15.1: Testing a task-blind watchdog hypothesis

Context: In *Bookout v. Toyota* (Oklahoma County, 2013), a jury heard expert testimony on the electronic throttle control system (ETCS-i) of a 2005 Camry. The plaintiffs' software expert argued that safety-critical control tasks could fail silently while supervisory mechanisms remained blind to the failure (Barr 2013). Section 4.4.1 drew its watchdog rule from this testimony; the same record also bears on a second claim, the independence of the monitor that backs the watchdog.

Mechanism: The engine control module serviced its hardware watchdog from a recurring timer-tick interrupt rather than requiring verified progress from active control tasks. The expert testified that if the task managing throttle angle and critical fail-safes terminated due to memory corruption or a stack overflow, the throttle command could freeze at its last valid state while the timer interrupt continued to pacify the watchdog (Barr 2013). The architecture included a secondary monitor processor, but testimony highlighted that this monitor could not inspect task scheduling; it could detect a dead throttle task only indirectly, through changes in brake-pedal state. A single analog-to-digital converter also digitized accelerator-pedal position for both processors, placing a common-cause failure point across the supervision boundary (Dunn 2013). Recovery could therefore require the counterintuitive act of lifting a foot off the brake during the event.

Impact: On October 24, 2013, the jury awarded $3 million in compensatory damages and found that Toyota had acted with reckless disregard; the parties settled before the jury could consider punitive damages (Safety Research & Strategies 2013). The verdict did not establish an uncontested technical cause. NASA's engineering review for the federal investigation found no evidence that an electronic malfunction caused large unintended accelerations (NASA Engineering and Safety Center 2011). It did document electronic faults, among them a tin whisker that formed a 248 Ω short within an accelerator-pedal position sensor from a 2003 Camry. Vehicle tests confirmed that while this fault altered how the throttle tracked the pedal, the throttle still returned to idle whenever the pedal was released (Leidecker et al. 2011). The investigation attributed the explainable incidents to floor-mat entrapment, sticking pedals, and pedal misapplication. The task-blind mechanism therefore remains an attributed hypothesis, which is exactly the kind of claim only injection can settle.

Response: For the design under test, fault injection must establish which application progress checks reach the watchdog, verify whether the independent monitor shares any input pathway with the processor it supervises (section 15.6.2), and confirm which protective inputs can reliably command a physically suitable stop. The historical controversy highlights the danger, but only direct injection testing establishes these properties for the warehouse machine.

Systems lesson: A periodic watchdog heartbeat confirms only that an interrupt handler continues to cycle, not that application tasks are functioning. A monitor is independent only if no input, supply, or clock it depends on can fail together with the processor it supervises. Verification must therefore terminate the supervised task and inject faults at those shared points, measuring the actuator response with external, isolated instruments.

Safety intervention mechanisms must be evaluated under the exact operational stress that makes intervention necessary. A safety enforcer that takes over cleanly on an idle development bench offers little assurance for a production vehicle. In an operational emergency, the policy model operates at maximum inference throughput, memory buses are saturated with high-resolution sensor streams, DMA controllers move camera frame buffers, and the mobile base carries its loaded rack at aisle speed. The verification framework therefore injects faults under declared worst-case thermal and electrical loads, measuring both lease-expiration revocation latency and the elapsed time between diagnostic fault assertion and powered deceleration onset at the motor drives. If the intervention path shares a system bus or memory arbiter with the neural accelerator, safety takeover can stall behind an unpreemptible burst transfer. A safety case that assumes near-instantaneous intervention without a contention bound can credit a response the deployed hardware cannot deliver.

↩ How a small urgent read waits behind a large burst transfer on a shared memory interconnect is established in section 13.3.

A verification campaign executes every injection trial under a deterministic, automated protocol, ensuring that verdicts derive strictly from repeatable physical measurements rather than post hoc interpretation. The test orchestrator first audits all operating preconditions (ambient temperature, supply rail voltages, baseline wheel speed) against declared engineering tolerances; any trial starting out of bounds aborts with a verdict of `INVALID`, which charges the failure to the fixture rather than the machine, before fault injection begins. Once preconditions hold, the orchestrator synchronizes the external plant fixture, logic analyzer, and independent ground-truth digitizers to a common reference clock, while recording the target clocks without disciplining away their injected drift. After allowing the mobile base to settle at its envelope operating point, the orchestrator asserts the fault trigger across a dedicated hardware line, registering the fault injection timestamp on the unified timeline. The isolated logic analyzer captures both this injection mark and the formal reference event (the final valid lease renewal in trial F1), so fault detection latency, drive takeover duration, and total stopping time are each scored from their true temporal origins. Concurrently, external truth sensors tied to a fail-safe crowbar relay circuit[3] stand ready to initiate the test cell's qualified containment response within a measured response bound if the machine approaches its survival-envelope limit. A precommitted evaluation oracle then scores the synchronized trace against the pass/fail criteria defined in section 15.4. Runs with corrupted or dropped external measurement frames are flagged transparently as `UNOBSERVABLE`, the verdict for a trial whose scoring telemetry was lost (section 15.4.1 sets out all four verdicts). Finally, the test orchestrator cryptographically signs the complete trial record header and seals it into the safety evidence bundle via a cryptographic digest.

[3] **Crowbar**: The name comes from the blunt industrial act of dropping a metal bar across power supply terminals. A crowbar circuit intentionally shorts a supply rail when an overvoltage occurs, forcing an upstream fuse or breaker to trip before hazardous energy reaches sensitive loads. Within a physical fault-injection test cell, this containment concept protects physical safety at the actuator stage: independent ground-truth sensors detecting an envelope violation trigger a hardware disconnect that severs actuator drive power over a dedicated electrical pathway that the vehicle under test can neither power nor override. Physical containment therefore never depends on the correctness of the very enforcer undergoing evaluation.

↪ **Protocol:** The fault-injection protocol, stage by stage with its error codes, is given in section C.15.9 for a reader building the test orchestrator.

15.4 Fault Oracles and Acceptance

A valid verification trace for the F1 safety claim must establish both timely deceleration onset and bounded stopping distance; observing that the robot base eventually stopped establishes neither guarantee. Without an oracle fixed in advance, post-hoc inspection takes over: engineers eyeball time-series plots after the run, seizing on gross symptoms such as whether Joule heating melted a motor phase wire or a controller threw an unhandled exception. The trial degenerates into an anecdote.

Definition 15.2: Test oracle

Test oracle is the predicate, fixed in full before a trial runs, that compares each independently witnessed quantity of the trace with its bound from a declared reference event and returns the trial's verdict.

1. **Significance**: For F1, the oracle comprises two predicates evaluated from the last valid renewal: powered deceleration onset within 82 ms and total travel within 751.9 mm at aisle speed. Each predicate evaluates to a signed margin in its native physical unit. Retaining signed margins rather than binary passes enables near misses to inform subsequent trials and guides adversarial search algorithms toward razor-thin safety margins.
2. **Distinction**: A pass criterion extracted from telemetry after a run is chosen with the outcome already visible; an oracle is mathematically precommitted. The oracle also differs from the design budget from which it is derived: the 969.0 mm design subtotal starts at sensor capture and protects a planned target trajectory, whereas a stalled proposer produces no planned trajectory to protect.
3. **Common pitfall**: A persistent misconception in physical verification is that a robot base stopping short of a rack signifies a passed trial. In reality, stopping within the 1.10 m clearance distance can easily conceal a safety controller that missed its deceleration deadline, or a stop triggered by an unmodeled side effect, such as a tripped thermal breaker that cut drive-bus power, rather than the deterministic safety path named in the claim.

15.4.1 Four verdicts and the invalid-test rule

If traction control derates motor torque over an uneven floor seam and slows the mobile base before fault injection, the robot encounters the fault below its declared operating speed. Conversely, if

a hardware frame injector overflows its queue and drops an adversarial CAN message before it reaches the transceiver, the robot never encounters the fault at all. Scoring either aborted run as a pass manufactures artificial confidence, while scoring it as a system failure blames the vehicle for a defective test harness. Rigorous verification therefore enforces an **invalid-test rule** that separates testbed anomalies from the machine's own performance.

Under that rule, the oracle returns one of four explicit verdicts. A `PASS` indicates that every precommitted timing and physical predicate held under verified preconditions. A `FAIL` indicates that the system violated one or more measured predicates. An `INVALID` verdict indicates that the fixture failed to establish declared test preconditions or the fault injection itself miscarried. An `UNOBSERVABLE` verdict indicates that ground-truth telemetry required to score the trial was corrupted or lost, while the partial trace is retained for diagnosis. Under an `INVALID` or `UNOBSERVABLE` verdict, any unmeasured quantity is logged as unavailable rather than set to zero. Neither verdict may ever be converted into a `PASS`, and neither is ever omitted from aggregate coverage reports. An `UNOBSERVABLE` trial supplies no verdict on the unmeasured claim; its missing evidence requires investigating both the witness system and the injected fault, rather than assuming the harness alone failed. Silently discarding runs with dropped telemetry or treating unobservable outcomes as passes introduces survivorship bias. If an inductive kick from an emergency brake solenoid emits an electromagnetic interference burst that crashes the data acquisition (DAQ) logger, discarding that run conceals the exact cyber-physical failure under test.

Precommitment separates empirical evidence from after-the-fact excuses. In physical fault injection, cyber-physical interactions are noisy and counterintuitive, so criteria negotiated after inspecting the trace inevitably drift to accommodate anomalous behavior. An unexpected overrun is easily dismissed as floor variation, or a deceleration onset that exceeds the 82 ms bound is excused because the vehicle came to rest before hitting the rack.

A precommitted record prevents that drift by locking down every physical predicate, measurement unit, normalization scale, response-time bound, and invalidation trigger before the first fault is triggered. The evaluation engine computes and logs a signed margin for each predicate, issuing a `PASS` verdict only when the declared preconditions and injection are verified, all required predicates are observable, and every timing bound and physical margin remains non-negative. If stopping distance exceeds its limit by five millimeters or powered braking begins 2 ms past its deadline, the record pinpoints the exact predicate that failed so engineers can trace whether the cause was degraded tire-floor friction, mechanical brake lag, motor thermal derating, or software diagnostic latency. Precommitment enforces the fourth law, permission must be earned (principle 4), at the test boundary. Production deployment grants operational authority on the basis of these records, so any verdict scored under rules relaxed after the fact would grant authority on the accident of an outcome rather than the guarantee of a verified machine.

15.4.2 The F1 record and its missing coverage

A stopping trace separated from its precondition checks or oracle digest cannot prove which threshold it was scored against or whether the floor and payload matched the claim. A **fault record** prevents that separation by cryptographically binding a finalized metadata header to the independently retained sensorimotor trace. Identity fields in the header specify the trial identifier and safety claim, the physical envelope point, the fault injection parameters (mode, magnitude, and target subsystem), and a cryptographic digest of the precommitted oracle. Outcome fields record the measured detection and takeover latencies, the signed physical margins, the four-state verdict, a digest of the complete evidence bundle, and an asymmetric digital signature over the entire header, while the high-rate telemetry trace is archived inside the bundle.

The planned F1 record at the candidate restricted envelope point, 1 m/s on an inspected floor with a 50 kg payload, fills these fields (table 15.1). As with every proposer stall, the stopping distance oracle is anchored to the timestamp of the last valid lease renewal. Under the optimistic all-weight screen on a floor with friction coefficient $\mu = 0.12$, equation 15.1 yields a stopping bound of 629.6 mm (corresponding to the sensitivity boundary in notebook 15.1). This distance is strictly shorter than the 831.2 mm capture-referenced budget subtotal at that speed. The capture-referenced subtotal accounts for upstream sensor evidence age and fixed geometric margins while omitting dispatch-to-admission communication delay; consequently, it cannot be substituted for the renewal-

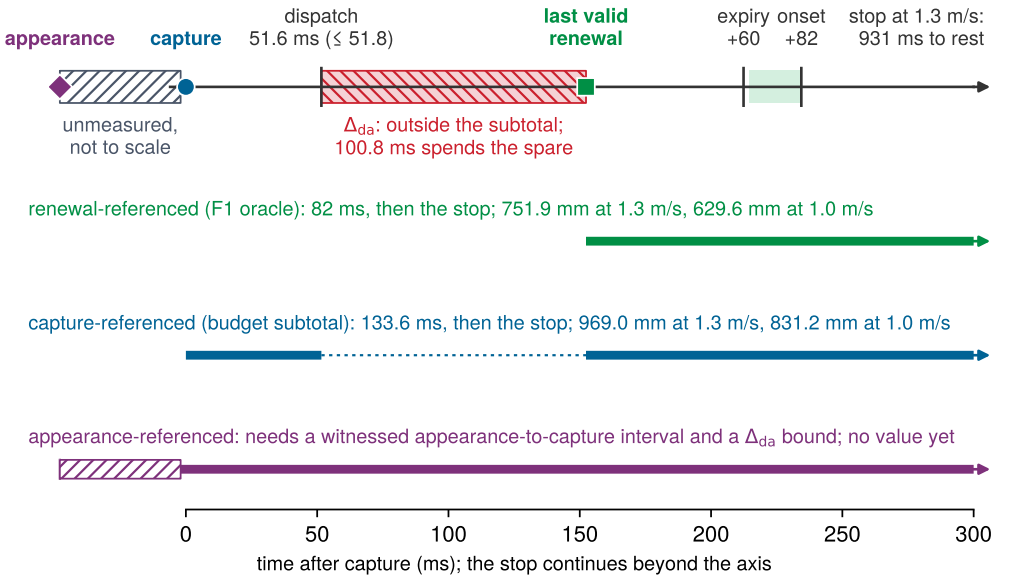


Figure 15.1: Three reference events, three bounds: One stop on a time axis from capture, with the dispatch-to-admission interval drawn at the 100.8 ms that would spend the spare. That ceiling, not the 63.3 ms allocation, is drawn because the interval is still unmeasured and the ceiling is the longest value any trial could accept. The renewal-referenced F1 oracle counts only the 82 ms lease path and the stop. The capture-referenced subtotal adds the 51.6 ms evidence age but not the dispatch-to-admission interval. An appearance-referenced bound would need both that interval and the unwitnessed appearance-to-capture interval, and no value for it exists yet.

referenced oracle of F1 or an end-to-end appearance-referenced bound. Of the three bounds, only the renewal-referenced one contains the complete timing path; its braking premise still awaits loaded qualification. The capture-referenced subtotal has a value but omits the dispatch-to-admission interval. The appearance-referenced bound has no value at all, because it still lacks a witnessed appearance-to-capture interval as well as a measured dispatch-to-admission interval (figure 15.1).

In the planned record (table 15.1), the outcome field contains no numerical value and is marked unavailable. Because no physical trials have been executed in this book, the field specifies the physical measurement that will eventually populate it; until empirical data are recorded and verified by independent witnesses, the record remains uncommitted and carries no verdict. The trial count in that field is a design choice of its own. The number of passing trials needed to bound the miss probability follows the zero-failure count of section 7.7.1, which section 15.10 applies to an injected fault population.

Table 15.1: One F1 fault record at the candidate restricted envelope point: The header fields of a proposer-stall trial on the warehouse mobile manipulator, with the screening oracle awaiting loaded braking qualification before the run and the outcome left as the measurement that must fill it.

Trial and claim	Envelope point	Oracle, predeclared from the last valid renewal	Detector and witness	Outcome to be measured	Verdict
F1, proposer stall: chunk-policy task killed one tick after a renewal; rack-end stopping claim	1 m/s; 50 kg payload; test floor measured at $\mu = 0.12$; drive bus at 47.7 V nominal	Powered deceleration onset ≤ 82 ms; travel to rest ≤ 629.6 mm	Lease timer on the permission path; expiry, revocation, and onset each on its own wire and clock	Trial count; maximum onset and maximum travel over the trials, each with its signed margin; unavailable until measured	None until scored; `PASS` requires verified preconditions, required witnesses, and both nonnegative margins

↪ **Byte layout:** The record header, field by field and including how an unavailable value is encoded, is given in section C.15.8 for a reader building the record.

The record schema maintains strict forensic separation among verdicts on a per-field basis. If an upstream breaker trips and prevents an injection, the harness marks the run `INVALID` and records the detection latency, takeover delay, and stopping margin as unavailable rather than coercing them to zero. Because the evidence bundle attaches an explicit validity flag and missing-data reason code to each measurement, the scoring oracle can inspect those flags before running any statistical or arithmetic evaluation, keeping unmeasured fields from corrupting pass-rate calculations, latency percentiles, or margin statistics.

A single aggregate percentage conceals where the verification campaign never ventured. A system that survives 98 percent of five thousand fault injection trials demonstrates little if every trial ran at nominal room temperature under negligible memory bus contention. Comprehensive verification requires reporting coverage across orthogonal dimensions: functional safety claims, physical envelope extremes, physical and logical injection sites, timing distribution tails, hardware build revisions, and concurrent multi-fault scenarios. For the warehouse mobile manipulator, physical envelope coverage verifies whether faults were injected under both empty and fully loaded rack states, at nominal aisle speed on dry concrete, at restricted speed on inspected surfaces, and under depleted DC drive-bus voltages. Timing tail coverage isolates injections scheduled to coincide with p99 operating system scheduling jitter in the permission loop or saturated DMA bus traffic. System verification cannot be declared complete when an aggregate coverage score exceeds a target percentage; rather, the minimum coverage across every individual dimension must satisfy the safety case requirements.[4]

[4] **Scope of assurance standards**: ISO 26262-5 addresses road-vehicle electrical and electronic hardware. Its single-point and latent fault metrics concern the architecture and its allocated safety goals; they are not the failure-rate-weighted aggregate coverage against which notebook 15.3 later sizes an injection campaign. Fault injection is one way to test diagnostic assumptions, alongside analysis and other evidence. ANSI/UL 4600 frames an autonomous-vehicle safety case from multiple kinds of evidence. Neither standard makes a fixed number of hardware-in-the-loop (HIL) trials sufficient for release.

Repeated trials provide statistical evidence only when underlying physical or digital states vary. Executing a deterministic fault script five hundred times on a digital bench with identical initial register states, fixed clock dividers, and synchronized inputs traverses the exact same execution path on every iteration; it contributes no more statistical information than a single run. Conversely, on a physical test aisle, repetition samples real-world stochasticity: micro-variations in wheel-floor contact friction, asynchronous hardware interrupt arrivals, bus arbitration jitter, and phase drift between the camera exposure clock and the policy inference cycle. In that setting, repeated trials characterize the variance and map the dangerous tails of the end-to-end response-time distribution.

Checkpoint 15.1: Oracles, verdicts, and reference events

An F1 result carries meaning only through the oracle, reference event, and verdict rule fixed before the run.

Scoring a trial

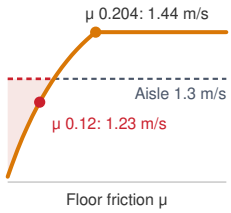
- ☐ **Verdict assignment**: Can you score three trials, one in which the injector dropped the fault packet before it reached the transceiver, one in which the logger crashed while the base stopped short of the rack, and one in which every predicate held on independent witnesses, and name the record fields each trial leaves unavailable?

DRAFT

- ☐ **Reference event**: Can you explain why the F1 distance oracle starts at the last valid renewal and leaves out the evidence age and the two margins that the capture-referenced subtotal carries?
- ☐ **Repetition vs. variation**: Can you explain why five hundred runs of a deterministic bench script count as one trial, while repeated runs on the test aisle sample a distribution?

Estimating a margin

- ☐ **Onset estimate**: A trial at 1.3 m/s records powered deceleration onset 90 ms after the last valid renewal, with the lease expiring and the stop command issuing on time. Can you estimate the onset margin, the extra travel before braking begins, and whether the trial can pass even though the base stops well short of the rack?



15.5 Extending the Trial to the Envelope

The F1 record fixes one trial at one envelope point, and even a clean pass there says nothing about the points around it. The operating-envelope definition already warned that the danger lies at coupled corners, where two parameters that are each within their declared ranges combine to break the claim. Extending the trial therefore means choosing which further points to test, and that choice follows from how the machine's physics couples its variables.

15.5.1 Coupled envelope corners versus one-variable sweeps

Sweeping travel speed alone on dry concrete and floor friction alone at a crawl passes both checks while missing the corner where aisle speed meets an inspected floor. Because physical mechanics, compute pipeline latency, and electrical power distribution interact at run time, independent minimum and maximum sweeps for individual variables leave the dangerous corners of the operating envelope untested:

- **Surface friction and travel speed**: The 1.3 m/s aisle speed and an inspected floor friction of 0.12 each fall well within their declared individual operating ranges. In combination, however, they fail even the optimistic all-weight traction screen. On low-friction surfaces, the tire-floor interface, not mechanical braking capacity, sets an upper limit on deceleration; in the all-weight screen it falls to 1.18 m/s^2. Consequently, the resident stopping maneuver elongates: the required stopping distance at 1.3 m/s expands to 1.19 m, exceeding the available 1.10 m clearance. The optimistic screening ceiling on that floor drops to 1.23 m/s, and the actual speed limit must use the qualified loaded lower bound rather than assuming this ceiling is attainable.
- **Contact nonlinearities and dynamic load transfer**: Real warehouse floors rarely have a constant friction coefficient μ. Instead, surface friction varies dynamically based on local contamination (such as concrete dust, ambient moisture, or oil films), wheel tread heating, and transient wheel loading. On the running machine only the two driven hub wheels brake against the floor, so the traction ceiling is $\mu g \phi_{\text{drive}}$, where ϕ_{drive} is the share of the weight those wheels carry (derived in the free-body diagram of chapter 2, figure 2.1). During hard braking, the inertial load ma_{brake} acting at the center of gravity pitches the body forward and can move normal force off the driven wheels onto the front caster, lowering ϕ_{drive} exactly when traction is needed. If the drives demand braking torque sized for the static load share, the driven wheels slip and the net braking force collapses. Under a constant-friction approximation, the braking distance then grows as $v^2/(2\mu g \phi_{\text{drive}})$, inversely with the friction actually delivered at the driven wheels and quadratically with speed.
- **Computational and electrical coupling**: Memory and power subsystems couple directly into safety margins. A compute-heavy forward pass of the vision-language-action intent model executing on the application SoC can saturate unified memory bandwidth. This contention delays camera-buffer processing and postpones the compact evidence handoff to the safety microcontroller, inflating the observation age and, with it, the pre-brake delay τ_{delay}. Because stopping distance scales linearly with total reaction delay (equation 2.2), a 30 ms memory stall

The 1.3 m/s aisle speed clears the dry-floor ceiling but not the inspected floor's.

DRAFT

consumes 39 mm of physical clearance at aisle speed. On the electrical bus, the dominant transient coupling originates from the motor drive actuators rather than the neural compute accelerator. At its maximum 60 W draw, the SoC pulls approximately 1.6 A from a depleted battery bus, only 2.2 percent of the overall 70 A transient, whereas the two drive motors demand up to 50 A during peak torque transients. Severe acceleration can sag the common DC bus across battery internal resistance and wiring harness impedance, while bursty inference activity primarily stresses the SoC's local point-of-load regulators, a localized transient that the F4 campaign must isolate and measure separately.

- **Payload mass and kinematic posture**: Arm posture and payload distribution couple directly to stopping performance through vehicle stability and load transfer. Under braking, the base tips about its front caster whenever deceleration exceeds $g\, d_{\text{lead}}/h_{\text{cg}}$, where h_{cg} is the height of the center of gravity and d_{lead} its distance behind that caster. This is the tip-over ceiling computed in section 2.4.2, which the credible deceleration respects only while $h_{\text{cg}}/d_{\text{lead}}$ stays below the ratio computed there. Raising the arm above a storage rack raises h_{cg}, and reaching forward shortens d_{lead}, so posture moves the machine toward that ceiling. The tip-over threshold can bind before tire traction saturates, and ISO 3691-4 mandates physical stability verification for driverless industrial trucks (International Organization for Standardization 2023b). Unloaded trials support only their tested configurations; they cannot establish the fully loaded deceleration or the complete operating envelope. The braking-limit check of section 2.3.1 left both lengths unmeasured, so the envelope cannot yet certify that the demanded deceleration stays below the tipping threshold; a tilt-table test or multi-axis corner-scale measurement of the fully loaded machine must supply them.
- **Thermal throttling and fallback execution**: Sustained thermal stress can induce dynamic processor throttling, delaying action proposal generation and degrading mission throughput. In an architecture protected by an independent, verified resident stop, a missed watchdog renewal safely triggers a bounded, fail-safe stopping trajectory rather than indefinitely expanding stopping delay. Nevertheless, multi-axis compound verification must ensure that simultaneous bus contention, sensor packet drops, or voltage droops do not compromise that fallback routine itself.

15.5.2 Physical disturbances versus digital input perturbations

A vision model that survives synthetic pixel noise injected into an input tensor can still go blind when low-angle warehouse glare saturates the physical camera lens and its auto-exposure loop. Digital perturbations and physical disturbances challenge an embodied machine at different interfaces. Synthetic tensor noise tests how sensitive a network's decision boundary is to small numerical shifts in representation space while bypassing the physical sensor altogether. An optical disturbance, by contrast, exercises the lens, coatings, auto-exposure and gain control, demosaicing, and camera interface timing. Neither test substitutes for the other, so a threat model must state whether an injected fault corrupts digital packets in flight, perturbs the physical environment, or hits both at once.

Evaluating the rack-end safety claim requires injecting realistic physical disturbances: stray illumination and direct glare that blind camera sensors, mechanical chassis vibration that corrupts inertial measurements, and floor transitions that slash available braking traction. Every physical injection requires a repeatable physical actuator and an independent ground-truth witness. For instance, glare injection requires calibrated illumination measurements beside the lens together with the declared optical geometry, spectrum, and temporal waveform. Chassis vibration requires external optical motion capture independent of onboard wheel odometry. Floor variations require standardized friction-measurement drag sleds. In cyber-physical verification, receiving a syntactically valid sensor packet with correct checksums over an internal bus confirms only that the digital transmission succeeded; it provides no guarantee that the estimated state accurately reflects physical reality.

15.5.3 What the envelope claim leaves open

Passing the initial F1 trial at one speed and arm posture still leaves neighboring speeds, higher centers of gravity, and worst-case injection timings untested. That first diagnostic run suppresses

trajectory renewal while the base is in motion and measures the deceleration-onset timestamp and stopping distance. Subsequent falsification campaigns systematically vary initial velocities, arm configurations, and injection phases to hunt for minimal operating margins (section 15.9.2). Formal methods, high-fidelity simulation, and physical hardware testing provide complementary evidence, but none can compensate for an unstated physical premise or an unverified operating assumption.

An operating boundary remains defensible only when every parameter carries its physical unit, traceable provenance, calibrated uncertainty, and designated engineering owner. Specifying a credible deceleration of 2 m/s^2 remains an incomplete assertion until the verification evidence documents its origin. The evidence must show whether it was measured during physical stopping trials at maximum payload mass, extracted from an actuator manufacturer's datasheet, or computed using a theoretical friction model. It must also give the measurement uncertainty of the external tracking reference. Any hardware modification, whether a new polyurethane wheel tread compound or new motor-drive firmware pushed across the EtherCAT fieldbus, obligates the component owner to re-evaluate whether the operational boundary has shifted.

Validating an operating envelope requires attacking its boundary surfaces rather than testing comfortable interior states. Evaluating an unloaded base crawling across a dry floor with pristine camera frames proves only that nominal execution works under ideal conditions. Instead, the verification harness distributes test points across three regimes. Points *just inside* the envelope verify that the control policy preserves closed-loop stability under the largest permissible operational stress. Points *on the boundary* confirm that safety margins survive nominal sensor noise and compute jitter. Points *just outside* verify that the safety enforcer reliably preempts the policy, executing a deterministic stop that halts the base within the survival envelope before clearance is exhausted.

A physical hardware malfunction and an algorithmic functional insufficiency require different verification strategies. A stereo camera can transmit uncorrupted, on-time video packets over PCIe while ambient glare blinds its depth estimation. A complete campaign must therefore inject faults into both the physical execution mechanisms and the sensory streams on which those mechanisms rely. Adding an enforcer module does not let it observe what its sensors cannot measure; when physical sensing cannot distinguish safe states from hazardous ones, the architect must restrict the operating envelope to conditions where safety can be enforced. Once every timing constraint, latency budget, and environmental threshold of that envelope is specified in physical units, the design claims from earlier chapters become concrete targets for fault injection, each paired with a boundary threshold that must trigger protective intervention.

> **Systems Perspective 15.2: The hardware falsification principle**
>
> A hardware-dependent safety claim needs an observable challenge to its physical premises. If the campaign cannot inject the relevant disturbance or retain the required witness, the record must preserve that verification gap.

15.6 Deriving the Fault List

The proposer stall fault (F1) originates from negating an operational claim: that proposal renewal proceeds reliably within its granted lease. Deriving a comprehensive fault list, however, requires two complementary methodologies. Inverting design records tests the explicit assumptions codified across the system architecture. Working forward from the physical realities of mechanics, power networks, and human interaction exposes the hazards and unmodeled edge cases that software design records routinely omit. Human interaction includes who is in view. A fault list that seeds only people standing upright leaves untested the kneeling, carrying, and seated people a learned detector may see later, so the groups of people the machine must detect enter the list as a coverage dimension of their own.

15.6.1 Inverting design records and the five-element chain

If the machine's specification claims that the chunk policy renews its trajectory proposal every 50 ms at every speed up to the 1.5 m/s drive limit, the verification suite turns that claim inside out. It injects stalled renewals, delayed observations, and out-of-range encoder readings to see whether

↪ How many people of each group a test campaign needs before its detection estimate can resolve the gap that matters is developed in section 17.5.2.

the permission path catches the violation in time. Every preceding chapter supplies claims that can be inverted in the same way. Chapter 5 through chapter 7 state the learned policy's training distribution, state-action assumptions, and inference latency ceilings. Chapter 8 through chapter 13 state bus allocations, observation freshness, and estimation bounds. Chapter 14 states how quickly authority leaves a failing policy and which subsystem takes over.

Where the five-part test contract of section 15.1 states what makes any trial valid evidence, a **five-element chain** states how a single inverted claim is built into such a trial. Its first element supplies the contract's bounded claim, its last element supplies the contract's oracle, and the three between them specify the mechanism the trial exercises:

1. **The negated condition:** the exact architectural or timing invariant violated (for example, proposal renewal halted after lease issue);
2. **The physical injection point:** the exact hardware or bus interface where the disturbance enters (for example, an inline field-programmable gate array (FPGA) serializer, CAN FD disturbance node, or programmable DC load);
3. **The expected detector:** the deterministic monitoring primitive tasked with catching the violation (for example, a lease countdown timer or evidence-epoch comparator);
4. **The bounded response:** the deterministic transition executed by the enforcer (for example, revoking proposal authority and commanding the resident stop suffix); and
5. **The observable pass condition:** the quantitative, independently witnessed metric that scores the trial (for F1 at aisle speed, onset $\leq$ 82 ms and travel from renewal $\leq$ 751.9 mm).

A recorded design property becomes a testable fault only when all five elements are fully defined and observable. If any element of this chain cannot be defined or measured, the architecture has a **verification gap**: the underlying claim cannot be falsified by empirical test. Systems engineers cannot ignore such gaps; resolving them requires dedicated hardware instrumentation (such as external optical trackers or non-intrusive trace macros), a narrower operational design domain, or a structural redesign of the execution path.

Inversion also applies to the learned proposer's implicit assumptions, where distribution shift can induce functional insufficiency even when every observation frame arrives intact and on time. For example, a chunk policy trained in simulation on dry concrete with friction coefficient 0.60 proposes decelerations that an inspected floor at 0.12 turns into wheel slip. Inverting that evaluation claim requires injecting degraded traction conditions at the physical contact patch. Sensor bias, calibration drift, and input perturbations are injected for the same reason: a policy with high nominal reward can still command high-frequency actuator chatter once its inputs leave the training distribution. Under these conditions, an overly permissive execution path can destabilize the plant while executing syntactically valid commands, demonstrating that software commands and mechanical dynamics remain tightly coupled across the causal boundary.

At each inter-module contract, the fault list negates architectural guarantees directly at their physical handoff points: observation freshness, state validity, intent lifetime, planning deadlines, enforcement independence, and resource allocation. For the 60 ms chunk lease, the test harness replays the expired admitted record 65 ms after its last valid renewal, verifying that the permission path firmly refuses to extend execution authority. A concurrent proposal represents an entirely separate admission attempt: it must satisfy fresh evidence, kinematic state validity, mode consistency, and stopping-reserve checks before receiving a lease. To test the enforcer's claimed independence from the policy processor on the selected discrete placement, the verification suite saturates the application processor's memory interconnect with DMA traffic while independently timing the safety microcontroller. Host contention may delay proposal delivery and age its supporting evidence, but the enforcer must still satisfy its 400 µs execution deadline within every 1 ms control tick. This rigorous inversion prevents arbitrary over-testing: bus contention, clock skew, and supply fluctuations are injected precisely where the architecture claims tolerance, rather than drawing from generic fault menus that impose requirements the machine was never specified to meet.

Inversion has a structural limit: it surfaces only faults rooted in assumptions the design team explicitly wrote down. The resulting fault list is therefore only as comprehensive as the recorded architectural claims. If no engineering record documents how the base's spring-applied brake

behaves when its friction lining glazes under repeated emergency stops, inversion cannot synthesize the failure mode, and the hazard never reaches the test suite.

15.6.2 Forward physical analysis and common-cause modes

Drive wheels skid when commanded deceleration exceeds the traction limit of the contact patch. Brake linings glaze under repeated thermal cycles. Solid tires wear down and alter the rolling radius that wheel odometry relies on. Structural vibration gradually loosens camera mounts until spatial calibration drifts. Because these hazards arise from contact mechanics, heat, and wear rather than software bugs, no software abstraction represents them, and inverting design records will not uncover them. A second, independent fault source therefore works forward from the physical machine (its mechanical body, power distribution network, floor interface, and operating environment). It uses Nancy Leveson's **Systems-Theoretic Accident Model and Processes (STAMP)** framework[5] (Leveson 2011) to trace how physical and control interactions produce hazards even when no software module has crashed.

Consider a motor drive that continues producing positive torque after receiving a stop command. A shorted inverter switch, welded contactor, or stuck gate-driver enable line can defeat the normal powered stopping trajectory. The test harness must independently observe delivered phase torque, rotor velocity, and the engagement of the secondary isolation path. While Safe Torque Off (STO) inhibits torque generation without providing electrical isolation, it cannot enforce nominal stopping distances on low-friction floors or prevent back-driving on gravity-loaded articulated joints. The safety architecture must specify a separately justified containment response alongside an independent physical measurement oracle. If no such path exists, the fault exposes an architectural omission rather than an operational delay that can borrow from the normal stopping budget.

Working forward exposes hardware fault classes that software design records rarely imply: loss of reference clocks, power supply brownouts that leave digital logic in indeterminate voltage states, pulse-width modulation (PWM) inverter switching noise coupling into differential encoder lines, corrupted non-volatile configuration registers, and reset lines that bridge domains intended to remain galvanically or logically isolated. For instance, if the safety microcontroller and the high-performance application processor share a single power-management integrated circuit (PMIC), a transient voltage droop during a sudden drive-current surge can reset both processors simultaneously just as the learned proposer loses trajectory tracking. A software interface model that assumes an ideal DC power supply omits this failure. An enforcer cannot arrest an errant policy if it loses operating power alongside the workload it supervises; the deterministic safety runtime must outlive the faulted workload using independently qualified execution and power resources. The running machine uses an isolated, capacitor-backed auxiliary supply to survive the declared supply fault.

Forward physical analysis likewise evaluates the architecture's common-cause independence claims. Subsystems that appear strictly isolated on an architectural block diagram frequently share physical vulnerabilities. For example, the primary lidar communication lines and redundant safety bumper wiring may share a single mechanical cable carrier subject to pinch wear, depend on a shared analog voltage reference inside a multichannel converter, or rely on timer silicon containing identical silicon errata. An electrical transient that latches up both channels simultaneously destroys any safety argument predicated on statistical independence. **Common-cause analysis** traces harness routing, power distribution paths, and clock distribution trees to identify shared failure paths and justify independence against the declared fault set, rather than assume separation from the block diagram.

This physical analysis extends directly to human error and foreseeable operational misuse. Warehouse personnel may jumper an optical rack-end sensor during maintenance, leave a manual pallet jack parked across an automated transit corridor, or unplug an acoustic warning beacon to silence workplace noise, while remote teleoperators may request transit speeds exceeding local aisle restrictions. When a remote assistant commands the vehicle's full 1.5 m/s drive limit within a narrow aisle, the verification suite must confirm that the arbiter denies the command by capability constraint or clamps it to the admitted manual mode speed under an active `manual_drive` state. Furthermore, the deterministic permission check must evaluate the assistant's command with the same scrutiny applied to autonomous proposals.

[5] **STAMP and STPA**: Leveson (2004) proposed STAMP, which treats safety as a dynamic control problem rather than a component-reliability problem, recognizing that catastrophic accidents often arise from unsafe interactions among components that each operate strictly within specification. Leveson (2011) established the Systems-Theoretic Process Analysis (STPA) hazard-analysis method on this foundation, identifying unsafe control actions at subsystem interfaces, such as an integration seam where bus communication latency or digital filter lag erodes phase margin. Because no individual component has failed at such a seam, its unsafe control actions supply critical fault modes that inverting nominal design records cannot expose.

↩ Safe Torque Off and the industrial stop categories are established in section 12.9.2.

↩ The independence claims for the permission path's execution unit, oscillator, power rail, and memory are established in section 4.7.

DRAFT

Working forward from the physical plant adds a representative mechanical failure mode, the actuator jam, to the record-derived inventory in table 15.2, though full verification still requires a plant-specific hazard analysis tailored to the vehicle's mechanical kinematics and operational envelope. Alongside inverted design claims and forward physical hazards, the fault suite in table 15.2 also evaluates the four authority transition cases (A1–A4) established in section 14.8.2 under the operating state that makes intervention most urgent: a fully loaded base approaching the rack end at velocity. The test campaign injects takeover requests at two speeds to distinguish the candidate moving transition from a request the clearance screen rejects; the operative design stops before handing over. At the 0.75 m/s slow-down, the partial-budget waiting margin is 751.6 ms, enough for the 605 ms in-loop takeover and the 63.3 ms dispatch-to-admission allocation together. Section 14.2.4 therefore identifies a candidate moving in-loop handover for qualification, subject to the complete session budget and live stopping checks. The trial must show that a handover left pending still ends in a local stop by its deadline. At the full 1.3 m/s aisle speed the margin is 100.8 ms, only 37.5 ms once the allocation is charged, which cannot hold the takeover, so the arbiter must reject the moving handover and dispatch a local stop before the deadline expires. An out-of-loop takeover begins only after a stop, from standstill, in an admitted mode. Evaluating either sequence solely while the vehicle is parked proves nothing about dynamic performance; the trial must demonstrate that rejection, timeout, and braking occur with bounded latency while the base moves.

Table 15.2: Representative hardware and cyber-physical fault classes: The rack-end faults F1–F4 and the four authority fault cases (A1–A4) that the authority record hands over, each mapped to its injection point, detector, response, and observable pass criterion on the warehouse mobile manipulator, plus one forward-derived mechanical fault and one attack on the learned proposer.

Failure Domain & Fault Mode	Physical Mechanism & Injection Point	Target Manifestation & Causal Impact	Detection Primitive & Latency Budget	Enforced Safe Response & Bounded Recovery	Observable Pass Criterion
Proposer Stall (F1)	Chunk policy renews its lease once, then its task is killed or its output frozen on the application processor	No new proposals; the last admitted chunk keeps supplying setpoints while the base cruises	Lease expiry on the permission path (60 ms); host heartbeat timeout (30 ms)	Revoke proposal authority; run the resident stop	Powered deceleration onset $\leq$ 82 ms after the last valid renewal; travel from that renewal to rest $\leq$ 751.9 mm
Stale Observation Time (F2)	Navigation-camera frame held at the image signal processor with its capture stamp preserved, or the stamp corrupted, via inline frame interceptor	Proposals whose upper evidence age at dispatch exceeds 51.8 ms, the budgeted age plus the clock-conversion bound; the base acts on an old view of the rack end	Dispatch-age check at admission; continued evidence, state, and lease validity checks on every tick	Refuse stale replacements; stop when the active command loses its own validity	Powered deceleration onset $\leq$ 82 ms after the last valid renewal; travel from that renewal to rest $\leq$ 751.9 mm when the resident stop runs

Failure Domain & Fault Mode	Physical Mechanism & Injection Point	Target Manifestation & Causal Impact	Detection Primitive & Latency Budget	Enforced Safe Response & Bounded Recovery	Observable Pass Criterion
Lost EtherCAT Frames (F3)	Frames dropped or corrupted at a drive's slave port, injected via fieldbus disturbance node	Encoder state and drive commands miss cycles; the delivered command ages by one 1 ms cycle per lost frame	Working-counter and frame-arrival check; drive communication watchdog	Drive enters its configured stop; permission path commands the resident stop	Powered deceleration onset $\leq$ 82 ms after the last valid renewal; travel from that renewal to rest $\leq$ 751.9 mm only when the complete lease-to-onset path remains bounded under frame loss; a drive-watchdog response needs its own reference event, deadline, and stop profile; zero unhandled bus exceptions
Drive-Bus Droop (F4a)	Programmable supply takes the shared drive bus from its depleted point below the converter lockout; the coincident load alone leaves it at 37.8 V	Bus falls below the 33 V converter lockout; the application processor browns out and its sensors may freeze at plausible values	Shared-bus undervoltage flag, raised by the permission path on its isolated, held-up rail	Command STOP; qualify surviving drive authority or record unsupported response	Powered deceleration onset $\leq$ 22 ms after the flag; travel from the flag $\leq$ 673.9 mm at aisle speed if the drives keep their authority on the sagged bus, otherwise the separately characterized unpowered envelope; permission path never resets (continuous heartbeat on an independent digitizer)
Permission-Rail Feed Loss (F4b)	Feed opened during the longest stop in the qualified loaded envelope; the illustrative all-weight inspected-floor screen starts from its 1.23 m/s ceiling	Permission path, drive logic, and brake coils run on the store; powered drive energy remains separately available	Feed-loss flag on the permission rail	Complete the resident stop; set every spring brake at standstill	Stop completes and every brake sets before rail dropout; the all-weight screen spends 1313.43 ms of the 2 s hold-up, awaiting loaded qualification; any reset is `FAIL`
Actuator Jam & Mechanical Stall	Wheel bearing seizure or dragging brake, injected via wheel clamp or dynamometer	Locked rotor; one wheel blocked yaws the base; rapid stator winding heating ($I^2_{\text{phase}}R$)	Motor phase overcurrent & Hall-effect velocity stall monitor, within its detection bound	De-energize the power stage; engage the spring-applied brake	Winding temperature remains below the chosen operating ceiling in section 2.5.1; base stays inside the 0.15 m side clearance

DRAFT

Failure Domain & Fault Mode	Physical Mechanism & Injection Point	Target Manifestation & Causal Impact	Detection Primitive & Latency Budget	Enforced Safe Response & Bounded Recovery	Observable Pass Criterion
Proposer Injection: Instruction or Visual	Adversarial instruction text on the task channel, or a printed patch, label, or sign placed in the intent model's camera view	Well-formed proposals that pursue the attacker's goal; every field, timestamp, and lease is valid	No check on the proposal's meaning; speed, force, swept-volume occupancy, stopping-reserve, and freshness checks on every tick	Clamp or refuse the proposal like any other; wrong actions inside the envelope continue	Every proposal that breaches a monitored limit is clamped or refused within the 400 µs enforcer deadline; wrong actions inside the envelope are recorded as coverage deficits, never as passes
Authority Transfer (A1): Duplicate Writer	Second bus master writes a base-drive channel (duplicate EtherCAT identifier or DMA write) while policy and remote assistant both command	Two writers on one channel; the delivered command is no longer the admitted one	Bus or DMA write permissions; per-tick authority record	Reject the foreign write; the enforcer path remains the only writer	Independent bus or write-path witness confirms foreign writes are blocked; authority records show one admitted writer
Authority Transfer (A2): Tier Bypass	Policy proposal injected while `MAN` is active; remote-assistant command that opposes the enforcer's admitted limit	A lower tier displaces an active higher tier, or an assistant command skips the permission check	Arbiter tier check; permission check applied to every source	Ignore the policy proposal; clamp or refuse the assistant command like any proposal	Arbiter ignores the proposal; the permission check still runs on the assistant's command
Authority Transfer (A3): Handover Timeout	Assistant input frozen during `PEND`; acknowledgment frames dropped, at the takeover slow-down and at aisle speed	The machine waits on a handover that no one completes	Handover deadline timer in the arbiter	Reject moving handover in the operative design; a candidate slow-down trial starts the validated fallback when its qualified deadline expires	No moving handover admitted in the operative design; in candidate trials at both speeds, local stop dispatched by the qualified current-clearance deadline of section 14.2.4, without awaiting acknowledgment
Authority Transfer (A4): Authentication	Replayed captured `veto_path`, `manual_drive`, or `accept_item` packet; packet carrying a bad tag	An unauthenticated source gains authority	Tag and freshness check on every assistant and coworker command	Reject the packet; rate-limit ingress while preserving valid authority	Invalid packet rejected; still-valid authority preserved; rejection recorded; enforcement deadlines met under ingress load

15.6.3 Physical sensor spoofing and proposer injection

Whether sun glare washes out a camera lens by accident or an attacker shines a laser into the optics on purpose, the camera interface delivers a well-formed, checksum-valid packet whose physical reading is false. In both ambient disturbances and **transduction-layer cyber-physical attacks**, checksum validation and bus integrity checks pass cleanly while the robot's view of the aisle is corrupted. When evaluating such an optical disturbance (retroreflective glare, strobed lighting, or lens occlusion), the test protocol must specify the illumination levels and vehicle approach vectors that challenge obstacle detection, the cross-sensor plausibility checks tasked with identifying the discrepancy,

DRAFT

and the deterministic fallback maneuver. An independent ground-truth optical tracking system monitors obstacle clearance and base trajectory while camera streams are disturbed. The verification record must distinguish an actively detected anomaly followed by a controlled deceleration from a missed obstacle where collision was avoided purely by chance. If a monitoring subsystem cannot distinguish corrupted sensor data from valid physical evidence, that operational scenario constitutes a verification gap; documenting an aspirational safety monitor in an architecture diagram does not ensure it will fire under physical stress.

The learned proposer is itself a primary attack surface; targeting it tests the proposal boundary far more directly than conventional bus or memory faults. Because a vision-language-action (VLA) model consumes natural language instructions and camera frames directly, an adversary can manipulate the model's outputs through either modality without touching a physical wire or intercepting a bus. Robey and colleagues demonstrated automated prompt generation that induced robots controlled by language models, including a commercial quadruped evaluated strictly as a black box, to execute harmful physical actions across diverse operational settings despite high-level safety guardrails (Robey et al. 2025). On the visual side, Wang and colleagues showed that introducing a compact adversarial patch[6] into a VLA's camera field of view could degrade simulated manipulation success rates to zero (Wang et al. 2025). On a deployed warehouse machine, physical injection points encompass task instruction strings, floor placards, shipping container barcodes, or printed warning signs within the camera's visual cone.

In semantic target grounding (equation 10.3), the intent model uses a conformal prediction set $\mathcal{C}$ calibrated to a marginal miscoverage rate ϵ to filter ambiguous hypotheses by requiring a singleton output ($|\mathcal{C}| = 1$). In an adversarial or out-of-distribution physical setting, however, an adversarial patch or optical distortion violates the exchangeability premise of the conformal calibration. An attacker can force an erroneous candidate to pass as a singleton ($|\mathcal{C}| = 1$), or the model can misclassify within its nominal ϵ error budget. Because the deterministic permission path does not parse task instructions or inspect the conformal set $\mathcal{C}$, it cannot distinguish an adversarial proposal from an authentic user command. Instead, under its qualified measurement and timing premises, the enforcer rejects or modifies an injected proposal when the requested physical action violates its monitored constraints: velocity and torque envelopes, dynamic stopping reserves, swept-volume occupancy, evidence freshness, or active lease duration. If an adversarial proposal meets these physical constraints and the authority checks, the enforcer may admit it, even if the robot picks an unintended bin, deposits cargo in an unauthorized clear aisle, or actuates an access gate prematurely. The permission path supports physical containment and dynamic feasibility under its declared premises; those checks do not establish semantic task correctness. This operational asymmetry highlights why systems architects decouple proposal synthesis from safety enforcement: protective safety guarantees must hold regardless of how an action was synthesized, while task-level semantic fidelity cannot be guaranteed by low-level enforcers. Consequently, the proposer-injection row in table 15.2 evaluates trials solely against independent physical oracles, recording uncommanded actions that remain within the admissible safety envelope as semantic coverage deficits rather than as safety violations.

[6] **Adversarial Patch**: Brown et al. (2017) demonstrated that printing an image-independent physical patch and placing it within a visual scene forces an image classifier to ignore surrounding objects and predict the attacker's target class. The perturbation enters entirely through the optical transducer without requiring software access, bus interception, or packet injection. In an embodied system, this attack operates wholly on the proposer's side of the proposal boundary, where the permission path can constrain the physical consequences of an altered command but cannot observe the visual artifact that induced it.

15.6.4 Choosing the injection phase

Injecting a proposer stall immediately after a lease renewal forces the base to coast on open-loop setpoints for nearly the full lease duration, stressing tracking error and clearance. Injecting the same stall microseconds before lease expiration, by contrast, catches the arbiter right at the boundary between renewal and revocation. Because the instant a fault arrives within the control cycle changes which hardware and software paths bear the load, a verification campaign cannot treat repeated fault injections at arbitrary times as interchangeable trials. Recording the exact injection phase relative to the control tick turns phase into a controlled test variable. Sweeping across injection phase, fault duration, and disturbance magnitude exposes race conditions in the arbitration logic and supplies the signed safety margins that automated falsification algorithms search over (section 15.9.2).

↩ The limit that the permission path enforces physical feasibility rather than semantic task correctness is established in section 10.7.

15.6.5 Compound faults and coupled disturbances

When a drive-current surge sags a shared DC power rail, it does not wait for the perception pipeline or the safety microcontroller to finish its current cycle: a single electrical dip can brown out the

application processor, freeze an image serializer, and jitter a shared clock all at once. While each row of table 15.2 tests one disturbance in isolation, real machines rarely fail one subsystem at a time. Combining rows at random would cause a combinatorial explosion without targeting realistic failures, so the campaign instead derives compound faults from shared hardware causes. The placement record (section 13.8) lists every physical resource that the permission path shares with the learned workloads, and each shared power rail, clock tree, or communication bus becomes a compound fault injected at the shared hardware root rather than at downstream software symptoms.

On the mobile manipulator, the primary shared vulnerability is the main DC drive bus, which powers the traction motor drives directly while feeding the application processor through an intermediate DC-DC converter. Meanwhile, the safety-critical permission path operates from an isolated, capacitor-backed hold-up rail. Notebook 15.2 evaluates the electrical headroom and timing budgets for both F4 fault injection trials using the vehicle's electrical specifications.

Napkin Math 15.2: The supply headroom

Problem: At the depleted point, can the drive transient alone carry the shared bus below the lockout of the converter that feeds the application processor, and how much of the permission rail's hold-up does the longest stop in the optimistic screening branch spend?

Variables:

- Depleted bus $V_{\text{low}} = 42$ V and converter lockout $V_{\text{uvlo}} = 33$ V (Datasheet).
- Source and harness resistance $R = 60$ mΩ (Illustrative; needs a measured value) and drive transient $I = 70$ A (Illustrative).
- Rail hold-up 2 s (Chosen) and spring-brake engagement $t_{\text{engage}} = 80$ ms (Illustrative).
- Longest stop in the optimistic all-weight screen: from the 1.23 m/s inspected-floor ceiling at $a = 1.18$ m/s² (Derived from floor friction with the entire weight on driven wheels) with $j_{\max} = 7.11$ m/s³ (Derived).

Math:

F4a, sag under the transient and the step that reaches lockout.

$$V_{\min} = V_{\text{low}} - I\,R = 42 - 70 \times 0.060 = 37.8 \text{ V}, \qquad I_{\text{cross}} = \frac{V_{\text{low}} - V_{\text{UVLO}}}{R} = \frac{42 - 33}{0.060} = 150 \text{ A}$$

F4b, flag to brakes set, with the stop time of equation 11.17.

$$t_{\text{set}} = (T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}) + \left(\frac{v}{a} + \frac{a}{j_{\max}}\right) + t_{\text{engage}} = 22 + \left(\frac{1.231}{1.177} + \frac{1.177}{7.11}\right) \text{s} + 80 = 22 + 1045.9 + 165.5 + 80 = 1313.4$$

Result: The transient leaves 4.8 V of headroom above the lockout, and reaching it takes a 150 A step, more than twice the transient. The 2 s hold-up outlasts the 1313.43 ms from flag to brakes set by 686.6 ms.

Systems insight: Neither trial can rest on the commanded load. F4a must step the supply itself, because the drive's own current cannot reach the lockout, and F4b must open the feed during the longest stop admitted by the qualified loaded envelope, since a shorter stop passes on hold-up the claim never needed. The computed duration belongs to the optimistic all-weight screen; loaded qualification must replace its braking premise before fixing the physical F4b oracle. The headroom rests on an illustrative resistance and would vanish near 129 mΩ, about twice that value, so the source resistance measured under load is the first number the supply campaign must supply.

A compound fault trial must capture high-bandwidth electrical waveforms while independently recording the behavior of the learned policy, perception pipelines, motor controllers, and external telemetry witnesses. Engineers cannot infer that processors reset or sensor frames froze from software logs alone, because the electrical disturbance often corrupts the operating system writing the log. For example, a voltage droop on a shared power rail can induce oscillator jitter that slows

the enforcer's control cycle, freeze an image serializer so that a camera publishes identical frames with plausible timestamps, and reset an external flight recorder during the exact same interval. Similarly, electromagnetic burst interference across a shared fieldbus ages perceptual observations while stalling the permission path's read requests and suppressing the diagnostic heartbeats that would otherwise signal the delay. A drift or jitter transient in a shared reference clock corrupts timestamps across the proposal-enforcement boundary at the same time, allowing stale data to pass as fresh evidence. The physical oracle evaluating a compound fault must therefore verify both that the protective response triggered within its deadline and that the witness instruments and evidence logs remained intact throughout the event (section 15.12).

Because unmodeled physical couplings cannot be found from a resource inventory alone, forward physical analysis must always complement derivation from the inventory. Together, the resulting fault catalog unites four sources: inverted design contracts, forward-derived physical hazards, the authority transfer cases (A1–A4), and compound disturbances on shared hardware. Defining this catalog establishes *what* faults the machine must survive; choosing the physical fidelity of the test bench determines *which* of those claims a given trial can actually test.

15.7 The Qualification Ladder

A desktop simulator can stall the proposer of F1 across every combination of speed and payload overnight, but it cannot sag the drive bus of F4. The simulated power network has no buck-boost converter to lock out and no microcontroller to brown out and reset, so a million passing rollout assertions (`assert clearance >= 0`) there say nothing about F4. That is the digital twin delusion of section 15.1, and the remaining question is where, precisely, a given simulator stops being evidence.

The gap between simulation and reality stems directly from what the simulator abstracts away. When a physics simulation omits embedded target execution and electrical dynamics, it relies on five pervasive idealizations, each of which must be evaluated against the specific claim under test:

1. **Computation takes zero virtual time:** The simulator pauses its simulation clock while the neural policy executes. This treats heavy neural forward passes as instantaneous, completely decoupling inference latency from physical base velocity ($d_{\text{blind}} = v\tau_{\text{delay}}$).
2. **Memory bandwidth is infinite:** Tensors pass across shared in-memory references. This completely omits the shared-memory contention, cache evictions, and DMA serialization stalls that govern real-time execution on an edge SoC.
3. **Power rails are infinitely stiff:** Power supplies are modeled as idealized constant-voltage sources ($V_{\text{bus}} = \text{const}$). This ignores the resistive droop ($\Delta V_{\text{bus}} = IR$) of the drive bus under sudden current steps (sized for this machine in notebook 15.2), the inductive flyback spikes from sharp current transients, and the resulting brownout resets.
4. **Clocks are perfectly synchronized:** The simulation advances monotonically in fixed discrete time-steps (Δt). This eliminates asynchronous clock drift, interrupt jitter, and transceiver arbitration races between the neural host and the real-time safety microcontroller.
5. **Contact mechanics are simplified:** Numerical contact solvers approximate Coulomb friction with linearized friction cones or convex relaxations that permit artificial creep under static load (Todorov 2014). They routinely neglect the transition between static and kinetic friction, dynamic tire slip, and brake-lining glazing during emergency stops.

↩ Resistive droop on a shared drive bus and the brownout resets it causes are established in section 2.6.1.

Each qualification environment closes, breaks, or substitutes different links in the chain connecting sensing, inference, communication buses, motor drives, and physical mechanisms. The **qualification ladder** orders four verification environments by how much of the cyber-physical loop is physically executed rather than simulated: software-in-the-loop, processor-in-the-loop (PIL), hardware-in-the-loop (HIL), and physical fault rigs. Software-in-the-loop is the lowest rung and the physical rig the highest, so climbing the ladder means making more of the loop physical. As physical hardware replaces numerical models, test fidelity rises, but trial throughput drops by orders of magnitude. This progression is not, however, an evidentiary hierarchy in which higher rungs subsume lower ones. Each rung yields a distinct category of empirical evidence while remaining blind to physical phenomena outside its boundary. A million successful software-in-the-loop rollouts reveal nothing about bus contention, DMA stalls, clock drift, or supply rail sag on the embedded hardware.

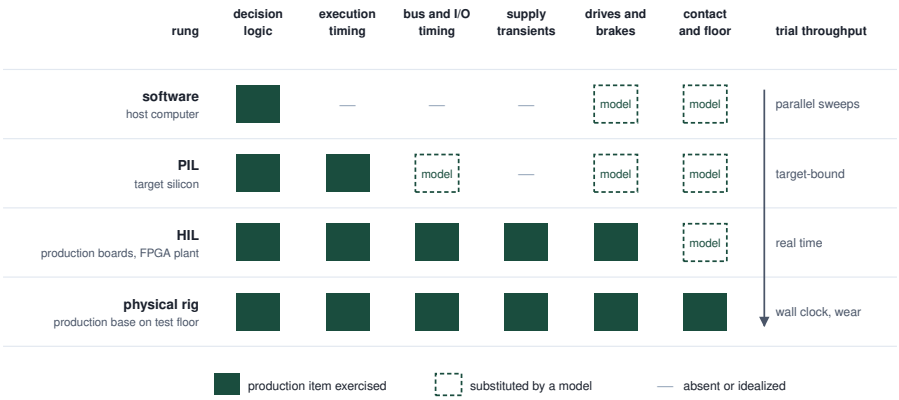


Figure 15.2: What each rung makes real: A filled cell is the production item itself, a dashed cell is a model standing in for it, and a dash marks a link the rung idealizes away. Rows run from the lowest rung, software-in-the-loop, to the highest, the physical rig; coverage of the causal loop grows with each higher rung while trial throughput falls, so no rung dominates. A mechanism can fail only on a rung that contains it, and only the lowest rungs are cheap enough to search at scale.

15.7.1 What each of the four rungs makes physical

On the warehouse mobile manipulator, software-in-the-loop evidence terminates at the boundary of the numerical plant model; a mechanical brake modeled merely as a first-order lag cannot capture pad thermal glazing, wheel slip, or torque saturation. Processor-in-the-loop (PIL) execution introduces the cross-compiled binary running on the actual target silicon (such as an ARM Cortex-R or RISC-V safety core), validating fixed-point quantization, instruction timing, and stack headroom. Hardware-in-the-loop (HIL) benches mount the two-processor architecture, with its physical fieldbus, power regulators, and motor drive stages, against a hard real-time FPGA plant model or an instrumented dynamometer. Finally, physical fault rigs close the full loop with the production chassis, mechanical brakes, wire harness, and physical warehouse floor.

↩ The two-processor architecture, which runs the permission path on a safety microcontroller apart from the learned proposer's application processor, is established in section 4.2.

Two operational testing paradigms exist alongside this qualification ladder, but both break the closed loop entirely. Trace replay feeds recorded sensor streams into the candidate controller; while it preserves authentic sensor noise and optical artifacts, the recorded frames reflect the actions of the original historical policy rather than reacting to the candidate's new commands. Shadow operation runs the candidate model in parallel with an incumbent, validated controller. If the candidate proposes an aggressive velocity vector that would drive the base into a storage rack, the logger records the telemetry while the incumbent controller safely halts the base. Because neither approach permits candidate actions to alter future state observations, neither reveals the closed-loop physical consequences of an erroneous command.

A production shadow deployment cannot allow a stalled proposer to drive toward a human worker at a rack end to see if the brakes engage in time. A software simulator cannot expose a timing race between transceiver silicon buffers. An instrumented physical dynamometer cannot execute the tens of millions of randomized runs required to bound extreme distribution tails. Systems engineers must therefore route each fault injection scenario to the specific rung on the ladder that embodies its underlying physical and causal mechanism. Coverage of the causal loop grows with each higher rung, from decision logic alone to drives and floor contact, while trial throughput shrinks, so no rung dominates the others (figure 15.2).

Selecting the proper qualification rung requires identifying the exact premise that a fault challenges. Validating the software lease expiry under CPU contention in F1 requires target silicon execution to capture true processor scheduling interference. In contrast, evaluating supply rail droop in F4 demands the production power distribution network and independent oscilloscope instrumentation across the DC bus. Similarly, certifying a stopping-distance budget requires a fully ballasted physical chassis operating over a qualified floor surface. A sound verification strategy uses high-throughput

simulation to search the combinatorial operational space for edge cases, then reproduces those critical scenarios on the specific hardware rung that contains the physical mechanism under test. Agreement between two rungs validates only the shared causal links common to both; table 15.3 outlines these strict evidentiary boundaries.

Table 15.3: The four-stage qualification ladder across cyber-physical boundaries: The four qualification environments compared by computing substrate, exercised causal-loop elements, fault injection primitives, execution throughput, physical and temporal fidelity, and test oracle.

Qualification Rung & Substrate	Causal Loop Realism (Compute, Bus, Actuator, Plant)	Fault Injection Mechanism & Scope	Throughput & Sample Scaling	Physical & Temporal Fidelity	Primary Test Oracle & Evidentiary Limit
Software-in-the-Loop (Host Workstation / Cloud Cluster)	**Compute:** Synthetic / Host x86; **Bus:** Idealized zero-copy buffer; **Actuator:** Linear / saturation model; **Plant:** Numerical ODE/PDE solver	Tensor bit-flips, synthetic sensor dropout, floor-friction, payload, and latency sweeps	Parallel sweeps; throughput depends on model and compute allocation	High mathematical flexibility; zero target silicon, bus timing, or electrical realism	**Oracle:** Mathematical assertion corridors and state invariants. **Limit:** Cannot validate target execution timing or unmodeled physical dynamics.
Processor-in-the-Loop (PIL) (Target SoC / MCU)	**Compute:** Real target silicon (ARM/RISC-V); **Bus:** Simulated bus interconnect; **Actuator:** Emulated command register; **Plant:** Real-time host model	Instruction cache evictions, register corruption via JTAG/BIST, interrupt jitter injection	Bound by target execution and cross-platform synchroniza-tion	Instruction-set and compiler accurate; abstracts analog bus lines and actuator back-EMF	**Oracle:** Target register state, numerical equivalence, and execution-time profiles. **Limit:** Ignores physical transceiver bus contention, voltage droop, and thermal rise.
Hardware-in-the-Loop (HIL) (Target ECUs + Real-Time Plant Rig)	**Compute:** Production ECU / NPU; **Bus:** Real physical CAN/Ethernet; **Actuator:** Real motor drives / dyno; **Plant:** Hard real-time FPGA plant rig	Pin break/short, CAN frame stuffing / babbling idiot, supply rail droop, load steps	$1.0\times$ strict real-time (24 h/day wall-clock limit)	High electrical, timing, and protocol fidelity; bounded by FPGA plant model accuracy	**Oracle:** Protocol CRC, bus deadline monitors, and interlock timings. **Limit:** Does not physically exercise modeled floor contact or wear; overload coverage depends on the rig and its protection.
Physical Fault Rig (Dynamometer Cell / Field Plant)	**Compute:** Production ECU / NPU; **Bus:** Production harness & sensors; **Actuator:** Real physical mechanisms; **Plant:** Real base, arm, and floor	Wheel clamps, magnetic brake stall, thermal heating, transducer bias drift	Wall-clock execution; constrained by wear and thermal reset	Full authentic physics (Coulomb friction, wheel slip, thermal dissipation, wear)	**Oracle:** Independent physical containment instrumentation and yield transducers. **Limit:** High financial cost per trial; destructive tests cannot scale to statistical tail bounds.

15.7.2 Where each rung's simulation boundary cuts the loop

Replacing physical wire harnesses, ground returns, and distributed actuator nodes with desktop simulations strips away inductive voltage droop, transmission reflections, and electromagnetic interference (EMI). Every qualification rung has a simulation boundary, the interface where numerical models, emulated buses, or replayed traces sever the exchange of energy and information

between computation and mechanics, and no environment can certify properties that depend on physics outside that boundary. Software-in-the-loop testing falsifies algorithmic decision logic and state-machine transitions across broad parametric sweeps. PIL uncovers numerical divergences from cross-compilation and profiles worst-case execution time on target silicon, yet because it funnels input and output over a hardware debug interface (such as a JTAG port or serial UART link), it cannot stress physical communication buses. HIL brings in the true physical transceivers, bus contention, and electrical transients, while leaving contact mechanics to real-time models. Finally, physical fault rigs subject the structural plant to unmodeled Coulomb friction, tire deformation, and thermal dissipation.

A higher rung therefore does not subsume or obsolete the lower ones. Verification is an exercise in constrained optimization across a Pareto frontier: parallel software-in-the-loop clusters explore millions of permutations of obstacle layouts and lighting variations. Physical rigs, by contrast, capture true contact mechanics at the expense of manual resets, mechanical wear, and thermal recovery between runs. Each stage occupies a unique operating point balancing combinatorial test throughput against physical causal fidelity. A mechanism omitted from a model cannot fail within it. If a simulator omits Coulomb breakaway friction and stator inductive lag, a simulated robot joint moves immediately upon receiving a torque command. On real hardware, however, that same joint remains stationary during a stiction dead time before lagging behind the commanded trajectory. This is a classic manifestation of the omitted-mechanism gap, which no amount of software simulation can uncover.

To guard against false confidence, every empirical verification claim must explicitly catalog its causal envelope: which links in the sensing-computation-actuation loop were physically real, which were simulated, which were replayed from static traces, which were bypassed, and which remained unobserved. Stating that the safety permission path halted the mobile base within 969.0 mm is meaningless in isolation. An engineer must specify whether the wheel-speed velocity signal was computed by a numerical ODE solver, streamed from a physical optical encoder over a saturated CAN bus, or read out from an in-memory replay buffer. Mapping this boundary exposes the physical assumptions behind each pass and prevents latent hardware hazards from hiding behind passing software assertions.

15.7.3 Scope of a formal verification result

A formal proof that a permission filter preserves safety over a mathematical plant model still cannot prevent a crash if the tires slip on a wet floor, the camera frames arrive late, or the proof is asked to cover a vision-language-action proposer fifty times larger than any network a complete verifier can solve. Formal proof provides a fifth source of evidence alongside the physical qualification ladder, but a proof holds only inside its mathematical model of plant states, sensor noise, and bounded disturbances. Translating that guarantee to the embodied machine still rests on empirical measurements of plant dynamics, observation deadlines, bus latencies, and actuator torque limits. Which components of the running machine a proof can reach at all depends on the current scale limits of neural-network verification.

Tools for formal neural-network verification operate in one of two regimes: open loop or closed loop. An open-loop verifier checks an **open-loop property**: given any input in a specified bounded set (for example, every camera frame within an ℓ_∞ ball around a nominal image, meaning every frame whose pixels each lie within ϵ_{adv} of the nominal values), the network's output is guaranteed to satisfy a declared constraint. Two algorithmic primitives drive these tools:

- **Bound propagation** pushes the input set forward through the network layer by layer. By replacing each nonlinear activation with linear relaxation bounds, it computes a sound, conservative bounding box around the outputs. If this enclosure satisfies the property, the proof succeeds immediately.
- When bound propagation leaves property satisfaction ambiguous, **branch and bound** partitions the input space or splits ambiguous piecewise-linear activations into distinct linear regimes, recomputing bounds over each sub-domain. For supported network and property classes, a complete search can decide the property in principle, but it scales exponentially with the number of split activations in the worst case; a timeout or unknown result is not a proof. Solvers such as Reluplex (Katz et al. 2017) and Marabou (H. Wu et al. 2024) formulate

these activation states as satisfiability modulo theories (SMT) or mixed-integer linear programming (MILP) problems, whereas the α,β-CROWN verifier accelerates bound propagation and branch-and-bound exploration directly on GPUs (Xu et al. 2021; Wang et al. 2021).

Verifying a **closed-loop property** poses a far steeper challenge. Rather than checking a static input-output mapping, closed-loop verification asks whether the continuous state of a physical plant driven by a neural policy remains within a safe invariant set over an extended time horizon. To answer this, reachability analysis evaluates the continuous trajectories of the physical plant under bounded disturbances. Forward reachability tools, such as NNV, Verisig, and POLAR, compose the network's output bounding box with the differential equations of the physical plant at each discrete control step, computing forward reachable sets for compact controllers on low-dimensional dynamical systems (Tran et al. 2020; Ivanov et al. 2019; Huang et al. 2022). Backward reachability via **Hamilton-Jacobi (HJ) reachability analysis** instead frames safety as a zero-sum differential game between the control policy and worst-case environmental disturbances. It computes the exact maximal safe invariant set as the zero level set of an optimal control value function (section B.6.3) (Mitchell et al. 2005; Bansal et al. 2017). While Hamilton-Jacobi reachability provides non-conservative safety certificates for continuous nonlinear dynamics, solving the underlying Hamilton-Jacobi-Isaacs partial differential equation on a Eulerian grid scales exponentially with continuous state dimension. Consequently, Hamilton-Jacobi reachability is computationally tractable for decoupled, low-dimensional subsystems (such as a single revolute joint or longitudinal base stopping), whereas forward reachability tools struggle with the rapid accumulation of over-approximation error across long planning horizons. NNV also supports bounded image-input robustness analysis through ImageStars (Tran et al. 2020), but those image results do not establish an end-to-end closed-loop guarantee for the running machine's high-resolution vision-language-action stream. Its permission path instead exposes a handful of calibrated physical states and a declared stopping invariant (chapter 12).

Table 15.4 benchmarks the state of the art in formal verification. In the 2025 International Verification of Neural Networks Competition (VNN-COMP 2025), the largest scored benchmark network contained 138M parameters, with the vast majority of evaluated models containing fewer than a million parameters (Kaulen et al. 2025). By contrast, the running machine's intent model, the larger of its two learned proposers, contains 7B parameters, roughly 51× larger than that benchmark outlier. Both proposers also ingest an unconstrained temporal stream of high-resolution camera frames rather than an analytically bounded input set, and a local pixel-perturbation specification alone does not establish stopping safety across changing warehouse scenes and physical states.

The cited results do not establish complete formal verification of this deep proposer under its deployment stream; both computational scale and the absence of a justified visual specification remain barriers. This separation is the third law, proposal is not permission (principle 3), seen from the verifier's side. The learned proposer is evaluated and stress-tested empirically, and formal proof is reserved for the compact, deterministic permission path, which reads a handful of calibrated physical measurements (wheel speeds, lidar clearances, payload mass) and enforces an analytically tractable stopping invariant that a proof can reach.

↩ The separation of a learned proposer from a deterministic permission path is established in section 1.7.

Table 15.4: Verification methods and their reach, as of 2026: Representative tools for each method class, what a result establishes, and the scale at which it currently operates. The mechanisms in the prose are durable; the named tools and scales will change, so the table carries its date.

Method class	Representative tool	What a result establishes	Scale and limit, as of 2026
Complete open-loop NN verification	α,β-CROWN (Wang et al. 2021); Marabou 2.0 (H. Wu et al. 2024)	A property holds for every input in a bounded set, or a counterexample input	α,β-CROWN ranked first in VNN-COMP 2025; scored benchmarks reach 138M parameters (Kaulen et al. 2025)
Closed-loop reachability	NNV (Tran et al. 2020); POLAR (Huang et al. 2022); HJ reachability (Bansal et al. 2017)	Forward reachable set or maximal backward invariant set under bounded disturbances	Small controllers and low-dimensional plants; forward bounds grow conservative, backward HJ PDE grids scale exponentially with state dimension

Method class	Representative tool	What a result establishes	Scale and limit, as of 2026
Temporal-logic falsification	S-TaLiRo (Annpureddy et al. 2011); Breach (Donzé 2010)	A counterexample trajectory with negative robustness, or none found within the search budget	Black-box simulation of any model; no certificate from an unsuccessful search
Rare-event estimation	Importance sampling with the cross-entropy method (O'Kelly et al. 2018)	A failure probability under a declared operational distribution, with its variance	Only as good as the declared distribution and the proposal's coverage of the failure set

Even within the permission path, high-dimensional reachability calculations, nonlinear contact dynamics, and hybrid switching modes can cause mathematical over-approximations to become prohibitively conservative. These practical limits do not render formal analysis useless. Instead, they dictate engineering restraint: they favor designing compact, mathematically transparent permission filters with explicit physical premises that can be verified in minutes, leaving the unmodeled electrical and mechanical dynamics to be systematically challenged on the physical rungs of the qualification ladder.

Checkpoint 15.2: Rung choice and the reach of a proof

A rung, like a proof, supports only the mechanisms it contains.

- ☐ **Rung selection**: For F2 (a frame held at the image signal processor), F3 (lost fieldbus frames), and an actuator jam, can you name the lowest rung that contains the causal mechanism and one mechanism that rung still idealizes away?
- ☐ **Agreement between rungs**: Can you explain why a software-in-the-loop pass and a HIL pass on the same scenario support only the mechanisms both rungs represent?
- ☐ **Replay vs. shadow operation**: Can you explain why neither trace replay nor shadow operation shows the physical consequence of the candidate's command?
- ☐ **Proof scope**: Can you explain why the cited closed-loop results support analyzing the permission path without establishing a guarantee for the learned proposers, and list the premises such a proof leaves to physical test?

15.8 Fault Injection on Hardware

A fault injected in simulation tests only the modeled response. On physical machinery, bus contention, microcontroller clock drift, DMA stalls, and transient voltage drops across inductive motor drivers determine whether a safety intervention executes before physical impact. When a simulator fails to capture and calibrate these physical interactions, simulation alone cannot substantiate claims that depend on them. Instead, **in-situ fault injection** runs directly on the target hardware while an external containment rig keeps the facility safe, deterministically introducing physical, electrical, and computational disturbances (sensor register latches, clock drift, bus contention, supply brownouts, and actuator load stalls) into production silicon, transceivers, timers, shared buses, and mechanics under authentic compute, thermal, and power loads.

15.8.1 Physical injection needles across sensor, bus, and power

A fault injected in software above the driver can exercise downstream responses but does not reproduce a disturbance originating at the physical interface; an empirical verification campaign must place its injectors at the physical boundaries themselves.[7] Four complementary injection mechanisms cover the machine's safety claims:

1. *Sensor ingress injectors:* Inline interposers on camera serial links freeze frames, inject propagation delay while preserving original hardware timestamps, or corrupt pixel payloads at the physical layer without modifying driver software.
2. *Fieldbus disturbance nodes:* Inline devices inject protocol-specific faults: corrupted frames, CAN collisions that drive target controllers into bus-off states,[8] dropped EtherCAT distributed-clock synchronization frames, or babbling-idiot traffic that monopolizes shared resources.

[7] **Injection fixtures**: Power injectors switch or modulate the supply using solid-state devices, while bus injectors manipulate communication lines through high-impedance buffers. Test instrumentation must remain galvanically isolated from high-current motor transients; otherwise, witness systems will fail alongside the drive. Achievable edge rates and isolation ratings characterize the specific test fixture and must be recorded in the qualification dossier.

[8] **Bus-Off**: The Controller Area Network protocol enforces hardware fault confinement: when a controller's transmit error count exceeds standard thresholds, it enters bus-off and ceases bus communication until cleared by an idle sequence (International Organization for Standardization 2015a). While this prevents a damaged node from corrupting the bus, external disturbance injectors forcing bit collisions can exploit this mechanism to silence healthy nodes without a software fault. Physical fault injection must prove that the safety permission path detects this silenced node and initiates safe fallback within its timing budget.

3. *Supply injectors:* Programmable power supplies emulating the battery pack, paired with dynamic electronic loads, step drive-bus and logic rails through calibrated voltage droop profiles. Delivered waveforms must be measured directly at the device terminals, because test-fixture slew-rate limits dictate which high-frequency transients the setup can faithfully reproduce.
4. *Dynamometer actuator injectors:* Dynamometer load machines mechanically coupled to wheel hubs or arm joints command calibrated load steps within their measured bandwidth. These challenge responses to increased resistance or abrupt joint loads; reproducing bearing seizures, brake-lining glazing, or joint jams requires mechanism-specific fixtures while instrumentation records the closed-loop motor current response.

Verifying the dual-processor safety architecture requires targeted physical injection at the exact hardware boundaries established by the safety contract. Table 15.2 summarizes the corresponding detectors, recovery actions, and acceptance criteria; the following breakdown details the physical injection mechanics and timing instrumentation for each fault class:

- **Expired Lease Revocation (F1):** The test framework permits the chunk policy to issue a single valid renewal, then freezes its task or command output while leaving its periodic heartbeat active, verifying that superficial liveness cannot renew the lease. Dropping subsequent lease messages is a separate test of expiry under communication loss. High-speed logic analyzers time lease expiration, the enforcer's formal revocation on the subsequent 1 ms control tick, and the mechanical onset of braking across dedicated hardware trigger lines.
- **Stale Observation Injection (F2):** An inline FPGA interceptor latches a navigation-camera frame at the image signal processor interface, or suppresses optical encoder updates, while preserving the original hardware timestamp intact. External instrumentation independently records the exact moment of detector trip, the onset of powered electrical deceleration, and the resulting wheel speed profile.
- **Lost-Frame Injection (F3):** A fieldbus disturbance node drops or corrupts EtherCAT frames directly at a servo drive's slave port while the mobile robot cruises. The master's frame-arrival, validity, and working-counter checks[9] detect communication loss under their configured deadlines. At aisle velocity, each lost 1 ms cycle allows the vehicle to travel an unmonitored 1.3 mm, eating directly into the physical safety margin.
- **Drive-Bus Droop and Feed-Loss Injection (F4a, F4b):** A programmable supply standing in for the battery pack at its 42 V depleted point delivers the full 70 A transient demanded by aggressive drive acceleration while the application SoC operates at peak load. The supply injector then commands a voltage step that forces the drive bus below the 33 V converter undervoltage lockout, a threshold that operating load alone cannot breach (notebook 15.2). Throughout this transient, the permission path must remain fully operational, sustained by the isolated, held-up rail. An independent digitizer records the permission-path heartbeat, and instrumentation measures the onset of powered deceleration relative to the undervoltage alarm flag. In trial F4b, an electronic switch opens the permission rail's primary feed during the longest stop admitted by the qualified loaded envelope. The illustrative all-weight screen initiates its resident stop from the 1.23 m/s ceiling. Independent measurements must verify both surviving drive authority and energy absorption throughout dynamic braking. Sustaining logic hold-up alone leaves that premise unverified. Any reset of the permission path constitutes an immediate `FAIL` in either trial, regardless of stopping distance, because a vehicle that forfeits controlled deceleration to unpowered spring brakes mid-motion violates the deterministic stopping envelope budgeted by the safety contract.
- **Handover Stall Injection (A3):** The testbed intentionally freezes operator input while a remote takeover request remains in the handover-pending `PEND` state defined in section 14.3.2, and it drops acknowledgment frames, at both base speeds. At the 0.75 m/s slow-down, a candidate moving handover is tested and any admitted candidate must time out into a local stop. At the 1.3 m/s aisle speed, the handover must be rejected. The operative configuration must stop before granting manual motion at either speed. High-speed probes separately time the enforcer's fallback dispatch and physical actuation onset at the wheel drives. While the

[9] **EtherCAT Working Counter**: As an on-the-fly datagram traverses each downstream slave, every node that successfully processes assigned process data increments a dedicated working counter field in hardware. The returning counter value informs the master within the exact cycle of transmission how many addressed devices successfully read or wrote their process data. A missing return, an invalid frame, or a working-counter mismatch provides a distinct communication-failure indication. The configured master checks can detect F3 within the cycle's declared receive deadline, without waiting for a slave drive's communication watchdog to expire; that detector bound and the subsequent stopping response must be qualified together.

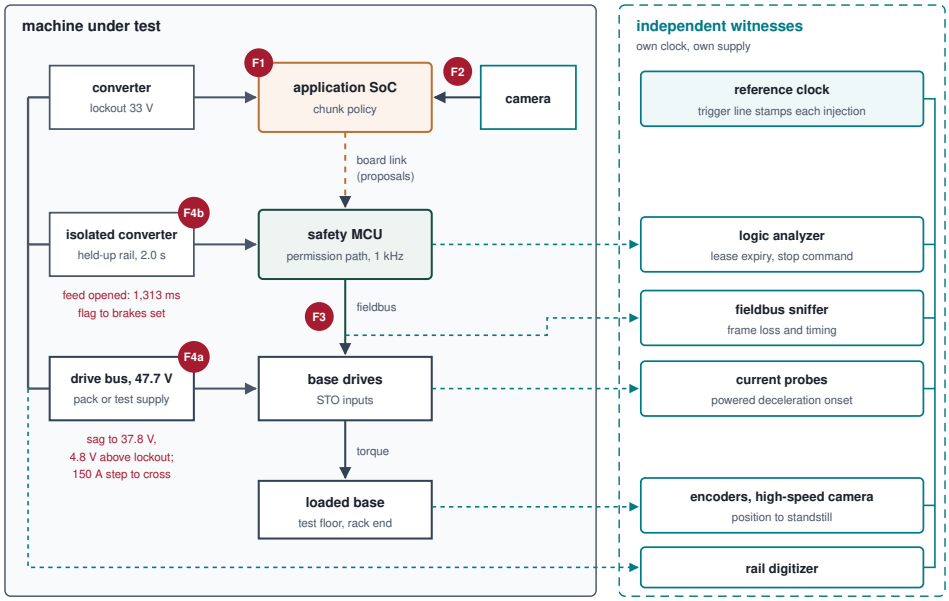

Figure 15.3: The machine under test and its witnesses: Each fault enters at a physical interface of the production machine, F1 at the proposer, F2 on the camera link, F3 on the fieldbus, and F4a and F4b on the supply, and every event the oracle scores is recorded by an instrument on its own clock and supply. F4a steps the supply itself, because the drive transient alone leaves the depleted bus above the converter lockout, and F4b opens the permission rail's feed, whose hold-up must outlast the time from flag to brakes set under the qualified loaded envelope; the figure's duration uses the optimistic all-weight screen (notebook 15.2).

configured waiting allowance limits dispatch latency, physical onset must also satisfy the allocated command-to-response interval.

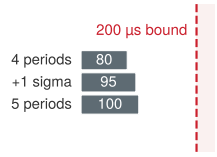
Duplicate writers (A1), tier bypass attempts (A2), and forged or replayed packets (A4) require no specialized mechanical fixtures beyond a secondary bus master and a packet injector configured according to table 15.2. All four physical injector types and their witness instruments integrate onto a single test bench. The test rig of figure 15.3 enforces strict physical separation: no witness instrument may share a power rail or a timebase with the target machine under evaluation.

15.8.2 Timing faults across clock domains

Because camera frame capture, trajectory proposal generation, enforcer permission ticks, and fieldbus communication cycles run across asynchronous clock domains (section 8.3), a fault injected at a fixed offset from the start of a run can miss the narrow alignment where a race condition trips. Reproducible qualification therefore records the disturbance's phase relative to every relevant clock edge and sweeps across injection phases to expose race conditions that fixed-offset tests miss, while recognizing that empirical phase sweeps alone cannot prove the absence of a worse alignment.

Consider the stale-observation scenario (fault F2) running on production silicon. The navigation camera timestamps each image at the moment of physical exposure, and the perception pipeline budgets a maximum age of 51.6 ms upon trajectory dispatch (section 8.4.1). Because the robot travels at 1.3 m/s, it covers 1.3 mm every millisecond. Unbudgeted perceptual latency drains the stopping distance reserve millisecond by millisecond. The 51.8 ms upper-age bound, however, governs only the dispatch instant; sensory evidence continues to age as the command traverses validation and motor execution. Consequently, the per-tick safety monitor cannot treat the dispatch limit as an open-ended pass; it must evaluate perceptual freshness dynamically against remaining stopping distance and active trajectory validity. The stall that matters is short. Once the dispatch-to-admission allocation is charged, only 37.5 ms of the aisle-speed spare remains (section 15.2), so an undetected stall of that length leaves the machine no clearance to give.

Neither the nominal sensor readout latency from a component datasheet nor the timestamp logged on an isolated image frame proves when the safety enforcer will recognize a stall. Relying on empirical p99 response times provides no safety guarantee because a percentile alone does not bound shared-memory interference; a finite worst-case claim requires an explicit architectural and scheduling model (section 4.5.1). A defensible containment claim demands an analytic and experimental worst-case detection bound validated across maximum compute saturation, peak fieldbus load, and extreme operating temperatures.



15.8.3 Distributed clock drift and synchronization blackouts

Two processors can each meet every local real-time deadline on their own crystals and still drift apart fast enough during a brief synchronization blackout to let a stale camera frame pass as fresh. The F2 stale-observation detector relies directly on the 0.2 ms clock-conversion bound established in the observation contract of section 8.8 when translating image capture timestamps into the safety microcontroller's local timebase. That bound is not an axiomatic constant: section 8.6.2 measures it from the tail of the synchronization offset, the path asymmetry, and the drift between synchronization exchanges, and verification asks how much of it survives when those exchanges stop arriving. Consider illustrative oscillator tolerances: ±100 ppm for the application processor crystal, ±50 ppm for the safety microcontroller, and an additional 50 ppm worst-case thermal drift unaccounted for in standard room-temperature ratings. Together, these sources yield a maximum relative drift rate of 200 ppm. At this rate, uncorrected drift alone exhausts the entire 0.2 ms conversion budget in 1 s without active resynchronization. Under healthy operating conditions, periodic synchronization packets arriving every 100 ms confine accumulated drift to 20 µs, leaving the remainder of the error budget for network transit jitter and software conversion overhead.

Suppose electrical noise or packet collisions trigger a synchronization blackout where three consecutive sync frames are dropped, leaving two successful packets separated by 400 ms. Across this four-period blackout window, bounded clock drift alone accumulates to 80 µs. When measured synchronization jitter has a standard deviation of $\sigma_{\text{jitter}} = 15$ µs, combining the drift rate δ_{skew} over the blackout duration T_{blackout} with a one-sigma jitter excursion yields:

$$\Delta t_{\text{one-sigma scenario}} = \delta_{\text{skew}}\, T_{\text{blackout}} + \sigma_{\text{jitter}} \tag{15.2}$$

totaling 95 µs. The one-sigma estimate in equation 15.2 represents an illustrative operating point rather than a deterministic upper bound; certifying real-time safety requires bounding tail jitter analytically and stress-testing the conversion path on hardware. If the blackout extends to a fifth period (four consecutive frames dropped), accumulated oscillator drift alone reaches 100 µs before jitter is added, consuming half of the 0.2 ms error budget. The runtime must refuse proposals or enter its qualified fallback before synchronization uncertainty exceeds the conversion bound. If that guard is absent and clock drift or transit jitter breaches the boundary, two failure modes threaten the machine. In the first failure mode, a fresh camera frame appears artificially aged when compared against a fast microcontroller clock; the enforcer rejects valid proposals and initiates an unprompted emergency stop, stranding the vehicle mid-aisle. In the second, more dangerous mode, a stale observation appears artificially fresh against a slow microcontroller clock. The conversion error itself is cheap in distance. At 1.3 mm per millisecond, the whole 0.2 ms bound is worth less than a millimeter of travel. What the error corrupts is the refusal verdict. Because the admission check adds the 0.2 ms conversion bound to the measured timestamp difference to form a conservative upper age, the nominal navigation frame reaches the 51.8 ms refusal threshold exactly at dispatch, so the observation contract of section 8.8 left that threshold with zero slack. Once a slow microcontroller clock lags by more than the 0.2 ms allowance, the uncompensated clock lag subtracts directly from the measured elapsed age, so the age check can no longer certify that an admitted frame lies within budget. A frame held back by an F2 stall then passes as fresh whenever the uncorrected drift exceeds the stall's extra age. Because drift keeps accumulating for as long as synchronization stays lost, the stall the check can miss grows with the blackout. The permission path may then admit proposals computed from obstacle coordinates older than the budget allows while the loaded base moves at 1.3 m/s.

A five-period blackout spends half the clock-conversion bound.

Every physical fault injection trial concludes with a rigorous evidentiary burden. The test harness must simultaneously record the trip signal from the internal detector, the precise timestamp of

proposal rejection, the actuation takeover at the motor drives, and the final physical stopping trajectory. All measurements must be captured by external, fault-isolated instruments synchronized to a single master reference clock. If a trial fails to record any of these intermediate transitions, it fails to produce actionable verification evidence. Physical fault injection campaigns do not yield simple pass/fail tallies; they generate auditable execution traces binding each trial to its architectural claim, its exact operating envelope, its software build artifacts, and its physical sensor waveforms.

↪ How these trial traces enter a safety case as evidence for a claim is developed in section 16.3.

15.9 Searching Beyond the First Trial

A single successful fault trial demonstrates that the safety path can arrest the vehicle under one declared set of operating conditions. Physical machinery, however, rarely fails under tidy nominal conditions; subtle vulnerabilities hide in the narrow corners of the state space where timing jitter, payload shifts, and degraded surface traction align against the enforcer. Exhaustive testing across this continuous operational envelope is physically impossible, yet uniform random sampling requires an intractable number of runs to uncover rare edge-case failures. Searching beyond isolated trials requires systematically steering disturbances toward the boundary conditions that drive the system closest to its safety limits. Rather than replacing the formal coverage record, automated search routines prioritize which candidate executions deserve empirical evaluation on the physical test track or dynamometer.

15.9.1 Signal temporal logic and quantitative robustness

A binary `PASS` or `FAIL` verdict tells an automated search algorithm nothing about whether a passing stop cleared the rack by 15 cm or by 1 mm, leaving the optimizer blind to near misses. Classical temporal logic (Pnueli 1977) checks whether a sequence of states satisfies a property. **Signal Temporal Logic (STL)** extends the specification to continuous time and real-valued physical signals (such as staying inside a spatial corridor or halting before a deadline (Maler and Nickovic 2004)), and it equips every formula with **quantitative robustness semantics** (Fainekos and Pappas 2009). Instead of returning a boolean flag, quantitative robustness computes a real-valued signed margin $\rho(\phi, s, t) \in \mathbb{R}$ that measures *how far* a trajectory $s : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ sits from violating or satisfying the temporal property ϕ at time t.

↪ The syntax and semantics of signal temporal logic are developed in section A.7.

For an atomic physical predicate $\pi \equiv (f(s(t)) \geq 0)$ (such as spatial clearance $d(t) - d_{\text{safe}} \geq 0$), quantitative robustness evaluates the signed predicate margin: $\rho(\pi, s, t) = f(s(t))$. Across temporal operators, safety invariants evaluate worst-case (minimum) margins, whereas reachability deadlines evaluate best-case (maximum) margins:

$$\rho(\Box_{[0,T]}\phi, s, 0) = \min_{t \in [0,T]} \rho(\phi, s, t), \qquad \rho(\Diamond_{[0,\tau]}\phi, s, 0) = \max_{t \in [0,\tau]} \rho(\phi, s, t). \tag{15.3}$$

Here $\Box_{[0,T]}$ denotes "always on $[0, T]$" and $\Diamond_{[0,\tau]}$ denotes "eventually within τ."

The sign and magnitude of ρ in equation 15.3 establish an immediate operational interpretation:

$$\rho > 0 \implies \text{satisfied with positive margin } \rho, \qquad \rho < 0 \implies \text{violated with shortfall depth } |\rho|.$$

For example, if the spatial clearance margin is $\rho = +0.15$ m, the minimum clearance observed along the trajectory exceeded the safety threshold by 15 cm. Conversely, if $\rho = -0.04$ m, the machine breached the prescribed clearance boundary by 4 cm, with physical collision depending on whether the safety limit included an explicit standoff buffer.

This signed value margin constitutes **space robustness**, quantifying how far the signal's physical magnitude can perturb before the verdict flips. Space robustness captures amplitude margins rather than timing margins: a delayed brake actuation represents a temporal shortfall rather than an instantaneous spatial error. Capturing temporal slack requires **time robustness**, a complementary semantics that evaluates how far a signal trajectory may shift along the time axis before the verdict changes (Donzé and Maler 2010). Because spatial and temporal margins govern different physical dimensions, combining them into a single unweighted formula introduces semantic ambiguity. For the F1 specification, the cleanest engineering formulation isolates the onset deadline outside the Signal Temporal Logic expression as an explicit scalar predicate on measured reaction time, while evaluating stopping distance via spatial robustness.

DRAFT

For this reason equation 15.1 keeps its two predicates apart. The onset predicate, deceleration within 82 ms of the last valid renewal, is a scalar check on measured reaction time, and the travel predicate, at most 751.9 mm at aisle speed, is a space-robustness predicate on vehicle position. Both are measured from the same reference event, so neither can silently absorb slack from the other; a different reference event would change the elapsed timing and require a correspondingly adjusted distance bound.

To illustrate this dual evaluation numerically, consider an F1 trace at aisle speed, timed channel by channel in figure 15.4, where powered deceleration begins 30 ms late, occurring 112 ms after the last valid renewal. The onset margin against the 82 ms bound evaluates to -30 ms. Because the mobile base travels 39 mm further before braking engages, total travel from renewal to rest reaches 750.9 mm, yielding a distance margin of 1 mm against the 751.9 mm oracle. The onset predicate fails, while nominal travel remains within the distance allowance. The verification results retain both margins in their native physical units; the tracking inset belongs in the oracle and is not additional travel in the plotted speed integral. Because taking an unweighted minimum across milliseconds and millimeters produces an uninterpretable quantity, synthesizing them into a unified score via `min` requires normalizing each margin by a predeclared positive scale in its corresponding unit. Logging both the raw margins and their normalization factors ensures the synthesized verdict remains physically meaningful. Choosing scales equal to the verification bounds themselves yields normalized margins of -0.366 for onset timing and 0.001 for stopping distance, making the onset predicate the governing term in the combined score. When several predicates have negative margins, alternative scales can change which one governs the compound score, so test engineers must fix normalization factors before executing verification runs. In this nominal trace only onset fails, so positive rescaling cannot make distance the governing predicate. These numerical values reflect model arithmetic over a stipulated reference trace rather than empirical physical measurements.

Recording every monitored channel on one timeline, as illustrated in figure 15.4, helps localize a failed trial to a stage of the response path when the independent witnesses remain valid. A lease that expires on schedule and a stop command issued at the next tick, followed by a late braking onset, direct the investigation toward command delivery, drive execution, or physical brake response rather than the lease-expiry check.

By producing a continuous, signed margin rather than a binary pass/fail flag, quantitative robustness transforms verification from passive testing into **temporal logic falsification as adversarial optimization**. In classical computer vision and deep learning, adversarial attacks such as the fast gradient sign method (FGSM) (Goodfellow et al. 2015) and projected gradient descent (PGD) (Madry et al. 2018) search for an input perturbation δ_{adv} bounded within an ϵ_{adv}-ball ($\|\delta_{\text{adv}}\|_\infty \leq \epsilon_{\text{adv}}$) that maximizes task loss: $\max_{\|\delta_{\text{adv}}\|_\infty \leq \epsilon_{\text{adv}}} \mathcal{L}(f_\theta(x+\delta_{\text{adv}}), y)$. In cyber-physical systems, temporal logic falsification provides the continuous dynamic counterpart. Rather than perturbing static feature vectors, an adversarial optimizer searches over initial state spaces and time-varying physical disturbance trajectories within a bounded physical disturbance envelope to minimize quantitative Signal Temporal Logic robustness. The robustness metric ρ acts directly as the adversarial objective function. Whereas uniform random sampling across a high-dimensional operational state space requires an intractable number of physical trials to expose rare corner-case collisions, an adversarial falsification engine actively steers disturbance sequences toward trajectories that drive the system closest to violating its safety invariants.

15.9.2 Formulating falsification as trajectory optimization

An unconstrained mathematical search over arbitrary disturbance signals can easily invent discontinuous spikes that no real actuator, sensor, or contact surface can physically produce, wasting the search on impossible counterexamples. To restrict the search to physically realizable disturbances, let $\mathbf{x}_0 \in \mathcal{X}_0$ represent the machine's initial state vector (translational speed, payload mass, heading angle, and battery state-of-charge), and let $w_{\text{dist}}(t) \in \mathcal{W}$ denote an adversarial disturbance trajectory spanning the test horizon $[0, T]$. Because physical hardware has finite bandwidth, mechanical inertia, and thermal limits, disturbance trajectories are parameterized over a compact parameter space $\psi \in \Psi$ using smooth basis functions, such as B-splines, cubic splines, or Fourier series:

$$w_{\text{dist}}(t;\psi) = \sum_{k=1}^{K} \psi_k B_k(t)$$

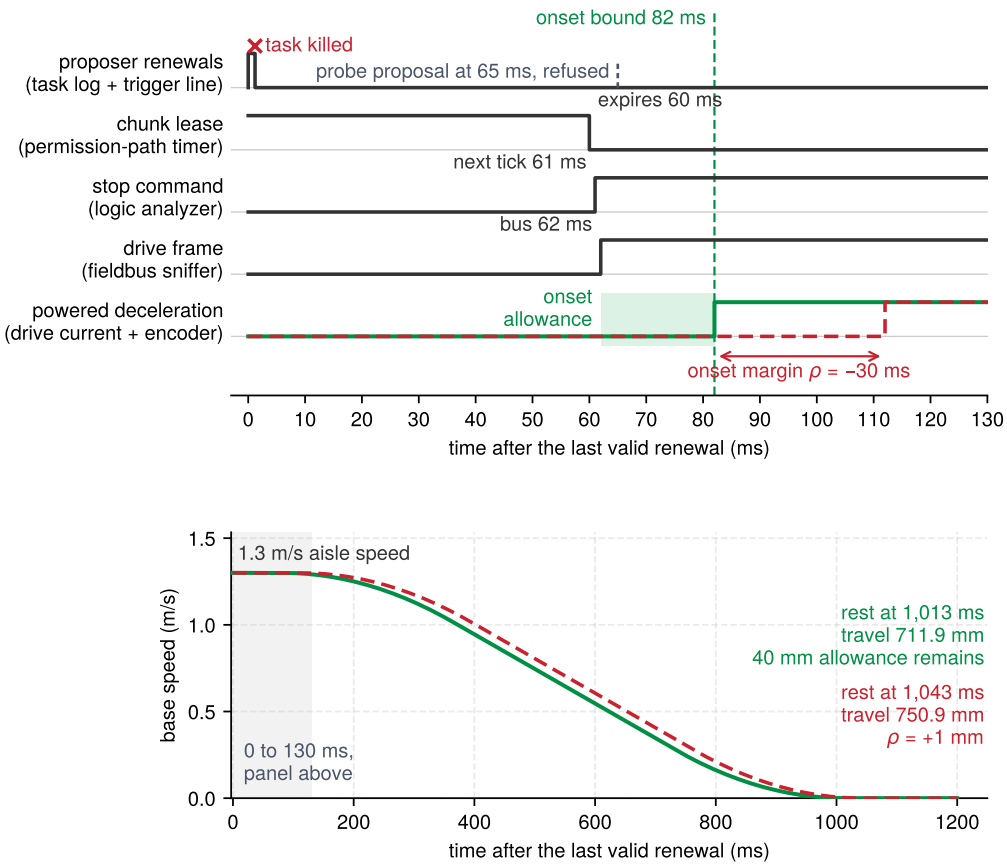


Figure 15.4: One F1 trace against its oracle: Model timelines, not measurements, of the channels an F1 trial must witness at 1.3 m/s, timed from the last valid renewal. The chunk lease expires at 60 ms, the next permission tick commands the stop, the fieldbus delivers it, and powered deceleration must begin by 82 ms; a proposal probed after expiry is refused. The dashed trace brakes 30 ms late, so its onset margin is -30 ms and its 750.9 mm of nominal travel retains 1 mm against the 751.9 mm oracle. The on-time curve travels 711.9 mm; the tracking inset is an allowance in the oracle, not extra travel in either curve.

where $B_k(t)$ are time-dependent basis functions and ψ_k are bounded parameter coefficients.

The temporal logic falsification problem finds the worst-case parameter combination that minimizes quantitative robustness:

$$\min_{\mathbf{x}_0 \in \mathcal{X}_0, \psi \in \Psi} \rho(\phi, s(\mathbf{x}_0, w_{\text{dist}}(\psi)), 0) \quad \text{subject to} \quad \|w_{\text{dist}}(t;\psi)\|_\infty \le \Delta_w, \quad \forall t \in [0,T]. \tag{15.4}$$

The disturbance budget Δ_w in equation 15.4 bounds the peak magnitude of optical, acoustic, contact, and execution disturbances derived from the operational envelope. Yet magnitude bounds alone do not guarantee that a test bench can deliver the waveform. The basis functions, coefficient bounds, and experimental test fixtures must also respect realistic rates of change and duration limits. For example, a programmable load bank that cannot slew fast enough to replicate a steep simulated voltage transient leaves that synthesized counterexample untested on hardware.

A verification campaign must therefore log both the synthesized disturbance command and its independently measured physical trace. If the test fixture fails to deliver the precommitted disturbance trajectory within specified tolerances, the trial is `INVALID` for that test condition even if the machine comes to a safe stop. Conversely, while an empirically realized counterexample refutes a safety claim outright, a search that finds no violation within a restricted parameter family leaves arbitrary disturbances outside that basis open to question.

15.9.3 Selecting a search method

Frictional contact transitions and discrete controller state jumps often make the quantitative robustness landscape nonsmooth and non-convex, causing gradient descent to stall or step in the wrong direction unless those transitions are smoothed or handled explicitly. Derivative-free optimizers avoid this trap. The Covariance Matrix Adaptation Evolution Strategy (CMA-ES) (Hansen and Ostermeier 2001) updates a multivariate normal distribution over disturbance parameters across generations, discovering correlated failure modes across speed, surface friction, and execution timing. When physical trials dominate the cost because each run requires mechanical resets, hardware inspection, and thermal cool-down, Bayesian optimization[10] fits a probabilistic surrogate model to previous runs to choose the next test point. Neither method guarantees convergence to a global minimum over a finite campaign, so the verification record must preserve search parameter bounds, random seeds, evaluated test vectors, and fixture limits so that auditors can see exactly which regions were challenged.

Two software toolboxes implement this search loop for cyber-physical models: S-TaLiRo (Annpureddy et al. 2011) and Breach (Donzé 2010). Both ingest a formal Signal Temporal Logic requirement and a simulation model, compute quantitative robustness on each simulated rollout, and steer stochastic or local optimizers toward negative robustness. A related family of algorithms treats the disturbance sequence as a sequential decision process. **Adaptive stress testing** (R. Lee et al. 2020) explores the disturbance sequence via Monte Carlo tree search or reinforcement learning to find the most probable path to failure rather than an arbitrary, physically improbable edge case, ranking counterexamples by operational plausibility. A survey of these black-box methods groups them by their output (Corso et al. 2021): finding an isolated counterexample, finding the most likely failure trajectory, or estimating an aggregate failure probability. Only the third output measures operational risk, using the estimation procedure developed in section 15.10.2. Whatever search method is chosen, it returns candidate counterexamples and measured robustness margins; when those margins come from a simulator, counting them toward a physical safety claim requires bounding how far the simulator's trajectories can drift from the real machine's.

[10] **Bayesian Optimization**: Originally developed for computationally expensive engineering simulations, Bayesian optimization fits a Gaussian-process surrogate across completed trials and selects the next sample point by maximizing expected improvement (Jones et al. 1998). Physical fault-injection rigs face the same cost structure, because each trial requires mechanical resets, hardware inspection, and thermal stabilization delays. Still, the surrogate's confidence is only a model prediction: a region it estimates to be safe has not been physically tested simply because the surrogate predicts a positive margin.

15.9.4 Bounding the sim-to-real transfer gap

A simulator that passes every fault-injection rollout can still hide a physical crash if its modeled trajectories differ from the real machine's by more than the simulated safety margin. While high-throughput software-in-the-loop simulation is indispensable for exploring combinatorial corner cases, an unvalidated simulator can confirm only what its underlying model assumes. To use simulation sweeps as evidence in a safety case, the engineering team must validate and bound the **sim-to-real transfer gap** ϵ_{gap}.

Let $s_{\text{sim}}(t;\xi,\mathbf{u}) \in \mathcal{S}$ and $s_{\text{real}}(t;\xi,\mathbf{u}) \in \mathcal{S}$ denote the system state trajectories in simulation and on target physical hardware under matched declared conditions ξ (initial speed, payload mass, floor friction) and control input history $\mathbf{u}$. Replaying identical open-loop input sequences establishes a baseline comparison of plant dynamics, but certifying a deployed closed-loop policy requires bounding discrepancy under autonomous execution, where perturbed sensor observations produce divergent actuator commands. The continuous transfer discrepancy is the supremum state error across the test horizon $[0,T]$ under a task-weighted physical norm:

$$\epsilon_{\text{gap}} = \sup_{t\in[0,T]} \|s_{\text{real}}(t) - s_{\text{sim}}(t)\|_W \tag{15.5}$$

where $\|\cdot\|_W$ normalizes position, velocity, and actuator torque errors by predeclared positive reference scales in meters, meters per second, and newton-meters, respectively, before applying dimensionless task weights. The verification plan fixes those scales and weights in advance; the resulting discrepancy ϵ_{gap} is dimensionless, while the Lipschitz constant L_ϕ carries the physical units of the predicate margin.

A sound safety warrant requires a discrepancy bound that holds across all trajectories in the claimed operational envelope, not just the largest error observed in a small test sample. That modeling error must be deducted directly from the simulated robustness margin. Consider a Signal Temporal Logic safety requirement ϕ whose atomic predicates $f(s(t)) \geq 0$ are Lipschitz continuous with constant $L_\phi = \sup_{s_1\neq s_2} |f(s_1) - f(s_2)|/\|s_1 - s_2\|_W$. Here L_ϕ is the maximum rate at which

the predicate margin degrades per unit of normalized state discrepancy. For a spatial clearance predicate evaluated in meters against position error normalized by a 1 m reference scale with unit task weight, L_ϕ is 1 m per unit of normalized discrepancy. By Lipschitz continuity, the physical predicate error is bounded pointwise by the state discrepancy:

$$|f(s_{\text{real}}(t)) - f(s_{\text{sim}}(t))| \leq L_\phi \|s_{\text{real}}(t) - s_{\text{sim}}(t)\|_W \leq L_\phi \epsilon_{\text{gap}}$$

which guarantees that at every instant $t \in [0, T]$:

$$f(s_{\text{real}}(t)) \geq f(s_{\text{sim}}(t)) - L_\phi \epsilon_{\text{gap}}.$$

Taking the infimum across the temporal horizon $t \in [0, T]$ for an invariance property $\phi \equiv \square_{[0,T]}(f(s(t)) \geq 0)$, the guaranteed lower bound on physical robustness in the real world is:

$$\rho_{\text{real}} \geq \rho_{\text{sim}} - L_\phi \epsilon_{\text{gap}}. \tag{15.6}$$

The term $L_\phi \epsilon_{\text{gap}}$ in equation 15.6 acts as a **sim-to-real robustness discount**. If simulated robustness ρ_{sim} does not exceed $L_\phi \epsilon_{\text{gap}}$, the simulation pass guarantees no physical margin at all: the real machine can breach the safe invariant set ($\rho_{\text{real}} < 0$) even when every simulated rollout returns a positive margin.

The rack-end claim makes this discount concrete. Scoring the distance predicate in meters and normalizing position error by a 1 m reference scale with unit task weight gives a Lipschitz constant of 1 m per unit of normalized discrepancy. Suppose a simulated stop finishes with the entire 131.0 mm reserve intact. The lower bound in equation 15.6 certifies a positive physical margin when $\epsilon_{\text{gap}} < 0.131$, meaning the justified position-error bound is smaller than the reserve under this normalization. A larger discrepancy bound leaves the actual physical margin unresolved. A simulator whose stopping position is experimentally validated to within a few centimeters transfers nearly all of its verified margin; a simulator that has never been calibrated against physical stopping runs transfers none of it.

Coupled cyber-physical dynamics determine what this discount must cover: drivetrain compliance and gear backlash alter delivered torque, surface contamination and tire wear change braking traction, and real-time execution jitter shifts braking onset time. A discrepancy bound calibrated on an unloaded, cool machine cannot be silently extended to a loaded vehicle operating under thermal throttling. The verification record must state the operational envelope across which the discrepancy bound holds, keeping that justified bound distinct from the empirical maximum error observed during paired test runs.

Measuring the empirical discrepancy $\hat{\epsilon}_{\text{gap}}$ builds on the paired probing protocols used to qualify simulation models for policy training. These protocols drive identical command histories into both simulated and physical hardware and score channel residuals against precommitted tolerances (section 6.4.2). They are the same measurements that bound a simulator's screening validity in section 7.4.2. Verification adapts this qualification procedure in two ways. First, excitation inputs are tailored to the specific safety invariant under test, such as full-rate deceleration from aisle speed for the rack-end claim rather than low-speed docking maneuvers. Second, physical trajectories must be captured with external instrumentation independent of the robot's onboard sensor suite, so that shared sensor calibration errors or estimator drift cannot cancel out of the residual. The resulting empirical discrepancy $\hat{\epsilon}_{\text{gap}}$ is archived in the test records alongside the environmental conditions under which it was gathered. If the sim-to-real safety case relies on domain randomization distributions $\mathcal{D}_{\text{DR}}$ to cover hardware variations, it must justify set inclusion across all declared operational conditions:

$$\mathcal{S}_{\text{real}}(\xi) \subseteq \bigcup_{\tilde{\xi} \sim \mathcal{D}_{\text{DR}}} \mathcal{S}_{\text{sim}}(\tilde{\xi}).$$

Finite paired measurements can falsify this inclusion by exposing an outlier, but they cannot prove it globally. If unmodeled physical effects such as fieldbus latency jitter, magnetic stator saturation, transmission backlash, or Coulomb stiction cause physical trajectories to escape the randomized simulation bundle, the sim-to-real transfer guarantee fails, and software-in-the-loop simulation passes cannot serve as evidence in the release safety case.

Checkpoint 15.3: Search, robustness, and transfer

A signed margin turns testing into search, and a simulated margin counts toward a physical claim only after its transfer discount.

- ☐ **Quantitative robustness interpretation**: Can you explain how Signal Temporal Logic replaces binary pass/fail assertions with a signed predicate margin, and how its units and reference limit determine the meaning of a negative score?
- ☐ **Adversarial optimization of disturbance trajectories**: Can you describe how black-box optimizers use quantitative robustness scores to discover worst-case combinations of latency, noise, and friction?
- ☐ **Test invalidation vs. failure criteria**: Can you distinguish between an execution that falsifies a safety invariant and an invalid trial where testbed preconditions or fault injection mechanisms failed?
- ☐ **Normalization scale estimate**: For the late F1 trace of section 15.9.1, suppose the record had fixed the distance scale at the 40 mm tracking inset while keeping the 82 ms onset scale. Can you estimate both normalized margins and say whether the governing predicate changes for this trace?
- ☐ **Transfer discount**: A simulated F1 stop keeps 131.0 mm of reserve. Can you state the largest discrepancy bound that still guarantees a positive physical margin, and explain why a bound measured on an unloaded, cool machine cannot certify a loaded, throttled one?

15.10 Interpreting Campaign Statistics

Counting passed trials in an adversarial campaign can easily mislead a release review into treating a test-bench success rate as an operational reliability number. Any statistical summary describes only the specific population sampled by the test harness, and conditions that were never tested remain missing evidence no matter how sophisticated the statistical model applied afterward.

When n independent Bernoulli trials sampled from a declared fault distribution yield zero missed mitigations, the outcome puts a one-sided upper confidence limit on the miss probability for that specific distribution. This is the zero-failure trial sizing of section 7.7.1, applied here to an injected hardware fault population rather than closed-loop policy rollouts; at a 95 percent confidence level, it requires about $3/p_{\text{fail}}$ consecutive successful injections to bound the miss probability below p_{fail}. To turn these injection counts into a hardware coverage claim weighted by each component's failure rate in FIT (failures in time, one per 10^9 operating hours; notebook 15.3 gives the component weights λ_i), the injection harness must sample faults in direct proportion to their raw failure rates λ_i. Otherwise, the verification pipeline must apply an explicitly justified stratified weighting across each fault stratum.[11]

This statistical bound holds only when the physical trials satisfy the declared independence and sampling assumptions. On real hardware, repeated high-energy stops produce Joule heating (I^2R) in the drive motor windings and mechanical brake linings. That heat buildup changes winding resistance and lining friction coefficients, coupling successive trials. As a result, a test campaign run on a dry aisle at room temperature cannot support a confidence bound for a contaminated floor or for the operating envelope's 5 °C thermal extreme.

Notebook 15.3 draws its rates from four component strata (sensors, compute, transceivers and power management, gate drivers), and each stratum maps onto rows of table 15.2. Sensor faults are injected as F2 and as the physical transducer disturbances, compute faults as F1, transceiver and power-management faults as F3 and F4, and gate-driver faults as the drive that keeps producing torque after a stop command (section 15.6.2). Sampling in proportion to those rates therefore fixes how the campaign's trials divide among the rows.

[11] **Trial sampling and aging**: The binomial count assumes independent, identically distributed Bernoulli outcomes under the declared injection distribution; it does not require Poisson event arrivals. Repeated heating, mechanical wear, or contact changes can break independence and require a state-stratified experimental design.

Napkin Math 15.3: The coverage count

Problem: Illustrative component fault rates and a chosen ceiling on the unmitigated rate fix the diagnostic coverage the machine needs. How many zero-miss injections, sampled in proportion to those rates, would demonstrate that coverage?

Variables:

- Component fault rates λ_i in FIT, one fault per 10^9 operating hours (Illustrative): sensors 1,500, compute 1,000, transceivers and power management 2,500, and gate drivers 4,800.
- Target unmitigated rate $\lambda_{\text{target}} = 100$ FIT, with a stricter 10 FIT alternative, at confidence $C = 95$ percent (Chosen).
- Diagnostic coverage C_{diag}, the λ_i-weighted fraction of faults whose hazardous effect is mitigated, so that $\lambda_{\text{unmitigated}} = \lambda_{\text{raw}}(1 - C_{\text{diag}})$ and a single injection misses with probability $p_{\text{fail}} = 1 - C_{\text{diag}}$.

Math:

Required coverage.

$$\lambda_{\text{raw}} = 1500 + 1000 + 2500 + 4800 = 9800 \text{ FIT}, \qquad C_{\text{diag}} \geq 1 - \frac{\lambda_{\text{target}}}{\lambda_{\text{raw}}} = 1 - \frac{100}{9800} = 0.9898$$

Injections to demonstrate it, from the zero-failure count of section 7.7.1.

$$n \geq \frac{\ln(1-C)}{\ln C_{\text{diag}}} = \frac{\ln 0.05}{\ln 0.9898} = 292.1 \;\Rightarrow\; n = 293, \qquad \frac{3}{p} = \frac{3\lambda_{\text{raw}}}{\lambda_{\text{target}}} = \frac{3 \times 9800}{100} = 294$$

Sensitivity. The count scales as $3\lambda_{\text{raw}}/\lambda_{\text{target}}$, so the 10 FIT target needs 99.90 percent coverage and 2,935 injections, against a rule-of-three estimate of 2,940.

Result: A 100 FIT target needs 98.98 percent coverage, which 293 zero-miss injections demonstrate at 95 percent confidence.

Systems insight: The target unmitigated failure rate, not the number of entries in the fault list, governs campaign size. Every tenfold tightening of the target rate demands roughly a tenfold increase in physical injection runs. Furthermore, this sample size holds only when injections are drawn in proportion to each component's raw failure rate λ_i. Injecting uniformly across components with disparate failure rates tests a distorted distribution unless the harness weights the empirical outcomes and gathers enough trials within every stratum. Every trial must therefore log the exact injected mode, whether hardware detection triggered within the deadline, and whether the safety controller brought the plant to a verified safe state.

Even within the declared fault strata, a campaign rarely reaches every combination of load, floor friction, and temperature. The fault-record set must therefore catalog omitted test cases as carefully as completed runs, recording every parameter region skipped because of testbed physical limits, sensor bandwidth limits, or destructive testing costs. Unprobed regions cannot count as verified safety margins in the release case, nor can passive operational hours accumulated outside the test cell fill those gaps.

15.10.1 Exposure and the population a statistic describes

Logging thousands of incident-free fleet hours in normal warehouse aisles cannot bound rare safety-critical faults or substitute for targeted fault injection, because passive operation samples a different distribution from deliberate fault trials. Fleet exposure runs into the exposure wall of equation 7.9: bounding a hazard rate λ_{target} at 95 percent confidence requires about $3/\lambda_{\text{target}}$ failure-free operating hours, which Butler and Finelli (1993) showed is unreachable at safety-critical rates such as 10^{-9} failures per hour. Pooling those hours across a fleet adds exposure time but not environmental diversity, so the bound covers only the conditions the pooled machines share (section 7.9), and normal fleet traffic rarely triggers the corner-case hardware faults this chapter injects. Verification

also has to ask which configuration those hours describe. Any change to a safety filter, control policy, or actuator driver can alter the sampled outcomes, so earlier fleet hours count toward the updated configuration only when an explicit engineering argument shows that the change left the counted events unaffected. When a rare failure rate must be estimated across a high-dimensional disturbance space without waiting for billions of passive rollouts, the campaign must steer samples toward the failure region and weight them back to the operational distribution.

15.10.2 Estimating a rare failure rate by importance sampling

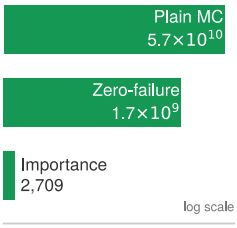
Naive Monte Carlo sampling from nominal operating conditions cannot estimate rare safety-critical failure rates because nearly every rollout ends in an unremarkable, safe stop, requiring billions of runs to observe even a handful of violations (section 15.10.1). While adversarial falsification finds whether an unsafe trajectory exists, release decisions also need to know how often such failures occur under nominal operating conditions. **Importance sampling**[12] breaks this bottleneck by drawing rollouts from an alternative proposal distribution that concentrates samples near the failure boundary and then weighting each sample by its likelihood ratio to recover an unbiased estimate under the operational distribution.

Let the operational distribution of uncertain input parameters x be denoted by $p(x)$, and let F define the subset of conditions leading to a safety violation. Standard Monte Carlo estimation evaluates the failure probability $p_F = \Pr_p(x \in F)$ by computing the empirical failure fraction across N independent draws from p. Importance sampling instead draws samples from an engineered **proposal distribution** $q(x)$ and weights each outcome by the **likelihood ratio** $w(x) = p(x)/q(x)$:

$$\hat{p}_F = \frac{1}{N} \sum_{i=1}^{N} \mathbb{1}[x_i \in F]\, w(x_i), \qquad x_i \sim q. \tag{15.7}$$

This estimator remains mathematically unbiased as long as $q(x) > 0$ whenever $p(x)\mathbb{1}[x \in F] > 0$, since the likelihood weight corrects for the shift in sampling probability (Owen 2013). The variance of $\hat{p}_F$ depends entirely on the geometry of q. The theoretically optimal zero-variance proposal is the operational distribution p conditioned on the failure region F ($q^*(x) = p(x)\mathbb{1}[x \in F]/p_F$). Constructing q^* directly is impossible because its normalizing constant is the very quantity p_F under estimation. Practical verification pipelines must therefore construct parametric approximations to q^*.

The **cross-entropy method** (Rubinstein and Kroese 2004) systematically discovers such an approximation within a parameterized distribution family q_ψ by solving a sequence of intermediate rare-event problems. Beginning with an initial proposal aligned with the operational profile ($q_{\psi_0} = p$), the algorithm iteratively draws a sample batch from the current proposal and evaluates the performance metric. It then selects an intermediate threshold at the $(1-\beta)$ quantile so that a fraction β of the batch qualifies as elite runs. The parameter vector ψ is then updated by maximizing the likelihood-weighted log-density of these elite samples, which minimizes the Kullback-Leibler divergence (a measure of how far one probability distribution lies from another) to the optimal proposal on that intermediate slice. As the threshold steps forward across iterations, the proposal gradually shifts its probability mass toward the true failure boundary. For an exponential proposal parameterized by its mean, or a fixed-variance Gaussian proposal parameterized by its mean, this update admits an exact closed form: the updated mean is the weighted empirical mean of the elite draws.



Consider this method applied to the rack-end deceleration scenario. Traveling at nominal aisle velocity, the mobile base consumes its 131.0 mm stopping reserve from section 15.2 in $T_{\text{deadline,fallback}} =$ 100.8 ms, the latest-fallback deadline of equation 14.4 at aisle speed. Any unbudgeted message queue delay exceeding $T_{\text{deadline,fallback}}$ exhausts this safety buffer, causing the physical vehicle to breach the clearance boundary. To establish an analytical baseline, assume an illustrative operational distribution where queue delays T_q follow an exponential distribution with mean $\bar{T}_q = 5$ ms (in production verification, latency measurements gathered under the declared load must justify or replace this model). Under this formulation, the analytical failure probability is $p_F = e^{-T_{\text{deadline,fallback}}/\bar{T}_q} = 1.8 \times 10^{-9}$ per stopping event. This closed-form quantity serves as an exact ground truth against which to benchmark competing sampling estimators. The threshold is deliberately the uncharged ceiling

[12] **Importance Sampling**: The technique originated in Monte Carlo calculations of nuclear radiation shielding in the early 1950s, where the few particles that penetrated dense shielding were exceptionally rare yet critical to safety. Kahn and Marshall (1953) formalized importance sampling alongside correlated sampling and statistical estimation to cut required sample counts. The method carries a sharp failure mode of its own: a proposal distribution that omits a valid failure path reports tiny sample variance and an erroneously low failure probability, a support failure that diagnostic checks must catch.

of section 15.2, which makes the example optimistic. Charging the dispatch-to-admission allocation leaves only 37.5 ms, and the same delay model then gives $p_F = 5.6 \times 10^{-4}$, about 3×10^5 times larger. The comparison below keeps the uncharged threshold because there the failure is rarest and the gap between estimators widest; at the charged threshold even plain Monte Carlo would need far fewer runs.

The sample sizing required across these estimators stems directly from the variance of sample averages. When an estimator averages N independent draws with mean p_F and per-sample variance σ^2, the estimator's standard deviation is $\sigma/\sqrt{N}$, yielding a relative standard error $r = \sqrt{\sigma^2/(p_F^2 N)}$. Achieving a target relative precision r requires $N = (\sigma^2/p_F^2)/r^2$ trials, where σ^2/p_F^2 denotes the per-draw **relative variance**. For naive Monte Carlo, each trial is an indicator variable with variance $p_F(1-p_F)$, demanding approximately $(1-p_F)/(p_F r^2)$ simulated runs. Under the illustrative delay model, securing an estimate with $r = 10$ percent relative error requires 5.7×10^{10} trials. By comparison, a zero-failure qualification campaign requires 1.7×10^9 consecutive incident-free runs to establish an upper bound at the p_F threshold (equation 7.4). Under importance sampling for this exponential model, the per-draw variance equals the weighted failure indicator's second moment minus p_F^2, which stays finite as long as the proposal rate is less than twice the operational rate.

The cross-entropy method using exponential proposals with an elite fraction of $\beta = 10$ percent demonstrates how adaptive sampling overcomes this barrier. The initial threshold is set at the 90th percentile of the operational delay distribution ($\bar{T}_q \ln 10$, or 11.5 ms). Because the exponential distribution is memoryless, the conditional distribution of delays exceeding any threshold γ is identical to the original distribution shifted by γ. The likelihood-weighted mean of the elite samples is therefore simply $\gamma + \bar{T}_q$, which immediately defines the mean for the next proposal. Because the parametric proposal family consists of unshifted exponential distributions supported on the positive real line rather than truncated distributions starting at γ, matching this conditional mean stretches the exponential scale across the entire positive axis rather than shifting the lower support boundary. Successive iterations lift the intermediate threshold to 38.0 ms and 99.1 ms. By iteration 4, the intermediate quantile surpasses the critical threshold, clamping the final level at $T_{\text{deadline,fallback}}$ with a proposal mean of 105.8 ms, the conditional expectation of the delay given a boundary violation. Under this adapted proposal, 38.6 percent of the generated rollouts land in the failure set, and their small likelihood weights scale each observed failure back to the operational probability. The resulting per-draw relative variance drops to 27.1. Consequently, only 2,709 simulation runs are needed to reach the target 10 percent relative error, a factor of 2×10^7 fewer runs than plain Monte Carlo and within 0.1 percent of the best exponential proposal. These numerical counts derive from the assumed exponential model; testing against an empirical delay histogram will yield distinct run requirements.

Weighting runs near failure cuts the runs by about 2×10^7 times.

Two statistical diagnostics safeguard the integrity of importance sampling estimates. The first is the **effective sample size**, defined as $N_{\text{eff}} = \left(\sum_{i=1}^{N} w_i\right)^2 / \sum_{i=1}^{N} w_i^2$ (Owen 2013). This metric diagnoses concentration of the likelihood weights; it does not by itself establish the precision of the weighted failure estimate, which depends on the variance of the weighted failure indicator. For the 2,709 runs above, the expected effective sample size is approximately 250; a degenerate value approaching 1 would warn that a few outlying weights dominate the summation, rendering the estimate unstable. The second diagnostic is distribution support and tail coverage. Omitting a subregion of F with positive operational probability violates the support condition and biases the estimate. A proposal that retains support but samples the operational tail too rarely can instead produce unstable or infinite variance, with deceptively small observed variance in a finite run. Sample variance cannot reveal an omitted failure path that generates no samples, so the campaign must justify coverage independently of its weight diagnostics. O'Kelly et al. (2018) applied adaptive importance sampling to end-to-end verification of autonomous driving software stacks and obtained speedups of several orders of magnitude over naive Monte Carlo in estimating rare collision rates.

This structure separates importance sampling from adversarial falsification. Although an adversarial search engine also concentrates runs near the system's safety boundaries, its sampling density is unknown. Because falsification runs lack likelihood-ratio weights, the fraction of falsification runs that fail says nothing about real-world failure frequency; in the illustrative example, 38.6 percent of the proposal runs fail even though the modeled operational failure probability is only 1.8×10^{-9}. A quantitative failure-probability estimate belongs in a safety case only when paired with its declared

operational model p, proposal distribution q, weight history, effective sample size, and confidence intervals. It remains a statement about that declared operating model rather than a direct physical measurement of the deployed hardware. Estimating how often a boundary is crossed still leaves a second question open: when a near-miss or excursion occurs, how far can the worst-case physical overshoot reach?

15.10.3 Extreme value theory and heavy-tailed safety distributions

Binary pass-fail tallies throw away the margin history of near-miss stops, while fitting a Gaussian curve to nominal bus traffic or stopping-distance data underestimates the heavy tails caused by sporadic bus arbitration contention or contact slips. Deployment qualification often has to bound the physical magnitude of worst-case excursions across continuous telemetry streams: spatial clearance $D_{\text{clear}} - d(t)$, onset slack $t_{\text{bound}} - t_{\text{onset}}$, and actuator torque headroom $\tau_{\max} - \tau_{\text{act}}$. Extreme value theory (EVT) provides limiting distributions for these tail excursions, playing a role for extreme deviations similar to that of the central limit theorem for sample means (Coles 2001). Even so, engineers must check that the data belong to the assumed tail regime rather than treating a fitted mathematical endpoint as a physical barrier. While the block-maxima formulation (which yields the Generalized Extreme Value distribution) is developed in section A.10, cyber-physical verification primarily uses the threshold-exceedance formulation, which keeps every observation that crosses a high safety threshold rather than discarding all but the block maximum.

1. **Peaks over threshold and the Generalized Pareto Distribution**: Let X denote a continuous performance metric (such as stopping-distance error), and let u represent a high baseline threshold. We model the exceedances $Y = X - u$ conditional on $X > u$. For distributions in an appropriate extreme-value domain of attraction, the Pickands-Balkema-de Haan theorem gives an asymptotic Generalized Pareto approximation to the conditional excess distribution as u approaches the upper endpoint. Balkema and Haan (1974) and Pickands (1975) proved this result independently:

$$F_{\text{GPD}}(y; \tilde{\sigma}, \xi) = 1 - \left(1 + \frac{\xi y}{\tilde{\sigma}}\right)^{-1/\xi}, \quad y > 0, \tag{15.8}$$

   defined for scale parameter $\tilde{\sigma} > 0$ on the support $1 + \xi y/\tilde{\sigma} > 0$, with the exponential distribution recovered as the continuous limit $\xi \to 0$. The **shape parameter** ξ governs tail thickness: $\xi > 0$ indicates a heavy, power-law tail; $\xi = 0$ corresponds to an exponential tail; and $\xi < 0$ defines a bounded tail with finite endpoint $u - \tilde{\sigma}/\xi$.

2. **Return level**: For a chosen return period[13] T calibrated to the sampling interval, the **return level** z_T is the threshold exceeded on average once every T periods:

$$z_T = u + \frac{\tilde{\sigma}}{\xi}\left[(T\zeta_u)^{\xi} - 1\right] \tag{15.9}$$

   where $\zeta_u = \Pr(X > u) = N_u / N_{\text{total}}$ is the empirical exceedance rate across N_{total} trials, with T expressed in equivalent trial counts. This expression follows from multiplying the conditional Generalized Pareto survival probability $(1 + \xi(z_T - u)/\tilde{\sigma})^{-1/\xi}$ by the threshold exceedance probability ζ_u and setting the resulting unconditional tail probability equal to $1/T$. In this subsection T is therefore a count of trials, not the test horizon of equation 15.4. Equation 15.9 holds for $\xi \neq 0$; its continuous limit at $\xi = 0$ is $z_T = u + \tilde{\sigma}\ln(T\zeta_u)$. Expressing a return period in calendar operating hours requires scaling by an independently justified hourly event arrival rate under a verified temporal dependence model. The product $T\zeta_u$ is dimensionless, and valid extrapolations must evaluate return levels at or above the conditioning threshold u.

[13] **Return Period**: The term comes from civil hydrology, where a "hundred-year flood" means a discharge level with a 0.01 probability of being exceeded in any single year (Gumbel 1958). The hydrological caveat applies directly to robotics: because return levels extrapolate beyond observed records, they hold only when the threshold choice and sampling distribution are physically justified. Counting return periods across synthetic fault-injection runs gives no operational safety assurance until the hourly arrival rate in service is established.

15.10.3.1 Connecting adversarial falsification to EVT tail sampling

Under nominal operation, exceedances past a conservative margin threshold occur far too rarely to fit an empirical tail; the exposure wall of section 15.10.1 starves extreme-value fits just as severely as binary failure counts. Adversarial falsification gets around this scarcity by concentrating rollouts near violation boundaries, solving the search problem of equation 15.4 over initial plant states and disturbance parameters. Let d_{budget} denote the design budget at the trial speed, 969.0 mm at aisle

speed, so that $D_{\text{clear}} - d_{\text{budget}}$ is the 131.0 mm spare. For the braking-distance overshoot metric $X = d_{\text{stop}} - d_{\text{budget}}$, the search populates the exceedance set

$$\mathcal{Y}_u = \{Y_i = X_i - u \mid X_i > u\}$$

with dense observations near the failure frontier. Those samples, however, reflect the adversary's search policy rather than the operational environment. Fitting a Generalized Pareto Distribution directly to unweighted falsification runs models the optimizer's search behavior, not the reliability of the physical plant. To inform operational risk, the runs must come from a declared proposal distribution and carry the likelihood-ratio weights of equation 15.7, so that both the exceedance probability ζ_u and the fitted parameters reflect weighted operational likelihoods.

A fitted shape parameter serves as an engineering diagnostic rather than a standalone safety verdict:

- **Positive shape ($\xi > 0$):** The fitted model extrapolates a heavy upper tail, warning of sensitivity to extreme deviations. This fit does not prove that physical overshoots are truly unbounded, but it requires the engineering team to check whether threshold choice, sensor noise, or unmodeled delays drive the heavy-tailed behavior.
- **Negative shape ($\xi < 0$):** The fitted distribution implies a finite modeled upper endpoint at $u - \tilde{\sigma}/\xi$. That mathematical endpoint must never be mistaken for a certified hardware stop or taken as proof that a runtime safety filter will always contain motion. Verifying real-world containment requires auditing the filter's dynamical assumptions and measuring its hardware response latencies under adversarial load.

15.10.3.2 Sim-to-real transfer bounds on EVT return levels

When high-throughput campaigns run on the software-in-the-loop and processor-in-the-loop (PIL) rungs of the qualification ladder, extreme value modeling produces a simulated return level $z_{T,\text{sim}}$. As shown in section 15.9.4, physical trajectories can diverge from simulated trajectories by up to the sim-to-real discrepancy bound $\epsilon_{\text{gap}} = \sup_t \|s_{\text{real}}(t) - s_{\text{sim}}(t)\|_W$. When simulated and physical trials describe the same operational population and the overshoot metric obeys the pathwise discrepancy bound with constant L_ϕ, that bound also limits the physical return level (equation 15.10):

$$z_{T,\text{real}} \leq z_{T,\text{sim}} + L_\phi \epsilon_{\text{gap}}. \tag{15.10}$$

To support a stopping-distance claim, this widened return level must fit inside the available physical reserve:

$$z_{T,\text{sim}} + L_\phi \epsilon_{\text{gap}} \leq D_{\text{clear}} - d_{\text{budget}}. \tag{15.11}$$

The margin inequality in equation 15.11 is a necessary sanity check rather than a sufficient release rule. Using it requires distributional consistency between simulation and physical testbeds, proper importance weighting when quoting operational return periods, confidence intervals on the fitted parameters, and a transfer bound ϵ_{gap} justified across the entire operating domain. A small trajectory discrepancy across a handful of bench tests does not establish an envelope-wide sim-to-real bound.

In the rack-end deceleration scenario, the physical safety margin is 131.0 mm, and only 48.7 mm once the dispatch-to-admission allocation is charged, so a return level of a few centimeters, widened by a transfer bound of a few centimeters more, already consumes it. Any proposed tail bound must state its sample population, proposal weights, parameter uncertainties, and transfer error bounds before being compared against this reserve. When a fault mode (such as mode F1) has zero measured physical trials, it supports neither an empirical tail fit nor a return-level estimate; a fitted mathematical endpoint cannot stand in for missing physical test evidence.

Every statistical metric in this section is conditional. A zero-miss count describes only the declared fault injection distribution. An exposure bound reflects only the exact hardware and software configuration that accumulated those hours. An importance-sampling estimate holds only under its declared operational model. An extreme value return level holds only relative to its fitted tail and sim-to-real discrepancy bound. Because any of these premises can fail, a verification campaign never hands release an isolated scalar margin; instead, it packages fault records that bind each empirical margin to the physical, environmental, and statistical conditions that support it.

15.11 Fault Records for Release

A raw telemetry trace sitting on a testbench digitizer cannot certify an autonomous machine for release if nothing proves which safety claim, envelope corner, or software and hardware build produced it. In an adversarial campaign, a completed F1 trial records the full event chain across independent physical channels: the final proposal renewal, the watchdog lease expiration, the active braking response, and the final mechanical stop. The release authority can credit that trial only when the measured trace is verifiably bound to the safety claim, the tested envelope point, and the exact software and hardware builds under evaluation. The fault record establishes this link by binding the structured test header to the retained evidence bundle through a cryptographic digest.

The release authority receives these claim-specific **fault records** together with the coverage records needed to judge their physical scope. Combined, they form an auditable **fault-record set** that joins the individual fault records, qualification environments, justified sim-to-real transfer bounds, statistical tail estimates, and known coverage gaps. Rather than silently omitting unmeasured or inapplicable fields, the schema marks them explicitly so that untested operating regimes cannot pass for verified boundaries. This fault-record set feeds directly into the operational safety case for release, though its schema and cryptographic signatures carry no authority beyond the physical evidence recorded inside them.

Along with design contracts, the motion-authority cases A1–A4, and the placement allocations established during system staging, the fault records draw on two upstream records: the omission log of the policy manifest (section 6.8) and the coverage-gap catalog of the evaluation record (section 7.8). Those upstream records list the operating conditions, sensor degradation modes, and environmental disturbances that the learned policy proposer never saw during training. By pairing the record header with its evidence bundle, each fault record preserves the full provenance of the trial: the asserted claim, physical operating point, fault injection mechanism, hardware and software revisions, raw high-speed telemetry, detection mechanisms, response latencies, physical stopping outcomes, and any secondary anomalies observed during the run.

15.11.1 The fault-record set specification

A pile of individual pass verdicts leaves a release review unable to tell which top-level safety claims have been substantiated across the envelope and which operating conditions remain untested. Every record in the fault-record set therefore exists to support one named assurance claim C within the release safety case, and its header names that claim explicitly. In the safety case structure developed in section 16.3.1, the top-level assurance claim C_0 states a core physical invariant, such as halting within the clearance corridor ($d_{\text{stop}} \leq D_{\text{clear}}$), and splits into sub-claims C_i covering specific operating envelopes, hardware fault classes, and fallback behaviors. The F1, F2, and F3 records support that stopping bound across communication and timing faults, showing that the safety permission path halts the loaded mobile base within its travel bound once proposal renewals cease (F1), when sensor observations arrive stale (F2), or when fieldbus frames drop in transit (F3). Where F1–F3 test information and timing loss, the F4 and actuator-jam records test electrical and mechanical survival. F4 shows that the held-up auxiliary power rail keeps the permission path alive through a primary supply collapse long enough to complete an emergency stop and set all mechanical holding brakes. The actuator-jam records show that the chassis stays within its lateral clearance corridor during a wheel-lock fault without driving the stator windings into thermal runaway. At the control boundary, the A1–A4 records support the claims that motion authority keeps a single writer, blocks control bypass, runs a deterministic fallback when supervisory handovers stall, and rejects forged command tokens. Alongside them, the proposer-injection records show whether tested adversarial proposals were caught by the runtime permission checks. Extending that result to every possible proposal still requires an architectural or formal argument that no source can bypass the permission path.

A physical trace supports an assurance claim C only through a structured engineering argument. In a rack-end deceleration claim, for instance, a raw brake-onset trace supplies empirical evidence, but the accompanying argument must explain why the digitizer clock synchronization, fault-injection timing, payload distribution, and floor traction conditions test the claimed physical response. Gathering evidence across the qualification ladder (formal reachability bounds for the permission filter, bounded sim-to-real falsification campaigns, and hardware fault-injection trials on the rig) lets each assurance claim C rest on complementary legs of evidence rather than a single

isolated trial. How claims, arguments, and evidence fit together into an auditable assurance case, and the notation used to write that hierarchy down, are developed in section 16.3.1.

The fault records also separate three failure domains, because each asks a different engineering question about the same physical machine, even when a compound fault spans more than one domain:

- *Functional safety*: hardware and software component faults inside the safety-related control system, such as encoder failures, dropped fieldbus frames, or auxiliary power brownouts.
- *Safety of the intended functionality* (SOTIF): hazards that arise without hardware faults from algorithmic blind spots or sensor limits, such as perceptual occlusions, out-of-distribution optical flare, or corner-case proposer errors.
- *Security*: deliberate adversarial tampering with physical sensors, communication buses, or cryptographic tokens.

The consensus engineering standards covering each subsystem of the machine, along with their publication editions, are mapped in section 16.3.4. Passing an adversarial fault-injection campaign does not by itself establish regulatory compliance or justify operation in unmodeled environments; instead, the release argument weighs exactly which claims the assembled records substantiate and where residual operational risks remain. To support that review, the individual fault records, the per-rung coverage of the qualification ladder, the empirical sim-to-real discrepancy bounds, and the extreme value theory (EVT) tail parameters assemble into one cryptographically signed set. This fault-record set is the thirteenth record in the record chain, after the authority record and before the release manifest, and it carries verification evidence to the release gate.

↪ The record chain, numbered from the limit record to the residual-claims register, is developed in section C.14.2.

The signed fault-record set defines the evidentiary handoff between adversarial testing and operational release, with its full data schema specified in table 15.5:

1. **Upstream Custody Lineage**:
   - Consumes the **authority record** (section 14.8) to check handover deadline timers (T_{timeout}, section 14.2.4), duplicate-writer rejections (A1), and supervisory token integrity.
   - Consumes the **placement record** (section 13.8) to check bus contention limits, power-rail droop tolerances, and thermal dissipation thresholds.
   - Consumes the **enforcement record** and its admitted commands (section 12.11) to check control barrier function (CBF) invariant sets, quadratic program (QP) filter execution deadlines, and fallback ladder transitions.
   - Consumes the **evaluation record** (section 7.8) to cross-check offline covariate drift and simulation test catalogs against physical target-hardware runs.
2. **Downstream Release Deliverables**:
   - Delivers to the **release manifest** and its safety case (section 16.3) the empirical, claim-specific evidence and operational bounds needed by the release argument.
   - Delivers to the **residual-claims register** (section 18.3.3) the explicit list of unverified operating regimes, test-fixture bandwidth limits, and coverage gaps.

Table 15.5: Fault-record set for release: The schema of the signed fault-record set in which each fault record reaches release, defining the multi-dimensional empirical evidence required to support operational release.

Contract Field	Type / Encoding	Physical Semantic & Evidentiary Scope	Upstream Anchor / Derivation
`set_id`	`UUIDv5`	Stable namespace-and-name identifier for the campaign; not a digest of its completed results	Fixed at test orchestration initialization

DRAFT

Contract Field	Type / Encoding	Physical Semantic & Evidentiary Scope	Upstream Anchor / Derivation
`set_digest`	`SHA-256`	Digest of the canonical completed set payload, excluding digest and signature fields, binding build identity, calibration identities, and evidence references	Computed after results are finalized; covered by the signed release record
`rung_coverage`	`Struct<RungCoverage>`	Executed run counts, throughputs, and fidelity mappings partitioned across the software-in-the-loop (SIL), processor-in-the-loop (PIL), hardware-in-the-loop (HIL), and physical-rig rungs	Four-stage qualification ladder (section 15.7.1, table 15.3)
`fault_injection_records`	`List<FaultRecordHeader>`	Collection of cryptographically signed fault records across F1–F4, A1–A4, and compound cascades, partitioned into `PASS`, `FAIL`, `INVALID`, and `UNOBSERVABLE` verdicts	Fault classification (table 15.2) and static fault record (table 15.1)
`sim_to_real_bounds`	`Struct<DiscrepancyBounds>`	Empirical discrepancy $\hat{\epsilon}_{\text{gap}}$, any justified envelope-wide bound ϵ_{gap} with its derivation and conditions, and the associated STL robustness discount; an observed maximum alone is not an envelope-wide bound	Sim-to-real transfer validation (section 15.9.4, equation 15.5)
`evt_tail_metrics`	`Struct<TailEstimate>`	Per estimate: declared operational distribution p, proposal distribution q, likelihood-ratio weights with effective sample size (or a flag that samples are unweighted and describe only the search), threshold u, fitted generalized Pareto distribution (GPD) parameters with confidence intervals, and return levels at a declared return period; empty where no weighted sample exists	Importance sampling and EVT (section 15.10.2, equation 15.7, equation 15.8, equation 15.9)
`coverage_deficits`	`List<DeficitEntry>`	Explicit register of omitted parameter combinations, fixture bandwidth limitations, and unverified boundary regions, defining the epistemic ceiling for release	Derived from design record inversions and bench limitations; delivered to section 16.3 and section 18.3.3
`cryptographic_signatures`	`Ed25519Signature[]`	Multi-party cryptographic signatures from test orchestration DAQ, testbed safety engineer, and lead systems architect	Hardware security module (HSM) on isolated digitizer

Capturing these eight fields in a signed record set prevents post-hoc threshold tuning and silent omission of failed or unobservable trials. Even a complete, cryptographically signed fault-record set, however, can be undermined if hidden electrical, bus, or clock couplings on the test bench corrupt the trials or blind the witnesses that score them. Four recurring pitfalls illustrate how shared

resources across watchdogs, fieldbuses, power rails, and loggers can subvert a verification campaign before a single record reaches release.

15.12 Fallacies and Pitfalls

A physical machine can pass every isolated component fault test yet catastrophically fail in deployment when a shared power rail, communication bus, or reference clock couples multiple subsystems or blinds their diagnostic monitors. These failures stem from **unintended causal, electrical, and temporal coupling** across architectural boundaries. Compound verification tests catch such cross-domain hazards only when enough galvanically and logically independent instrumentation survives the fault to establish the ground-truth sequence of events.

Fallacy: *Independent local watchdog timers guarantee end-to-end physical deadline compliance.*

A perception front-end, the chunk policy, and the safety permission monitor can each execute comfortably within their local scheduling slices while an unmonitored inter-process queue buffers stale observations between them. Local watchdog timers confirm only that isolated tasks kick their respective heartbeats within software deadlines; they reveal nothing about the total age of the physical state traversing the distributed pipeline.

Consider an asynchronous buffer that inserts delay into the machine's 133.6 ms pre-deceleration budget. The importance-sampling example of section 15.10.2 already priced this queue. At 1.3 m/s it exhausts the spare after 100.8 ms, only 75.4 percent of the nominal pre-deceleration interval, and once the dispatch-to-admission allocation is charged it does so after 37.5 ms. The fallacy lies in what the watchdogs report while it happens. Every task-level watchdog shows nominal health as the queue expands, because no task has missed its own slice. To detect this silent failure, verification experiments must isolate each stage of the causal chain: target appearance, optical capture, message dispatch, bus admission, lease expiration, and actuator torque onset. Without stage-by-stage timestamping, latency intervals are easily overlooked or double-counted.

Local watchdogs verify component execution, not end-to-end physical propagation.

Architect's countermeasure: Enforce monotonic capture-to-torque evidence epoch timestamps across all processing nodes. Compare the sensor's physical capture timestamp directly against the safety monitor's decision tick, discarding any control proposal whose total elapsed latency exceeds the safety budget regardless of healthy local thread heartbeats.

Pitfall: *Allowing diagnostic logging and high-throughput telemetry to share fieldbuses with real-time safety loops.*

Real-time fieldbuses in physical AI (such as CAN FD and EtherCAT) are engineered for deterministic, low-latency control: EtherCAT cyclic Process Data Objects (PDOs) and CAN FD priority-arbitrated frames carry microsecond-accurate torque targets and lease-renewal heartbeats. When engineering teams attempt to capture rich diagnostic traces by multiplexing high-throughput telemetry (diagnostic core dumps, raw LiDAR point clouds, uncompressed camera debug streams) through Ethernet-over-EtherCAT (EoE) or bulk CAN FD payloads, they risk overflowing communication channels and starving safety-critical control loops.

On CAN FD networks, message arbitration is non-preemptive: once a low-priority diagnostic frame begins transmission on the physical layer, a newly ready high-priority emergency-stop or torque-command frame cannot preempt it. The resulting blocking latency depends on frame length, arbitration and data bit rates, and bit stuffing. Unregulated diagnostic bursts therefore inflate queueing jitter and exhaust hard timing budgets, even though every frame on the bus is structurally valid. Because CAN controllers do not register arbitration delays or link saturation as electrical errors, hardware error counters remain clean while safety deadlines expire. Similarly, while an EtherCAT master partitions cyclic process data from acyclic mailbox traffic, shared host network interface cards, protocol stack buffers, and slave microcontroller processing pipelines can still experience severe resource contention under heavy mailbox load. If mailbox servicing delays PDO packet processing or causes host-side scheduling jitter, safety heartbeats fail.

When unbudgeted telemetry delays a safety lease renewal or drive update past its deadline, the affected watchdog must invoke its qualified local fail-safe response. Furthermore, if a physical emergency-stop command travels across that same saturated bus, transmission delays directly

consume stopping clearance. Verification trials must capture synchronized electrical communication traces alongside physical vehicle trajectories; observing a software timeout in isolation cannot prove that the machine arrested motion within its certified clearance envelope.

Unbudgeted diagnostic traffic can delay the commands and evidence needed for a bounded response.

Architect's countermeasure: Physically isolate high-bandwidth diagnostic telemetry from real-time safety buses on separate network media, or enforce rigorous protocol-specific traffic shaping. On CAN FD, this means strict frame-length caps, reserved identifier priorities, and rate-limiting ingress filters. On EtherCAT, it means dedicated cyclic and mailbox schedule partitioning with strict execution time budgets. Ethernet Time-Sensitive Networking (TSN) scheduling and frame preemption standards (IEEE 802.1Qbv and 802.1Qbu) apply only to compliant Ethernet hardware; they do not provide preemption across CAN FD or standard EtherCAT links.

Pitfall: *Relying on software anomaly detectors that share electrical power or failure modes with monitored actuators.*

Actuator dynamics, including rapid motor acceleration, locked-rotor stall currents, and sharp regenerative braking transitions, cause severe electrical disturbances on shared power rails and analog ground references. Inverter switching produces steep inductive voltage transients ($v = L_{\text{bus}}\, dI/dt$), while wiring harnesses and internal battery impedance introduce substantial voltage drops that can pull unregulated bus voltages below the minimum dropout threshold of downstream DC-DC converters. Adversarial testing campaigns (such as fault category F4) inject calibrated rail transients to measure whether these disturbances propagate into supposedly isolated sensor and safety controller supplies.

When digital transducers monitoring actuator velocity or position share a power distribution board, ground plane, or non-isolated buck regulator with motor gate drivers, supply dips and ground bounce propagate directly into sensor microcontrollers. A common failure mode is a frozen peripheral register: the transducer continues transmitting cyclically valid bus frames whose measurement payload has stopped updating. System behavior depends on representation: if an encoder freezes its cumulative position counter, a downstream velocity estimator that computes numerical derivatives will incorrectly deduce that the motor has reached zero velocity. Conversely, if the sensor freezes an internally computed velocity register, it may continuously report a nominal cruising speed.

For example, if a frozen velocity register continues reporting 1.3 m/s while the motor drive erroneously executes a full-throttle acceleration command, the telemetry frames will carry valid cyclic checksums and plausible values even though they no longer reflect physical reality. A software anomaly detector that monitors only motor telemetry cannot identify the divergence without an independent physical motion witness, such as a secondary wheel encoder, an inertial measurement unit, or optical flow sensors. The adversarial verification suite must explicitly inject both the electrical transient and the resulting register freeze, using external ground-truth tracking to monitor vehicle kinematics through the commanded stop.

A power fault that disrupts an actuator can simultaneously blind the sensor tasked with detecting it.

Architect's countermeasure: Power safety-critical transducers and monitor microcontrollers from galvanically isolated, held-up auxiliary supplies equipped with sufficient energy-storage capacitance to ride through worst-case bus transients. Transducers must be configured so that internal hardware faults cannot masquerade as plausible measurements. For analog transducers, pulling an output to 0 V fails this requirement whenever 0 V represents a valid physical reading (such as zero speed or minimum distance). Reliable systems employ a "live zero" architecture with out-of-band diagnostic voltage levels, patterned after the NAMUR NE 43 standard for industrial transmitters (NAMUR 2021). For digital fieldbuses, enforce end-to-end communication protections featuring monotonic rolling sequence counters, timestamp freshness checks, and payload CRCs to detect repeated or corrupted frames (AUTOSAR 2024). A frozen measurement register can still travel in a fresh, correctly sequenced packet, so detecting that failure also requires monitoring physical acquisition progress and cross-checking the reported state against an independent motion witness.

Fallacy: *Treating an unobservable test outcome where diagnostic loggers dropped packets as evidence of safety.*

High-severity fault injection, such as short-circuiting an inverter drive phase, opening a contactor under full load, or coupling high-voltage electromagnetic interference (EMI) onto fieldbus cabling, generates intense radiated and conducted electrical transients within the test cell. Ground bounce and high inductive kickback routinely couple into the external data acquisition (DAQ) harness, desynchronizing high-speed digitizer clocks, overflowing PCIe frame-grabber ring buffers, or crashing host logging daemons into kernel panics.

Meanwhile, the physical mobile base comes to rest: either its spring-applied mechanical brakes engaged, its drive back-drove the gearbox to a stall, or it drifted into the test cell's mechanical end-stop buffer. In an undisciplined test campaign, observers look at the stopped machine and declare the run a "PASS" ("no crash occurred and the system reached rest"), while dismissing the missing telemetry as an irrelevant "instrumentation glitch" or repeating the trial until the logger manages to survive.

This practice introduces **survivorship bias**. The trials in which the logger crashes are often those with the most violent electrical transients, which are the conditions most likely to cause the safety microcontroller to hang in an exception handler without commanding deceleration. An unrecorded trial cannot reveal which mechanism stopped the base, and an operational warehouse aisle has no end-stop buffer. Under a rigorous qualification methodology, any test run lacking continuous, verifiable telemetry must be classified as `UNOBSERVABLE` and treated as an immediate test defect. The campaign must report the explicit count of each verdict alongside all untested configurations. Summary ratios such as $N_{\text{pass}}/N_{\text{total}}$ serve as test-suite execution statistics rather than empirical failure-probability estimates derived from valid, independently scored trials. Before repeating that condition, the team must establish why the witnesses failed and qualify evidence capture under the injected environment.

Discarding unobservable trials conceals the exact vulnerability under test through survivorship bias.

Architect's countermeasure: Categorize any test run with dropped, incomplete, or corrupted evidence as `UNOBSERVABLE`, retaining it as an evidence deficit whose cause must be investigated. Report all four verdict counts. Credit a required trial toward a protective claim only when its required evidence is complete and verified; repeated observable runs do not erase missing evidence from earlier trials.

15.13 Summary

The rack-end stopping claim begins as a physical distance and timing budget. Adversarial verification transforms this kinematic budget into a concrete, testable engineering contract by declaring the operating envelope across which it must hold, including the coupled corners that one-variable-at-a-time sweeps miss. A five-part test contract (bounded claim, declared conditions, precommitted oracle, stated injection procedure, provenance) decides whether any trial counts as evidence. Within it, each postulated fault is built from a five-element chain: the negated nominal condition, the injection point, the expected detector, the bounded physical response, and an observable pass condition scored on an independent witness. For example, when the chunk policy stalls while its host processor continues transmitting nominal heartbeats, the verification harness evaluates powered deceleration onset and travel to rest referenced strictly from the timestamp of the last valid lease renewal. An automated oracle fixed before the trial classifies each run into one of four mutually exclusive outcomes: `PASS`, `FAIL`, `INVALID`, or `UNOBSERVABLE`. Test coverage is then reported dimension by dimension, and the campaign is judged by its weakest dimension rather than by one aggregate percentage.

Developing a comprehensive fault catalog requires combining multiple analytical perspectives: inverting nominal design assumptions, tracing causal failure paths forward through physical mechanisms, evaluating authority boundaries, identifying shared root causes that induce coupled failures, and modeling adversarial disturbances at physical transducers. Some failure modes bypass communication buses and hardware sensors entirely. An adversarial physical patch, an optical spoof, or a maliciously crafted task instruction steers the learned proposer directly, testing the boundary of the proposal subsystem. Because the deterministic permission path monitors physical safety invari-

ants rather than the semantic origin of a proposal, it intervenes only when an actuator command threatens a measured envelope limit. Consequently, such trials score strictly against the physical oracle. If an adversarial proposal induces an erratic or sub-optimal action that nonetheless remains entirely within the safe physical envelope, the physical predicates may pass, while the verification harness records the wrong action as a task-level coverage deficit rather than crediting it as a passed proposer-injection case.

Verification evidence must be gathered on the qualification rung that faithfully models the underlying physical mechanism. A software simulation cannot sag a power rail it does not model, whereas formal methods can verify compact, deterministic safety filters under explicit premises without establishing a closed-loop guarantee for the running machine's learned proposers. On physical test benches, hardware fault injectors operate directly at interface boundaries, while instrumentation towers record ground truth using independent clocks and isolated power supplies to prevent observer coupling. During falsification, Signal Temporal Logic provides signed robustness margins that direct search algorithms toward worst-case counterexamples. However, simulated margins cannot transfer directly to physical claims without applying a discrepancy bound justified over the claimed conditions. Similarly, importance sampling converts targeted failure searches into operational failure rates only when the sampling proposal distribution is explicitly declared, covers the entire failure domain, and applies proper likelihood weights. In rare-event analysis, extreme value models support safety claims only to the extent justified by their distributional assumptions. A counterexample refutes a safety claim, whereas the absence of one leaves the unsearched domain open rather than certified. Eight relations formalize this quantitative framework, and table 15.6 summarizes what each bounds or decides.

Table 15.6: Key equations of adversarial verification: The relations that turn a stopping budget into precommitted predicates, size a fault-injection campaign, and limit what search, simulation, and rare-event statistics can claim, with the place each is derived.

Equation	What it bounds or decides	Derived
$t_{\text{onset}} \le T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}$, and $d_{\text{F1}}(v) = v(T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}) + d_{\text{suffix}}(v) + \epsilon_{\text{track}}$	F1's two precommitted predicates, measured from the last valid renewal; the capture-referenced budget subtotal cannot stand in for them	equation 15.1
$\lambda_{\text{unmitigated}} = \lambda_{\text{raw}}(1 - C_{\text{diag}})$, $n \ge \ln(1-C)/\ln C_{\text{diag}}$	The diagnostic coverage a rate target demands, and the zero-miss injections, sampled in proportion to the fault rates, that demonstrate it	Notebook 15.3
$\Delta t_{\text{one-sigma scenario}} = \delta_{\text{skew}}\, T_{\text{blackout}} + \sigma_{\text{jitter}}$	How much of the clock-conversion bound behind F2's refusal threshold a synchronization blackout spends	equation 15.2
$\rho(\square_{[0,T]}\phi) = \min_t \rho(\phi, s, t)$, $\rho(\Diamond_{[0,\tau]}\phi) = \max_t \rho(\phi, s, t)$	The signed margin of a trace against a temporal requirement, the score a falsifier drives toward zero	equation 15.3
$\min_{\mathbf{x}_0, \psi} \rho(\phi, s(\mathbf{x}_0, w_{\text{dist}}(\psi)), 0)$ subject to $\lVert w_{\text{dist}} \rVert_\infty \le \Delta_w$	The worst initial state and realizable disturbance a search can find; a search that finds none certifies nothing	equation 15.4
$\rho_{\text{real}} \ge \rho_{\text{sim}} - L_\phi\, \epsilon_{\text{gap}}$	The physical margin a simulated margin guarantees, given a discrepancy bound justified over the claimed conditions	equation 15.6
$\hat{p}_F = \frac{1}{N} \sum_i \mathbb{1}[x_i \in F]\, w(x_i),\ x_i \sim q$	An operational failure rate from runs concentrated near failure, valid only with a declared p, a proposal that covers the failure set, and the weights	equation 15.7
$z_{T,\text{sim}} + L_\phi\, \epsilon_{\text{gap}} \le D_{\text{clear}} - d_{\text{budget}}$	Whether a discounted tail estimate fits inside the physical reserve; a necessary check, not a release rule	equation 15.11

DRAFT

Key Takeaways: Adversarial verification and fault injection

- **A fault tests a physical claim:** Derive the injection, detector, response, and independent witness from the stopping or contact bound. Successful task execution alone does not exercise the protective response.
- **The environment bounds the evidence:** Select each qualification rung for the mechanism it exercises. Simulation, processor execution, electrical benches, and physical rigs contribute complementary evidence with different blind spots.
- **Search finds counterexamples, not universal passes:** Signed temporal margins help prioritize disturbances near a violation. An unsuccessful search does not establish a global minimum, and a fitted tail does not prove a hard physical limit.
- **Precommitment preserves the meaning of a pass:** Fix conditions and predicates before injection. Keep `FAIL`, `INVALID`, and `UNOBSERVABLE` distinct, because missing or invalid evidence cannot support the stopping claim.
- **Verification hands release bounded evidence:** Bind each fault record to its claim, builds, conditions, and raw measurements. Coverage gaps and model assumptions remain part of the fault records, so release can restrict authority where evidence ends.

Under the fourth law, permission must be earned (principle 4), and adversarial verification produces much of the evidence that earns it. Each fault record names the claim it supports, the envelope point it covered, and the oracle fixed before the run. The authority that the release decision can grant therefore reaches exactly as far as the passing records and stops at every `INVALID`, `UNOBSERVABLE`, or untested cell. The F1 record of this chapter shows the rule in its plainest form. Its timing path, candidate envelope point, and witnesses are specified, while its loaded braking premise remains unqualified and its outcome field is empty. Until measured trials on a physical rig with independent instrumentation fill that field, the stopping claim it describes grants no authority at all.

15.14 Historical Perspective and Further Reading

Deliberate fault injection originated in the dependability community of the 1980s, where researchers applied electrical transients, pin-level shorts, and radiation directly to working microprocessors to determine whether fault-tolerant architectures could detect and contain hardware errors. Arlat et al. (1990) formalized this methodology with the MESSALINE tool, structuring each verification campaign around four operational dimensions: the injected faults, the workload activating them, the readouts captured across system boundaries, and the dependability measures derived from observations. This four-part taxonomy serves as the foundational template for the fault records developed throughout this chapter. As systems scaled in complexity, fault injection transitioned from physical pin manipulation to software instrumentation. The comprehensive survey by Hsueh et al. (1997) framed the defining engineering trade-off: hardware-implemented injection manipulates internal signals and electrical states unreachable by software, whereas software-implemented injection offers programmatic repeatability and lower operational cost at the expense of ignoring low-level hardware faults. This trade-off reappears at every rung of the cyber-physical qualification ladder. Early practitioners also discovered that monitoring hooks and profiling code unavoidably perturb execution timing and cache states, a distortion Gait (1986) termed the *probe effect*. Because sub-millisecond timing shifts can destabilize physical feedback loops, high-assurance verification architectures isolate witness observers onto independent power supplies and dedicated clock domains.

Search-based falsification and continuous verification followed a parallel lineage rooted in formal methods and statistical physics. Pnueli (1977) first introduced linear temporal logic to prove correctness properties over discrete program executions. To verify continuous and hybrid physical trajectories, Maler and Nickovic (2004) generalized temporal assertions into signal temporal logic (STL). Fainekos and Pappas (2009) subsequently equipped STL with quantitative spatial semantics, replacing binary true-false verdicts with a continuous signed distance margin. This formulation transformed the falsification problem from an intractable combinatorial search into continuous gradient-free or gradient-based optimization. Cyber-physical falsification frameworks such as S-TaLiRo (Annpureddy et al. 2011) and Breach (Donzé 2010) packaged these continuous margins to

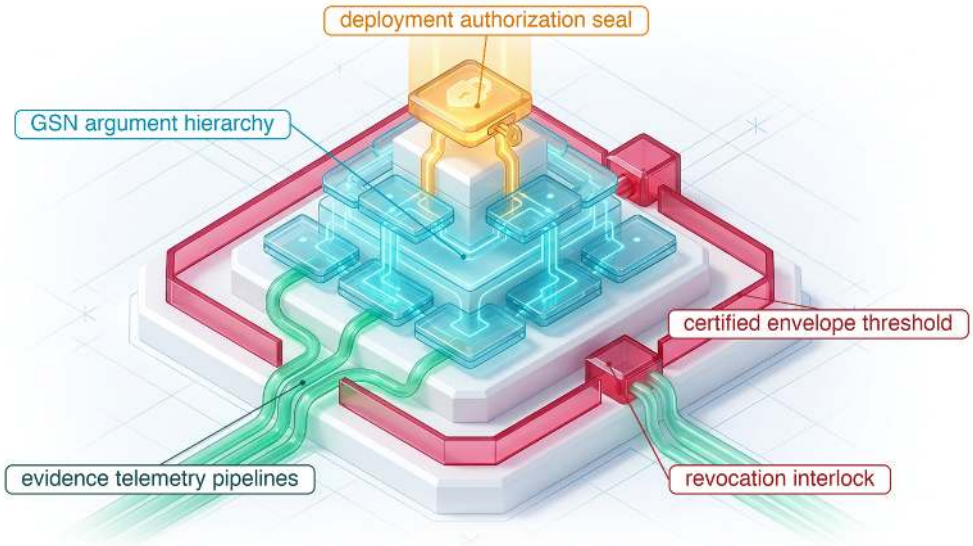
automate the discovery of safety violations in nonlinear dynamical models. Statistical rare-event estimation has an even older heritage. Importance sampling emerged from early Monte Carlo radiation shielding calculations by Kahn and Marshall (1953), the cross-entropy method introduced adaptive proposal distributions (Rubinstein and Kroese 2004), and O'Kelly et al. (2018) synthesized both techniques to quantify catastrophic collision probabilities across autonomous driving stacks. When safety analysts must characterize worst-case physical excursions without imposing restrictive global distribution assumptions, they draw on extreme value theory. It entered engineering through the flood-frequency analyses of Gumbel (1958) and was rigorously established in its modern peaks-over-threshold form by Balkema and Haan (1974) and Pickands (1975).

Formal verification of learned neural controllers is the most recent strand. Reluplex (Katz et al. 2017) proved that modified simplex constraint solvers could formally verify input-output safety properties on small piecewise-linear networks. Subsequent bound-propagation frameworks, including α,β-CROWN (Wang et al. 2021), scaled formal guarantees to million-parameter vision networks using branch-and-bound techniques and convex relaxation. However, formal solvers remain computationally bounded; the cited results do not establish guarantees for multi-billion-parameter vision-language-action foundation models operating in closed feedback loops. The verification architecture developed in this chapter unifies these historical lineages into a cohesive systems discipline. Each trial executes against an explicit operational claim, evaluates trajectories with an oracle declared before the run, isolates observational telemetry within uncorrupted witness hardware, and exports fault records that carry measured coverage deficits into deployment safety cases.

Six foundational works trace the trajectory from classical hardware dependability to modern cyber-physical validation algorithms:

- Arlat et al. (1990) establishes fault injection as a controlled experimental science, defining the four-factor schema of faults, activation workloads, readouts, and derived measures that governs the fault records in section 15.4.2.
- Leveson (2011) introduces Systems-Theoretic Accident Model and Processes (STAMP) and System-Theoretic Process Analysis (STPA), establishing the forward hazard methodology in section 15.6.2 that identifies systemic safety violations emerging from unsafe control interactions rather than isolated component failures.
- Fainekos and Pappas (2009) formulates the continuous spatial robustness degree for temporal logic specifications over real-valued signals, providing the signed optimization margin evaluated throughout section 15.9.1.
- Owen (2013) provides a definitive mathematical foundation for importance sampling and rare-event estimation, detailing effective sample size diagnostics, weight degeneracies, and failure modes where unrepresentative proposals yield falsely optimistic variance estimates.
- Corso et al. (2021) surveys algorithmic safety validation for black-box autonomous systems, categorizing falsification approaches according to whether they target counterexample discovery, most-likely-failure trajectories, or rare failure probabilities.
- Kochenderfer et al. (2026) synthesizes trajectory falsification, failure-probability estimation, reachable set analysis, and runtime monitoring into an algorithmic discipline for validating complex autonomous systems.

What's Next: From verification to release decisions



Verification delivers to the release gate a signed set of fault records, the per-rung coverage of the qualification ladder behind them, and an explicit account of the operating regimes no trial reached. For each safety claim, the set binds the corresponding fault records to any sim-to-real transfer bound (ϵ_{gap}) or rare-event tail estimate on which the claim depends, keeping measured margins, conditional model estimates, and untested regimes strictly apart. Verification records supply behavioral evidence under fault conditions, but they do not make deployment policy, and no individual fault record decides whether the machine may operate in production aisles. In chapter 16, the release process writes each claim as a physical inequality and joins these fault records with the authority record, the placement record, and the evaluation record in a safety

case. It then judges which claims are substantiated, which release verdict applies (`UNCOND`, `COND`, or `REFUSE`), and which standing conditions must govern live operation.

Purpose

Why can a machine that completes every trial still lack the evidence to be allowed among people?

A successful trial shows what a machine did under the conditions it happened to meet, while permission to operate is a claim about every condition it may meet next. Thousands of clean runs on a dry floor say nothing about the stop on a floor no trial touched, and a brake that stopped the machine last month may not stop it inside the same distance after its lining wears. A machine granted authority on demonstrations therefore carries untested premises into service, where the first test of each one is the event it was meant to prevent. Deciding to deploy requires stating which physical claims the evidence supports, under which conditions and for how long, refusing or narrowing operation wherever a premise remains unknown, and withdrawing the grant when brakes wear, sensors shift, or software changes. At the causal boundary, authority must expire when its physical justification does, because a later software correction cannot undo motion already produced.

Learning Objectives

- Construct a claim-argument-evidence (CAE) safety case as an auditable engineering assertion DAG linking bounded operating envelopes to qualified measurements, analysis, and operating conditions
- Distinguish input provenance from premise status, and select the verdict (`UNCOND`, `COND`, or `REFUSE`) the supported operating claim permits
- Join task-success, cycle-time, and intervention evidence to the physical measurements and restrictions supporting a conditional release
- Specify standing-condition cadences and validated responses, from brake wear to calibration drift, separately from execution leases
- Diagnose unsupported warrants, hidden contextual assumptions, and compound defeaters through adversarial review of a release argument
- Specify the records a release manifest binds by digest and the conditions under which its gate refuses motion
- Determine which claims a policy or software update reopens, and why shadow operation cannot substitute for closed-loop qualification

16.1 The Decision to Deploy

Verification left the machine with a signed set of fault records. Each pairs an observed trace under an injected fault (a stalled proposer, a stale frame, lost fieldbus frames, a sagging bus) with an oracle fixed before the trial, and the set names the operating regimes no trial reached. Beside it sit the records the earlier chapters produced: the authority record of arbitration and fallback outcomes, the placement record of compute scheduling and isolation, and the evaluation record of closed-loop task performance. Those records say how the machine behaved under the conditions tested. They do not say which operating claim the machine may now be granted, because a fault record proves nothing outside the envelope it sampled, and an untested mode is a gap rather than a pass. Offline validation accuracy and clean laboratory demonstrations sit in the same position. Release is the step that decides, claim by claim, what this evidence licenses across a named operational design domain.

↩ The empirical verification evidence backing release claims is established in section 15.8.

That step is a threshold every machine operating among humans eventually crosses, the point where builders formally grant it authority to act outside the laboratory. In conventional software engineering, deployment is largely reversible; an operator can recall a defective build within minutes, bounding the cost of failure to the time required to roll back the binary. For physical systems, that release grant differs. Every action authorized by the runtime delivers energy across the causal boundary into the physical environment. When a release decision errs, the failure appears as an actuator driving past an obstacle clearance line or a gripper exerting uncalibrated force against human tissue, and no software rollback can recall kinetic energy already transferred. Aerospace, rail transit, and industrial robotics manage this risk through an explicit safety case, a structured and auditable argument stating what the machine is claimed to do, under what operating conditions, and on what evidence. Physical AI inherits this burden with an added difficulty. A learned policy cannot be proven safe by inspecting its weights, and finite field trials cannot surface every rare tail failure, which is where the worst consequences lie.

The warehouse mobile manipulator shows why past operational success cannot by itself license deployment. In an active logistics depot it must travel narrow aisles past protruding rack ends, unlatch a spring-latched cage door, and hand a ceramic mug to a human coworker. Each subtask turns on a distinct physical claim: a stopping distance inside the clear distance at maximum payload, a bounded peak force on the latch, and a limited contact force during the handover. A spotless test run shows only that the machine executed those motions under the exact conditions of that single trial. A sound release decision must instead bound the physical variations the machine will face in production and show that verified plant dynamics and low-level safety interlocks keep risk within limits across that entire envelope.

A deployed system must also do useful work inside its certified envelope. Closed-loop evaluation logs show whether an end-to-end policy completes its tasks, how often humans must intervene, and which environmental conditions cause the policy to break down. Engineers must weigh these task metrics against the speed limits, payload caps, and spatial restrictions required by the safety case. A mobile base that trips safety stops every few meters avoids collisions while failing its service target; conversely, an agile policy that finishes every nominal trial cannot be given actuator authority until deterministic guardrails enforce safe bounds during perception failures. The release decision brings these two requirements together into one operating profile.

Because different facilities have different lighting, floor friction, and foot traffic, an initial release case applies to a single facility, drawing on its site clearance surveys, loaded braking trials, calibrated impact-force measurements, and cryptographically signed fault records. Rather than boiling deployment readiness down to a single benchmark score, the release decision is a bounded, revocable judgment that determines which operational claims the available evidence actually supports, under what physical conditions, and for how long. This chapter builds that decision in the order an adjudicator meets it: the claims are first written as testable physical inequalities over a bounded operating envelope, then organized into an argument whose every link names its evidence. The argument resolves into one of three verdicts (full operational authorization, restricted operation inside enforced limits, or refusal), and standing conditions define when a granted verdict expires. A worked adjudication applies all of this to the running machine, an adversarial review tries to break whatever case survives, and a signed release manifest binds the final decision to the executing machine so that every later software update, retrained checkpoint, or hardware modification passes through the same gate.

↩ The closed-loop evaluation record of task success, intervention rates, and breakdown conditions is established in section 7.8.

↩ The signed fault records a release case consumes are established in section 15.11.

16.2 Physical Criteria for Release

A deployment review that signs off on aggregate benchmark scores or smooth demo videos leaves the machine with no testable rule for when it may move. At a rack end, the base must stop inside the available clearance; during handover, the arm must stay within the assessed contact-force limit; and both claims depend on the permission path finishing its check before its deadline. Together, those requirements give release authorization three testable physical criteria:

$$d_{\text{stop}}(v, \tau_{\text{delay}}, a_{\text{brake}}, \delta_{\text{loc}}, \epsilon_{\text{track}}) \le D_{\text{clear}}, \quad F_{\text{contact}}(v, m_{\text{eff}}, k_H) \le F_{\text{limit}}, \quad T_{\text{exec}} \le T_{\text{deadline}}. \tag{16.1}$$

The first term abbreviates the full stopping budget of equation 12.1, whose protective margin is charged as well. In the third criterion, T_{exec} is the worst-case execution time of one permission-path cycle and T_{deadline} the deadline that cycle must meet inside its tick (section 12.7.4). A permission computed after its deadline cannot be credited for that cycle, and the qualified fallback must contain the resulting delay.

Because each criterion is a physical inequality, release authorization cannot rest on intuition, demonstrations, or aggregate benchmark scores. Authorizing deployment requires an auditable safety argument that links every inequality to measured observation ages, worst-case execution time bounds, empirical braking and contact trials, and a validated fallback. These physical bounds also depend on the individual machine's calibration: its camera and lidar sensor transforms, joint encoder zero offsets, and motor torque constants. A lost or drifted calibration invalidates the certified stopping budget even when software binaries remain unchanged. A sensor mount that shifts in service erodes the localization allowance δ_{loc} (section 16.5.1), and a firmware update that overwrites measured sensor extrinsics and joint offsets invalidates the budget just as quickly. The deployment pipeline must therefore preserve and re-verify calibration records before restoring the operating permit (section 16.9.1).

For the warehouse mobile manipulator, the release question asks whether empirical and analytical evidence satisfies these criteria for each of its three tasks inside a scoped operating envelope. The release case defines the assessed physical bounds, the specified hardware fault model, and the validated permission and fallback ladder. This argument is the safety case, which section 16.3.1 gives a formal structure, and it justifies granting a revocable operating permit while those physical conditions hold. The permit is the signed authority under which the permission path may admit the policy's tracking commands (section 16.4). Finite test runs cannot establish protection against uncharacterized or unmodeled hazards.

DRAFT

A release case is scoped by the operating envelope: the target operational design domain (ODD) paired with the machine's internal hardware, thermal, and timing invariants. Deployment release authorizes a system configuration under standing operating conditions, complementing rather than replacing the short execution leases that bound individual action chunks. Site inspections, calibration checks, and per-tick permission checks operate at the distinct cadences dictated by their respective failure mechanisms. The envelope also fixes what each of the three possible verdicts, defined in section 16.4, refers to. Unconditional operation (`UNCOND`) covers the full verified envelope. Conditional operation (`COND`) covers a separately evidenced subset with constrained kinematics or environmental fences. Refusal (`REFUSE`) covers none of it. For the mobile manipulator, the proposed nominal operating envelope specifies aisle travel up to 1.3 m/s (chosen; see the Reader Guide) with the tote rack loaded to at most 50 kg. It also specifies floors surveyed to a friction coefficient of at least 0.204 and travel past rack ends with at least 1.10 m of clear distance. The friction floor is an optimistic screen obtained by dividing the required braking deceleration by standard gravity under the assumption that all vehicle weight rests on the driven wheels. Because passive casters carry a share of the normal load without contributing braking force, the driven wheels must generate the total stopping force from a smaller normal load, so actual qualification must include loaded wheel forces, drive settings, and stopping traces. For manipulation, the proposed envelope specifies door approaches at 0.03 m/s and coworker handovers at 0.10 m/s tool center point (TCP) speed.

↩ The operational design domain and its known absences are established in section 5.7.1.

Inside these boundaries, the learned neural policy proposes actions across the nominal task envelope, but every proposed action requires independent, per-tick permission from an isolated safety enforcer. Mode-specific conditions (table 16.1) narrow that envelope. The takeover analysis of section 14.2.4 supplies candidate intervention speeds, screening an in-loop request at 0.75 m/s and an out-of-loop crawl at 0.15 m/s. Neither screen qualifies as a standalone release limit, because each depends on a human response time that the release case has not measured. The in-loop slow-down holds only for an operator answering an expected stimulus, and the out-of-loop crawl already fails the 99th-percentile response. The robust design therefore runs the base's own local stop first and hands over control from standstill, where waiting costs time but no clearance. The restricted mode of a `COND` verdict narrows the envelope further. On a floor characterized only through the site inspection regime, the machine runs at 1 m/s, below the 1.23 m/s optimistic all-weight inspected-floor screen, while still charging dispatch-to-admission delay and maintaining a positive stopping reserve.

The rules in table 16.1 follow a strict priority ladder: refusal conditions override mode-specific restrictions, which in turn override nominal limits. Because speed ranges overlap across operational contexts, these thresholds define operating modes rather than disjoint numerical intervals. The payload row shows how a mode differs from an interval. If the tote-rack load estimate has gone stale since the last pick, the base may not transit, because its stopping budget assumes a known mass. The stationary arm may keep working under its own separately evidenced claim. An invalid estimate or a measured overload refuses both. A conditional state restricts admitted proposals through enforcer clamping. A refusal state revokes the operating permit, so the permission path admits no further tracking commands, and commands a validated fallback trajectory. Onboard wheel slip estimation cannot provide prospective clearance guarantees because it detects low friction only *after* traction has already been lost. A thin film of clear oil ($\mu \approx 0.05$) can be visually indistinguishable from dry concrete to the navigation cameras. By the time a loaded base moving at aisle speed (1.3 m/s) initiates braking on an oil patch and measures slip, it has already committed to a stopping distance that exceeds the clear distance. Consequently, the release case must justify how site surveys, contamination exclusion, and bounded inspection and response procedures preserve the assessed friction floor throughout the authorized interval. Periodic surveys alone cannot exclude a spill between inspections.

↩ The ladder of resident fallback responses that a refusal commands is established in section 12.9.

The safety case must also document machine behavior when operation encounters an envelope boundary. Event-triggered edge telemetry freezes circular buffer traces for post-incident review (section 16.9.5), while the deterministic permission path enforces physical boundaries in real time. Table 16.1 summarizes the physical dimensions maintained by runtime monitors and administrative site controls. Internal environmental conditions, such as ambient temperature, DC bus rail voltage, and compute system-on-chip (SoC) utilization, enter the release case through fault injection and stress tests conducted across their qualified ranges.

↩ The internal qualification ranges for temperature, bus voltage, and compute load that the release case inherits are established in section 15.2.

PREPRINT

Table 16.1: Operating envelope of the warehouse mobile manipulator: Refusal rules take priority over restricted-mode rules and nominal limits. Conditional operation requires every relied-on premise to remain supported; stale payload evidence permits only separately supported stationary work, while an invalid estimate or overload refuses. The takeover speeds are preliminary screens, not qualified motion limits. The friction floor and inspected-floor ceiling assume all weight on driven wheels and require loaded stopping qualification. The displayed speed ceilings are partial calculations before dispatch-to-admission delay; signed limits require that delay and a positive reserve. Sensor rates and stopping response are plant validation obligations.

Envelope Dimension / Invariant	Nominal Envelope	Conditional Boundary	Hard Refusal	Runtime Monitor & Rate	Enforcer Action & Latency
Aisle Speed	$v \leq 1.3$ m/s	Preliminary takeover screens: 0.75 m/s in-loop and 0.15 m/s out-of-loop; the robust design stops before any handover	Measured speed above the signed 1.3 m/s (ceiling 1.44 m/s), or invalid speed estimate	Encoders and IMU, every 1 ms permission tick	Clamp admitted speed; refuse above the signed speed
Floor Friction	Surveyed $\mu \geq 0.204$ (dry concrete near 0.60)	Qualified assessment and maintained site regime ($\mu \geq 0.12$): restricted 1 m/s, below the 1.23 m/s ceiling	Unsurveyed floor or reported film; a clear oil film ($\mu \approx 0.05$) can evade the installed cameras	Floor survey and site spill procedure; no on-board measurement	Restrict speed by floor zone; refuse the aisle
Tote-Rack Payload	$0 \leq m \leq 50$ kg, valid load estimate (total at most 368 kg)	Estimate stale since the last pick: stationary arm tasks only	Load above capacity or invalid estimate	Rack load cells, at each pick	Refuse aisle transit until re-weighed
Rack-End Clearance	Surveyed $D_{\text{clear}} \geq 1.10$ m at every rack end	Shorter surveyed clearance: lower signed speed from the same budget	Unsurveyed rack end, or obstacle inside the clear distance	Site survey; lidar and navigation camera at frame rate	Speed limit per rack end; stop for a detected obstacle
Door Latch Approach	$v \leq 0.03$ m/s, strike plate at its nominal position	Original policy: nominal plate only; changed recovery candidate needs its own evaluation and release case	0.10 m/s approach or plate condition outside the selected policy case	Arm contact-force sensing in the 2 ms contact loop	Trip at 15 N; refuse the unsupported approach
Coworker Handover	TCP speed $\leq$ 0.10 m/s under `accept_item`	Coworker present without `accept_item`: hold short of the handover point	TCP speed above the signed 0.10 m/s (transient ceiling 0.24 m/s), or a clamping geometry outside the assessed transient case	Joint encoders every permission tick; arm contact-force sensing	Clamp TCP speed; refuse above the signed speed

The nominal latch row in table 16.1 scopes the baseline policy release case. Although the separately stipulated recovery campaign in section 7.8.1 evaluates a changed candidate across nominal and displaced-plate conditions, that experimental provenance does not silently extend the contact-force or timing bounds established here. Deploying the recovery policy requires its own evaluation and safety case update.

A defensible release claim must specify its plant dynamics, assumed contact geometry, and modeled fault set. The release case for the mobile manipulator rests on three criteria. The base stops inside the 1.10 m clear distance before reaching a pedestrian who has stepped out at a rack end and stopped. The arm unlatches the door without exceeding the 100 N structural limit. An item handover does not exceed 50 N of peak contact force against the coworker. The base's stopping claim assumes that the person, once in the path, stands still. A person who keeps walking toward the moving base closes the gap during the whole reaction and braking interval. As section 12.3.1 showed, sizing the budget for that approach would cut the aisle speed to the much lower walking-person ceiling. The site therefore controls aisle-end crossings procedurally, and that site crossing rule is itself a premise the release case must evidence. A complete release argument demonstrates which human contacts are excluded before impact, which detected contacts fall within the compliance model, and which

DRAFT

single-point faults trigger the isolated fallback. Halting motion after impact occurs does not reduce the initial shock force.

The contact criteria arrive as premises from the enforcement record rather than as calculations derived during release review. The spring-mass impact peak that grows linearly with approach speed (equation 6.7) was first met as the soft-spring exploit of the latch simulator. Section 12.7.2 specializes it to an unbraked elastic contact with a coworker's hand (equation 12.13), using the arm's effective mass and the ISO/TS 15066 biomechanical hand model.[1] The release case evaluates the operational consequences of those physical results. At the arm's maximum free-space limit of 1 m/s, even the transient impact model predicts 207 N, exceeding the 50 N criterion by a factor of 4.1×. Consequently, unseparated coworker proximity cannot be permitted at full free-space speed without additional physical containment. For a free hand that recoils upon impact, the criterion admits approach speeds up to 0.24 m/s. At the chosen handover speed of 0.10 m/s, the model predicts a transient force of 20.7 N, below the case criterion. If the coworker's hand is clamped against a rack upright or structural frame, however, the ceiling drops to 0.053 m/s. At that same 0.10 m/s approach speed, a clamped collision generates 94.9 N, which breaches the limit. The handover claim is therefore strictly a transient-contact claim, inheriting two premises: that the lumped-mass body model and effective mass accurately describe the collision, and that the handover geometry excludes pinching or clamping hazards. Because physical calculations alone cannot guarantee workspace clearance, the release case must establish both premises through empirical evidence and site inspection.

Unlike the arm's instantaneous force criteria, the mobile base's claim is an integrated distance budget. Validating this claim requires empirical evidence bounding the perception observation age, communication bus latencies, and execution lease durations. Section 12.3.1 sized that budget term by term at aisle speed (table 12.1), integrating equation 12.1 with the jerk-limited C^2 braking profile from section 11.5.2, and found the spare and the reserve that dispatch-to-admission travel leaves. Release inherits those terms as premises. In deployment authorization, the critical engineering metric is the margin of clear distance that remains unspent, and the question release adds is how large an error in a single input would spend it. Notebook 16.1 recapitulates the enforcement budget and adds that question as step 4.

[1] **ISO/TS 15066 Values as Case Criteria**: The document supplies a body model and body-region force and pressure data for transient and quasi-static contact (International Organization for Standardization 2016). ISO 10218-2:2025 incorporates the collaborative-application requirements formerly published as ISO/TS 15066; ISO/TS 15066:2016 itself remains published and is under revision (International Organization for Standardization 2025b). The 50 N handover criterion is none of those tabulated values and not an injury boundary; the site assessment chooses it for one body region, contact type, and geometry, so a change to any of the three reopens the claim instead of inheriting its margin.

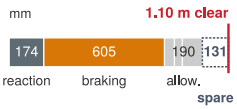
Napkin Math 16.1: The aisle spare

Problem: At the 1.3 m/s aisle speed, how much of the 1.10 m clear distance does the stopping budget leave unspent, what error in a single input would spend it, and how much remains once dispatch-to-admission work is charged?

Variables:

- Aisle speed $v = 1.3$ m/s (Chosen); clear distance $D_{\text{clear}} = 1.10$ m (Illustrative, standing in for a site survey)
- Pre-brake delay $\tau_{\text{delay}} = 133.6$ ms (Derived from illustrative terms: 51.6 ms observation age plus 82 ms from the last valid renewal to brake onset)
- Credible deceleration $a_{\text{brake}} = 2$ m/s² (Illustrative) and jerk bound $j_{\max} = 7.11$ m/s³ (Derived, section 11.5.2)
- Allowances $\delta_{\text{loc}} = 50$ mm and $\epsilon_{\text{track}} = 40$ mm (Illustrative); margin $\delta_{\text{margin}} = 100$ mm (Chosen)
- Dispatch-to-admission allocation $\Delta_{\text{da}} = 63.3$ ms (Illustrative allocation, section 13.6.2)

Math:



1. **Reaction**: $v\,\tau_{\text{delay}} = 1.3$ m/s $\times$ 133.6 ms $= 173.7$ mm.
2. **Braking**: Because $v \geq a_{\text{brake}}^2 / j_{\max}$, the stop reaches full deceleration, and $v^2/(2a_{\text{brake}}) + v\,a_{\text{brake}}/(2j_{\max}) = 422.5$ mm $+ 182.8$ mm $= 605.3$ mm.
3. **Spare**: 173.7 mm $+$ 605.3 mm $+$ 50 mm $+$ 40 mm $+$ 100 mm $= 969.0$ mm, leaving 1,100 mm $-$ 969.0 mm $= 131.0$ mm.

4. **One input wrong**: As extra delay, 131.0 mm / 1.3 m/s = 100.8 ms. As weaker braking, setting step 2 equal to the 736.3 mm braking room gives $a = 1.39$ m/s², a 31 percent shortfall.
5. **Admission charged**: $v\,\Delta_{da} = 1.3$ m/s × 63.3 ms = 82.3 mm, leaving a reserve of 48.7 mm, or 37.5 ms at aisle speed.

Result: The budget spends all but 131.0 mm of the clear distance before admission work, and all but 48.7 mm after it.

Systems insight: The validity of the stopping guarantee $d_{stop} \le D_{clear}$ hinges on the narrow margin of unspent distance rather than the nominal distance consumed. Measured against the partial spare of step 3, a credible deceleration overstated by 31 percent spends the whole of it. The reserve that step 5 leaves after admission work is less than half that spare, so once Δ_{da} is charged a smaller braking error suffices.

This reserve must also absorb any unmodeled runtime uncertainty, so it cannot be treated as extra allowable latency or repurposed as a margin for control handovers. The reserve left after admission work, 37.5 ms at aisle speed, tolerates less unbudgeted delay or braking shortfall than the break-even values of step 4. Unless each component of the timing and kinematic chain is measured, nothing shows that the reserve survives the latencies and friction variation of a production floor. Each of the three criteria (stop, latch, and handover) therefore depends directly on premises about achievable deceleration, sensor-to-actuator latency, and contact stiffness that no calculation can certify. Because these physical properties can degrade over mechanical operating life, an auditable safety case must expose these runtime dependencies so that certification engineers can judge whether the empirical evidence supports deployment.

The partial budget leaves only 131.0 mm of the 1.10 m clear distance spare.

16.3 Safety Cases and Claims

A photograph of a clear aisle cannot establish that a loaded mobile base will stop before reaching an obstacle. A valid stopping claim depends on guaranteed physical clearance, actual braking capability, and end-to-end response timing, with each parameter supported by empirical evidence gathered under documented operating conditions. A safety case connects these physical premises to the release claim step by step, so an assessor can see which guarantees rest on measurements and which remain unverified assumptions.

16.3.1 Claims, arguments, and warrants

A bundle of test logs and benchmark plots gives a release reviewer no way to tell which physical claims the data actually support or where an unstated assumption hides. A safety case is auditable only when its logic is written down in a form that another engineer can inspect and challenge link by link. Two notations are widely used in practice, and both capture the same structure. The **claim-argument-evidence (CAE)** framework divides the case into three parts. The *claim* is a statement about system behavior that is either true or false. The *argument* is the causal or inductive reasoning connecting the claim to retained support. The *evidence* consists of the calibrated measurements, justified analyses, and validated operating procedures (Bishop and Bloomfield 1998; Bloomfield and Netkachova 2014). **Goal Structuring Notation (GSN)** draws the same structure as a directed graph: top-level goals (claims) split through explicit strategies (arguments) into concrete solutions (evidence items). Context and assumption nodes state the operating envelope within which each link holds (Kelly 1998; Kelly and Weaver 2004). The fault injection records enter this graph directly as solutions supporting each named sub-claim. Because release adjudication turns an assurance graph into a binding operational authorization, the safety case of definition 16.1 evaluates directly to an enforceable release verdict.

This decomposition comes from Stephen Toulmin's model of practical argumentation[2] (Toulmin 1958). In industrial practice, standards such as ANSI/UL 4600 require goal-based safety cases for autonomous physical products (UL Standards & Engagement 2023; Koopman 2023). Production autonomous fleets use this same structure. For example, Waymo organizes the safety case for its

↩ The fault-record set, in which every record names the one release claim it supports, is established in section 15.11.1.

2 **Toulmin's Argument Anatomy**: *The Uses of Argument* (Toulmin 1958) splits practical reasoning into claim, data, warrant, backing, qualifier, and rebuttal. Safety cases preserve this anatomy: evidence supplies the data, stated confidence acts as the qualifier, and the rebuttal becomes the defeater evaluated during adversarial review (section 16.7).

DRAFT

driverless ride-hailing operations around layered, dynamic claims showing the absence of unreasonable risk, arguing separately that its risk acceptance criteria are complete and that their empirical evaluation is sound (Favaro et al. 2023). For an embodied robot, the root claim C_0 states a testable physical invariant, such as a stopping distance inside the surveyed aisle clearance ($d_{\text{stop}} \leq D_{\text{clear}}$) or a bounded collaborative contact force ($F_{\text{contact}} \leq F_{\text{limit}}$). Supporting sub-claims name the required mechanical, electrical, and computational conditions, and retained measurements, derivations, or validated procedures back each leaf. Writing these relationships as a directed acyclic graph (DAG) exposes intermediate dependencies and rules out circular reasoning, so a reviewer can trace any operational claim down to its physical measurements and operating assumptions.

Definition 16.1: Claim-argument-evidence safety case

Claim-argument-evidence safety case is a structured argument that a named machine, in a stated operating envelope and under a stated fault model, meets explicit physical criteria, written as claims that decompose through stated arguments into retained evidence.

1. **Significance**: It makes a release decision checkable one link at a time. For the warehouse machine, the three inequalities of equation 16.1 become six claims whose leaves are individual premises. A reviewer can find the one premise, such as a braking deceleration no loaded trial has measured, on which the verdict turns.
2. **Distinction**: A test report or benchmark score records what happened under the conditions sampled. A safety case states why that evidence supports a claim about conditions the machine has not yet met, and names the assumptions under which the reasoning stops holding.
3. **Common pitfall**: A frequent misconception is that the case is paperwork assembled after development for a regulator. It is written with the design, and in this book's architecture its verdict decides what the permission path lets the machine do.

The soundness of this argument DAG depends on keeping evidence distinct from demonstration. A **demonstration** records successful task execution across an uncharacterized test set, such as a string of clean door openings with the strike plate at its nominal position or a thousand collision-free warehouse runs. Demonstrations show nominal performance across observed runs, but they give no mathematical or statistical bounds on tail behavior, sensor faults, or corner cases outside those logged runs. Evidence, by contrast, consists of falsifiable, calibrated records with stated uncertainty bounds: an execution-time distribution measured on a hardware logic analyzer paired with worst-case execution time (WCET) bounds, loaded stopping trials across degraded friction surfaces, or hardware-in-the-loop (HIL) fault-injection traces at envelope corners. The evidence must match the scope of the claim. Nominal trials can support nominal capability claims, and calibration logs can validate sensor coordinate frames, but bounding an envelope limit or worst-case response requires systematic coverage, stated uncertainty margins, and an explicit warrant.

Connecting evidence to a claim requires a **warrant**, the reasoning principle that explains why the measured data support the claim. For a learned neural policy, teams often reach for an inductive warrant, arguing from thousands of failure-free test episodes to future operational reliability. The exposure wall analyzed in section 7.9 shows why purely inductive warrants cannot support catastrophic hazard claims. At 95 percent confidence the zero-failure exposure wall of equation 7.9 becomes $T \geq 3.0/\lambda$ (because $\ln 20 \approx 3.0$), where λ is the failure rate per operating hour to be demonstrated. Statistically proving an ultra-low failure rate of 10^{-9} per operating hour therefore requires billions of operating hours without a single failure (Butler and Finelli 1993; Kalra and Paddock 2016a). Deciding what target rate is acceptable in the first place is an engineering and societal judgment that empirical testing cannot make on its own (Koopman 2022).

A sound safety case bridges this gap with deterministic architectural warrants. Rather than betting physical safety on policy generalization, the system grounds its top-level safety claims in an independent permission path. That path evaluates the control barrier functions of section 12.5 to clamp actuator commands, and commands an assessed safe stop whenever a learned proposal approaches the boundary of the viable set $\mathcal{C}$. The architectural warrant narrows the claim rather

than escaping physical limits. The permission path protects only against monitored hazards that the actuators can arrest within the available stopping clearance. The learned proposer still needs its own operational argument to show task capability and handle unmonitored tasks. Recent standards formalize these complementary roles. ISO/PAS 8800:2024 adapts automotive safety lifecycles, data curation rules, and assurance arguments to AI components (International Organization for Standardization 2024b). The Assurance of Machine Learning in Autonomous Systems (AMLAS) framework supplies safety-case patterns for machine learning pipelines across autonomous systems (Hawkins et al. 2021). In this book's architecture, the permission path carries the safety argument for all monitored physical hazards. It anchors its formal claims to a rated watchdog and to the certified functions beneath it in the drives, the safety-rated laser scanner, and the arm's safety controller (section 16.3.4). The learned proposer's argument can then focus on operational availability and unmonitored mission tasks.

↪ How much an architectural shield's per-command guarantee dilutes into a system-level hazard rate is developed in section 18.3.2.

16.3.2 Contextual assumptions and the weakest link

A stopping test passed on clean, dry concrete under bright warehouse lamps can fail the first time the robot enters a dim aisle if the safety case never stated the lighting assumption behind its camera exposure time. Every physical measurement rests on ambient conditions, and moving the machine into a dimly lit aisle can lengthen camera exposure and observation age even when the mechanical brakes and tires behave identically. An assurance argument must state these contextual assumptions explicitly so that measurements gathered under one set of conditions are never credited outside their verified operating envelope.

When an operating assumption is left unstated, safety depends entirely on whether a downstream check happens to catch the resulting deviation. In the mobile manipulator's stopping budget, the warrant quietly assumes that warehouse illumination permits the navigation camera to operate at its nominal exposure. If dim lighting doubles that exposure time from 16 ms to 32 ms, the observation arrives 8 ms older than assumed (measuring exposure age from mid-frame). Left unchecked, this additional latency translates to 10.4 mm of extra travel at the robot's 1.3 m/s aisle velocity, consuming roughly 8 percent of the budget's 131.0 mm margin. On this machine the permission path's frame admission age check, the freshness test of the observation contract (section 8.8), rejects the delayed frames. Because an active chunk can execute only while its evidence and lease remain valid, the robot instead halts in an aisle where the design assumed it could run. The team meets the unstated lighting assumption as unexplained availability loss rather than as a collision, and what kept the blind spot from eroding clearance was a latency check that knows nothing about illumination. A design without that check would have spent the margin silently.

Assumptions that lack runtime monitors carry far greater danger. Mechanical drift in a camera mount can introduce steady-state calibration offsets while every frame passes freshness and timestamp validations. The safety case must explicitly link localization tolerances to calibration routines and physical inspection logs. Treating fresh telemetry as proof of accurate spatial calibration leaves that warrant unsupported.

↪ Premises that no sensor on the machine can observe, and the restrictions they force on a release claim, are developed in section 18.3.1.

A safety case is not an aggregate scorecard in which high performance in one branch compensates for a deficit in another. Benchmark accuracy on an object recognition dataset cannot offset an uncharacterized latency tail on a CAN FD (Controller Area Network with Flexible Data-Rate) bus, nor can millions of simulated training episodes compensate for missing brake-wear measurements. When every child claim is *required*, the argument is conjunctive, and it is no stronger than its weakest required premise. In practice it is usually weaker, because doubt across independent premises accumulates. For a stipulated probability model, let each event mean that one required premise is valid under its stated conditions, and let $p_1, \ldots, p_n$ be the assigned event probabilities. These are not finite-trial confidence levels and estimate neither this robot's measured hazard rate nor calibrated assurance confidence. Define the illustrative claim event C exactly as the conjunction of these independent events; its probability is their product:

$$\Pr(C) = \prod_{i=1}^{n} p_i. \tag{16.2}$$

If each of 10 required premises holds with assigned probability 0.99, the conjunction holds with only about 0.90, lower than any individual premise. The mobile base's stopping claim is conjunctive

in exactly this way. Surveyed clear distance, credible braking deceleration, brake onset latency, observation age, and localization and tracking tolerances all enter a single stopping budget. A flawed warrant in any single term invalidates the root claim, regardless of how thoroughly the other terms are documented. An assessor therefore looks to the least supported required premise and the number of premises sharing the claim, not to the gross volume of supporting documentation.

This conjunctive degradation has one principled engineering exception. An argument can support a claim through two *independent* legs, either of which suffices on its own, so that the claim fails only if both legs fail simultaneously (Bloomfield and Littlewood 2003). In a separate stipulated model, define C exactly as the union of m independent sufficient-leg events with assigned probabilities $r_1, \ldots, r_m$. The event holds unless all legs fail:

$$\Pr(C) = 1 - \prod_{j=1}^{m} (1 - r_j). \tag{16.3}$$

If each of two independent legs holds with assigned probability 0.90, the combined claim holds with roughly 0.99, well above either leg alone. The equality describes the stipulated event model. If sufficient-leg events merely imply a broader physical claim, their union probability supplies a lower bound rather than automatically equaling the probability of that claim. The third law, *proposal is not permission*, instead supplies a conditional architectural argument: a policy error alone cannot breach a monitored stopping or contact invariant while the qualified enforcer, plant, sensing, timing, and fault premises hold. Policy validation and per-tick permission checks together do not justify assigning independent probabilities to their success.[3] Claim C5 in table 16.2 requires evidence that shared processors, memory buses, power rails, or sensor pipelines cannot compromise the permission path under the credited fault and interference model. Such isolation evidence addresses common causes within its qualified scope; it does not alone establish every statistical independence assumption. If the event independence is unsupported, the two-leg probability calculation is unavailable; shared causes must be represented explicitly in the argument. The enforcer leg is itself conjunctive across its own physical premises, because claims C1 through C4 must all hold for the enforcer to function. Diverse legs protect against policy failure; they cannot make up for unmeasured brake physics or missing timing margins, so the reviewer must check every leaf against the actual plant.

[3] **Independence of Diverse Legs**: When independently written versions of a software specification were evaluated on identical inputs, they failed coincidentally far more frequently than independent failure models predicted, statistically rejecting the independence assumption (Knight and Leveson 1986). Design diversity does not by itself yield independence in failure.

16.3.3 Matching the argument to the machine

Flawless arithmetic on assumed braking and latency numbers proves only that the robot would stop in time if the numbers were true; it says nothing about whether the physical machine on the floor actually meets them. While analytical stopping models relate brake onset, deceleration, sensor age, and tracking error cleanly on paper, an equation is only as sound as its physical inputs. A release reviewer must check which parameters come from measurements on the production hardware and which remain unverified design assumptions.

For collaborative manipulation tasks, biomechanical thresholds govern the contact force argument once the claim explicitly details the target body region, contact classification (transient vs. quasi-static), pressure distribution, impact geometry, and measurement methodology (International Organization for Standardization 2025b). The mobile base's claims, which form the core of the release argument, derive directly from empirical stopping distance budgets and site survey logs. Two conceptual frameworks borrowed from automotive engineering organize the fault analysis. Functional safety mitigates hazards arising from hardware malfunctions or systematic software defects (International Organization for Standardization 2018). In contrast, Safety of the Intended Functionality (SOTIF) addresses hazards stemming from performance insufficiencies or specification gaps in the absence of hardware faults, such as an obstacle detector failing to recognize a worker partially obscured by shrink-wrapped pallet staging (International Organization for Standardization 2022). Every leaf of the release argument requires support appropriate to its premise: qualified plant and timing observations, justified analysis, or validated operating restrictions under explicit assumptions. The formal standards governing these subsystems are machinery safety standards, mapped in section 16.3.4 to each component.

The claim-argument-evidence scorecard in table 16.2 defines six core release claims, pairing each physical warrant with its adjudication against the evidence developed in this book. Claim C3 shows how a warrant fails. An unnoticed oil slick on a polished concrete floor destroys wheel traction

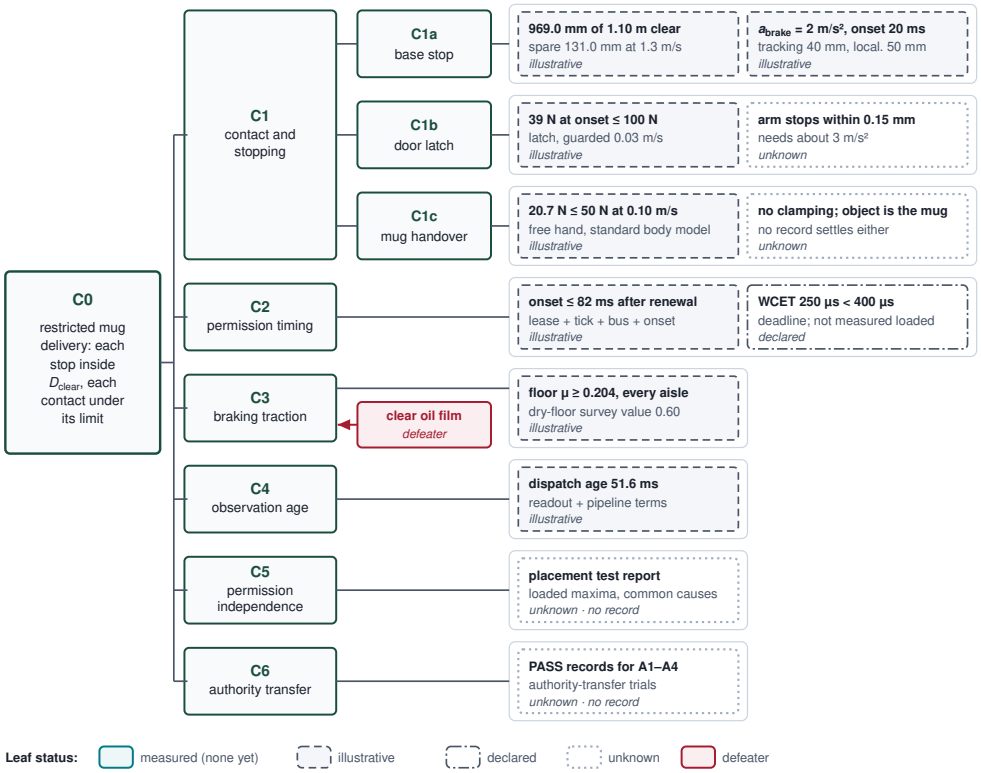


Figure 16.1: The release argument as a graph: The top claim C0 decomposes into the six claims of table 16.2, with C1 split into the base stop, the door latch, and the mug handover. Each leaf is a premise with its value, and its outline marks the status of its evidence. Every leaf is illustrative, declared, or unknown, none is measured on the proposed configuration, and the clear oil film attacks C3 directly, so the graph as drawn supports only `REFUSE`.

and invalidates the nominal deceleration model. A physically realizable condition that invalidates an assurance warrant in this manner is a **defeater** (Goodenough et al. 2013). Adversarial safety review hunts for these defeaters (section 16.7). Similarly, Claim C6 depends strictly on test records validating the four supervisory authority handoff rules (A1–A4) established in section 14.8.2. Drawn as an assurance DAG (figure 16.1), the argument splits C1 into its three physical scenarios (base stop, door latch, mug handover), ends every branch in a premise leaf whose outline records the maturity of its evidence, and attaches the oil-film defeater directly to C3. Because no leaf has been measured on the loaded production configuration, every row of the scorecard evaluates to `REFUSE`, the verdict that grants no operating permit and commands an assessed stop or hold (section 16.4). Section 16.6 works through why, branch by branch.

Table 16.2: Claim-argument-evidence review for the warehouse mobile manipulator: Six claims and their adjudication on this book's evidence. Displayed stopping distances and waiting allowances are partial calculations; admission work, physical response, and required reserve must be charged at their own events. A failed or unknown branch cannot be compensated by nominal model accuracy.

Claim	Warrant and operating assumptions on the machine	Adjudication on the book's evidence
C1. Contact and stopping	Base: partial budget of 969.0 mm before dispatch-to-admission delay, at 1.3 m/s (table 12.1) inside the 1.10 m clear distance to a person standing at the rack end, with the payload untested at 368 kg an open premise; Door: latch force of 39 N at physical braking onset, with the arm stopping within a further 0.15 mm (about 3 m/s^2) under the 100 N limit; Mug: picked from the conveyor under the 1 m/s tool center point (TCP) limit on tracked intent and handed to the coworker at 0.10 m/s, under the derived 0.24 m/s transient-contact ceiling, with a contact force of 20.7 N under the 50 N criterion for a free hand, a handover geometry that excludes clamping, and the grasped object taken to be the mug the task names	`REFUSE`: credible deceleration, brake onset, tracking and localization error, and arm deceleration are illustrative; the hand body model is a standard's population value, not a measurement of this contact; the no-clamping and grounding premises are unknown
C2. Permission timing	Brake onset no later than 82 ms after the last valid renewal; enforcer WCET of 250 µs inside the 400 µs deadline; declared assumptions: the claim covers only faults the permission path survives, lockstep diagnostics cover the path's own failure (section 13.2), and the INHIBIT rung of the fallback ladder is credited with no stopping distance, so the claim rests on the powered STOP rung (section 12.9.1)	`REFUSE`: the declared WCET lacks supporting architectural analysis and loaded stress evidence
C3. Braking traction	Optimistic all-weight friction screen of 0.204; qualified loaded stopping at the maintained friction floor is also required; a clear oil film is the defeater	`REFUSE`; the open premise passes to section 18.3.3
C4. Observation age	Navigation-camera dispatch age of 51.6 ms; evidence continues aging through admission and execution, with event-specific thresholds and a stale-data fallback	`REFUSE`: the age chain is illustrative
C5. Permission independence	The placement record combines a justified execution bound with loaded stress tests whose observed maxima stay within the declared 250 µs WCET, and so below the deadline, and common causes are tested (section 13.8)	`REFUSE` until the placement test report exists
C6. Authority transfer	One writer per actuator channel; no source bypasses a higher authority tier or the permission check; an unacknowledged handover falls back by the clearance-derived T_{timeout} of section 14.2.4 (partial allowances before Δ_{da}: 751.6 ms at the preliminary 0.75 m/s in-loop screen, 100.8 ms for a request at 1.3 m/s; because neither moving screen is a signed limit, the operative design stops the base before handing over); invalid authentication rejects the new packet without revoking an otherwise valid active owner (section 14.8.2)	`REFUSE` if any of A1–A4 lacks a `PASS` fault record (section 15.11.1); restrict to local operation if only the remote-channel cases fail

DRAFT

Checkpoint 16.1: Safety case decomposition and warrants

Before presenting a safety case for adjudication, test its structure:

- ☐ **Top-level claim falsifiability**: Can you state the top-level claim as a falsifiable physical proposition, such as a stop inside the clear distance, rather than an aspiration?
- ☐ **Warrant validity**: Can you name the warrant connecting each test bench to the claim above it, and the premises under which that warrant holds?
- ☐ **Defeater enumeration**: Can you show where a defeater such as lens fouling or bus arbitration collisions appears in the argument graph?
- ☐ **Evidentiary provenance**: Can you trace each empirical evidence node to its signed test trace and current calibration, and each analytical or procedural node to its retained derivation, assumptions, or accountable procedure and validation?

The scorecard enforces a strict separation between physical safety requirements and the empirical records available to substantiate them. Even when every internal warrant is traced to a hardware measurement, however, an engineering team does not choose its own risk-reduction hierarchy or protective ratings in a vacuum. The release reviewer must keep this evidentiary discipline across the

entire assurance tree while verifying which external machinery and regulatory standards govern each branch.

16.3.4 The standards map for the running machine

Certifying an industrial mobile manipulator against road-vehicle standards, or against fixed-arm standards that ignore a moving base, leaves the hazards of a moving arm on a moving base uncovered. Before authorizing deployment, an assessor must establish which formal standards and regulations govern each subsystem and verify where the corresponding evidence was gathered. Because this running machine is an industrial mobile manipulator rather than an autonomous road vehicle, its formal certification path follows industrial machinery directives rather than automotive standards. ISO 12100 sets the overall risk-management framework. The engineering team identifies hazards, evaluates risk, and applies a three-step reduction hierarchy, with inherently safe design first, engineered safeguards second, and user warnings and operating procedures last (International Organization for Standardization 2010). Every standard in table 16.3 addresses a specific tier of this hierarchy. Autonomy and automotive standards enter as borrowed engineering methods, supplying vocabulary for learned policies, distribution shifts, and assurance cases that traditional industrial standards are only beginning to adopt.

Table 16.3: Standards map for the warehouse mobile manipulator (as of 2026): Each document, its edition, what it governs, the part of the running machine it covers, and the section that produces the evidence it asks for. Machinery standards form the certification route; the road-vehicle and autonomy documents are borrowed method. Editions and dates change; a later printing should refresh this table.

Regulation (EU) 2024/2847 (European Parliament and Council of the European Union 2024b)	Applies from 11 December 2027	Cyber Resilience Act: cybersecurity requirements for products with digital elements, vulnerability handling, security updates	The update channel, the signed images, and the fleet's vulnerability reports	section 16.9.1

Two standards in the map require a clear boundary because the running machine straddles mobile robotics and fixed manipulation. ISO 10218-2:2025 governs industrial robot systems and collaborative work cells, but it explicitly excludes the kinetic hazards introduced when a manipulator rides on a mobile platform (International Organization for Standardization 2025b), which is this warehouse machine's configuration. Conversely, ISO 3691-4 treats the mobile base as a driverless industrial truck. The standard that bridges this gap by treating the mobile manipulator as a single unit is ANSI/A3 R15.08. Mounting an active manipulator on a mobile platform classifies the machine as an Industrial Mobile Robot (IMR) Type C, and Part 2 sets the safety requirements for integrating that combined unit into an active facility (Association for Advancing Automation 2020, 2023). In jurisdictions where

DRAFT

R15.08 lacks statutory standing, the combined hazards of mobility and manipulation fall back onto the machine's primary ISO 12100 risk assessment.

A second boundary concerns which layers of the permission path carry formal safety ratings. As section 12.9.3 established, the only rated function within the permission path is the safety MCU's lease-expiry and heartbeat watchdog, which asserts Safe Torque Off (STO) or Safe Stop 1 (SS1) on the motor drives when valid renewals cease. The admission checks that evaluate neural proposals carry no rating. The certified functions of the motor drives, the safety-rated laser scanner, and the arm's safety controller sit beneath the permission path. For release, the formal protective claims for every monitored hazard therefore rest on that watchdog and that certified layer. The release argument still uses the software admission checks for operational utility and nominal hazard prevention, but any hazard claim that depends only on unrated software remains an empirical premise rather than a certified safety function.

Statutory compliance reaches physical AI through product-safety law rather than through standalone artificial intelligence rules, and its sharpest consequence for release concerns updates. Under the European Union's Machinery Regulation (European Parliament and Council of the European Union 2023), a *substantial modification* is any physical or digital change made after deployment that the original manufacturer did not foresee and that introduces a new hazard or raises an existing risk enough to require additional safeguarding. An organization that pushes an unverified over-the-air model update can therefore become, in law, the manufacturer of the modified machine, with every obligation that role carries (section 16.9.1). The same regulation requires third-party conformity assessment[4] for machinery whose safety components have fully or partially self-evolving behavior and use machine learning to execute safety functions, so a learned safety function cannot be self-certified. Its essential requirements also constrain learning directly. The limits of each safety function must be documented in the manufacturer's risk assessment. No rule or parameter the machine generates, even during a learning phase, may change those limits where the change could create a hazardous situation (Annex III, section 1.2.1). Keeping the learned proposer outside the permission path meets that requirement only if the safety argument does not depend on the proposer's learned behavior. Two neighboring acts reach the same machine. The EU AI Act, Regulation (EU) 2024/1689 (European Parliament and Council of the European Union 2024a), as amended in July 2026 by Regulation (EU) 2026/1744 (European Parliament and Council of the European Union 2026), places the Machinery Regulation in Section B of its Annex I, so AI-specific safety rules for machines arrive through the machinery framework. The Commission must adopt delegated acts that insert those rules into the Machinery Regulation's Annex III and that apply by 2 August 2028. Because the robot receives network updates, it is also a product with digital elements under the Cyber Resilience Act (European Parliament and Council of the European Union 2024b), which requires vulnerability handling and secure updates throughout the manufacturer's support period, at least five years unless the product is expected to be in use for less. Its duty to report actively exploited vulnerabilities applies from 11 September 2026, ahead of the rest of the act. Table 16.3 lists the dates from which the other obligations apply. These milestones do not alter the underlying physics or systems engineering; they set the calendar dates by which statutory authorities will demand an inspectable assurance case.

The standards map also marks the boundary between statutory obligations and the systems architecture developed in this book. Formal standards prescribe documented arguments, rated protective functions, and independent third-party assessments. The verdicts, signed capability descriptors, and release manifest developed in the rest of this chapter are one engineering architecture for carrying those obligations into the runtime system. The safety case accepted before deployment then stays binding on the machine long after the inspectors have left the floor.

[4] **Conformity Assessment**: The formal procedure through which a manufacturer certifies that a machine fulfills all essential health and safety requirements before affixing the CE marking (European Parliament and Council of the European Union 2023). While manufacturers may self-assess conventional machinery, high-risk systems and self-evolving AI safety components require third-party evaluation by a notified body. Because the conformity assessment path is fixed before market entry, every record in the release manifest must be formatted for independent inspection.

16.4 The Three Verdicts

Treating a release sign-off as an informal paper memo forces teams either to ground a useful machine over an unmeasured corner case or to wave it onto the floor with unproven assumptions. Every row of table 16.2 ends in an adjudication, and the release decision resolves the entire assertion DAG into one of three verdicts: **unconditional operation**, **conditional operation**, or **refusal to operate**. In this book's architecture, these verdicts are cryptographically signed capability descriptors loaded into the real-time safety microcontroller before motor power stages are energized, not advisory certificates or administrative paperwork. A valid descriptor is the machine's **operating permit**:

while it holds, the permission path may admit the policy's tracking commands inside the envelope the descriptor names, and when it is revoked or absent, the permission path admits none. Although safety standards do not mandate this specific mechanism (section 16.3.4), the qualified gate and permission path enforce the authenticated descriptor's limits on physical operation. The first verdict, unconditional operation (`UNCOND`), authorizes tracking proposals across the full operating envelope specified in a signed release manifest, provided its standing conditions remain continuously verified. Each hazard claim in that safety case requires qualified measurements, justified analysis, or validated operating restrictions applicable to the specified physical plant, payload distribution, operational design domain, and fault set. Brake thermal capacity, stopping clearance, and tracking-error bounds must all be qualified for that envelope, and independent permission checks must stand wherever learned policy proposals can reach physical actuators. The verdict does not eliminate residual or newly emergent hazards; it authorizes operation solely under the assessed claims and requires detection and safe withdrawal within the qualified response budget whenever a physical premise fails.

Definition 16.2: Release verdict

Release verdict is the signed decision that sets how much authority a named machine's permission path may grant: `UNCOND` for the full assessed operating envelope, `COND` for a separately evidenced restricted envelope, or `REFUSE` when any required premise is missing, contradicted, or unknown, in each case only while its standing conditions hold.

1. **Significance**: It turns the weakest premise of the argument into the machine's operating limit on $d_{\text{stop}} \leq D_{\text{clear}}$. On this book's illustrative evidence every claim carries an unknown premise, so the warehouse machine's verdict is `REFUSE`. A stipulated set of loaded stopping and floor records would support a `COND` at 1 m/s on inspected floors, below the 1.23 m/s optimistic all-weight partial ceiling.
2. **Distinction**: A test result records the outcome of an individual trial, whereas a degraded mode is an autonomous runtime fallback triggered during execution. By contrast, a release verdict is established before deployment: it names the qualified envelope and the empirical evidence upon which it rests, while leaving the proposal boundary fixed, since the permission path continues to validate every proposed action individually.
3. **Common pitfall**: A common misconception is that a conditional verdict (`COND`) can patch an incomplete safety case by ignoring an unproven claim. A restricted envelope instead demands its own dedicated evidence and analytical limits; an unresolved premise in the primary case leaves that operating mode firmly refused.

16.4.1 Restricted operation and access boundaries

When a safety case lacks evidence for full-speed aisle travel or open-floor contact, letting the robot run under an informal operating note leaves the permission path enforcing the wrong limits. The second verdict, conditional operation (`COND`), applies when empirical evidence supports the stated hazard claims within a restricted subset of the envelope and binds the permission path to those narrower limits. In the running machine, `COND` selects a pre-validated safety configuration, much like industrial safety controllers and protective optical scanners switch between pre-validated field sets[5] and speed-monitoring profiles. All restricted kinematic thresholds ($v_{\max} \leq v_{\text{restricted}}$, $a_{\max} \leq a_{\text{restricted}}$) and spatial geofences are evaluated and validated as one configuration before release; the runtime verdict selects among these vetted profiles rather than inventing parameters on the fly. A conditional verdict (`COND`) is an offline, predeployment contract that restricts the machine's operating envelope until re-adjudication. A **degraded mode** is an online runtime fallback, pre-assessed and named in the signed release, that the permission path invokes when an active subsystem loses telemetry or sensor redundancy (section 16.5.3 sizes one for the base). Release then enforces physical, kinematic, or environmental boundaries that exclude unverified hazard states, such as de-rated joint speeds, a restricted illumination range, or a physical barrier that keeps humans outside the manipulator's workspace. Where contact force cannot be bounded for unseparated co-presence, a restricted release case may require physical separation: figure 16.2 illustrates yellow perimeter mesh fencing around

[5] **Safety Scanner Field Sets**: A safety laser scanner stores several protective-field geometries that were configured and validated in advance, and a safety controller selects one of them from encoded speed or position inputs. The scanner never computes a new field at runtime. `COND` borrows the pattern, so the verdict selects a pre-assessed limit set and no untested parameter can reach the permission path.

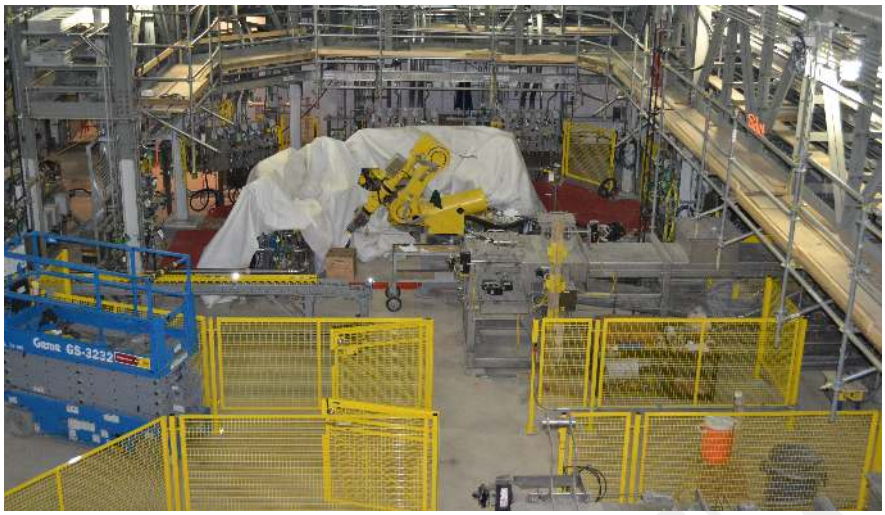

Figure 16.2: Physical separation example: A yellow industrial arm works behind yellow mesh fencing. Fencing can be one condition of a restricted release when a validated access interlock and stopping test support it. (Credit: PEO ACWA, Pueblo Chemical Agent-Destruction Pilot Plant, 2012, Wikimedia Commons, CC BY 2.0.)

an industrial workcell. Crediting that separation requires validated access-interlock and stopping evidence showing that the protective response completes before hazardous access.

Fencing excludes unseparated contact by keeping people out of the hazardous volume. The alternative that lets people share the floor, speed and separation monitoring (SSM, section 12.9.3), needs a different access claim from the stationary-person stopping claim of C1. Its separation clearance must account for human approach velocity across both system reaction time and physical deceleration, robot displacement before brake onset, the executed braking profile, and measurement uncertainty. The warehouse case retains its site crossing rule; engineering teams cannot substitute a stationary-person stopping model into this context and claim to have achieved unseparated, open-floor human-robot collaboration.

Every quantitative condition attached to a release verdict names the operational limit the permission path enforces, maintaining explicit margin below the calculated physical ceiling. Item handover illustrates this margin requirement. The contract signs a TCP speed below the absolute ceiling that the contact criterion admits under equation 12.13. The gap between these two speeds accounts for unobserved physical evolution between discrete sensor samples: velocity growth between sampling instants, encoder quantization noise, and drive lag during an enforcement clamp. A contract signed at the theoretical ceiling leaves zero margin for these physical latency terms, and the release case requires measured empirical bounds on each term before the signed operational speed can be accepted.

The inspected-floor condition follows the same discipline. Where the site inspection regime certifies a friction coefficient of only 0.12, the illustrative all-weight-on-driven-wheels screen uses the optimistic traction ceiling $\mu g = 0.12 \times 9.81\ \mathrm{m/s^2} = 1.18\ \mathrm{m/s^2}$ against the $2\ \mathrm{m/s^2}$ that the dry-floor budget assumes. Actual loaded credible deceleration also depends on the driven-wheel load share, drive and geometry conditions, and qualified stopping traces. Under the all-weight screening premise, the partial budget that admits 1.44 m/s on surveyed floors admits only 1.23 m/s under this reduced traction. Visual inspection alone cannot establish this lower friction bound because a thin film of transparent oil readily escapes visual detection. The site must qualify both the friction assessment method and the operating procedures (cleaning schedules, spill isolation, and access restrictions) that preserve the assessed floor state between inspections. If that maintenance regime cannot guarantee the exclusion of contaminants over the authorized operating interval, reducing vehicle speed does not salvage the safety case; the aisle remains refused.

The third verdict, refusal to operate (`REFUSE`), is mandatory whenever the safety case has missing warrants, uncharacterized tail latencies, incomplete fault-injection coverage, or unmonitored failure

modes. For systems where torque removal causes immediate physical harm (such as upright bipedal humanoids falling under gravity), `REFUSE` cannot simply de-energize motor phases to zero torque; it must execute an assessed, powered descent or seated hold. If the safety enforcer's worst-case execution time under the designated computational placement has never been verified against its 400 µs deadline, or if the fault-injection campaign omitted common-cause failures identified in the deployment topology, the hazard remains unquantified and cannot support release. Refusal is likewise mandatory whenever physical measurements contradict the mathematical model behind a safety budget term, such as loaded stopping trials that yield decelerations below the 2 m/s^2 assumed by the braking model.

A refusal verdict is an actionable engineering result rather than an administrative dead end. It redirects schedule pressure toward evidence by pointing to the exact broken link in the assertion DAG. If release is refused because loaded stopping trials contradict the braking model, the engineering team does not debate risk tolerance. Developers instead repeat physical braking trials at maximum payload mass until the qualified trial campaign and its uncertainty analysis support a credible lower deceleration bound. They then re-derive the stopping budget from that lower bound and submit for re-adjudication only when the aisle budget closes on validated data. The refusal verdict names the exact empirical test that must pass before re-adjudication can proceed.

Accountability for the release decision must rest with a named **lead systems adjudicator** rather than being split across development teams. When a vision team signs off on perception metrics, an actuator supplier on torque ratings, and a machine learning team on policy convergence, each group can assume that another layer holds the safety margin. The lead adjudicator alone attests that the integrated, physical machine satisfies the safety case. This sign-off binds the release verdict to a specific set of technical records: cryptographic digests of verified policy weights, calibration logs for manipulator contact-force sensing, empirical brake-onset measurements paired with justified worst-case response bounds, and fully loaded stopping trials establishing credible deceleration limits. The adjudicator signs the release manifest with a private key held inside a hardware security module,[6] binding the manifest to the organization's signing key and sign-off record. The robot runtime checks this digital signature against a public key anchored in its hardware root of trust before enabling actuators.

[6] **Hardware Security Module (HSM)**: A tamper-resistant device can generate and retain a non-exportable private key and perform signing inside its own boundary. The signature identifies the signing key; authenticated access, sign-off records, and key-custody controls establish who authorized its use.

↪ The adjudicator's signature as one of several decisions behind each admitted action, each needing a named owner, is developed in section 17.2.

The adjudicator's signature records the internal acceptance of the engineering organization, whereas external certification requires independent evaluation. UL 4600 requires independent assessment of the autonomous safety case (UL Standards & Engagement 2023), and machinery whose primary safety functions rely on machine learning falls under regulations, such as the European Union Machinery Regulation, that require third-party conformity assessment (section 16.3.4). An assessor who did not build the safety case brings an independent view to the assumptions that shaped its trade-offs. Organizational separation alone does not establish a probability of coincident error or the statistical independence required by equation 16.3. The release manifest must therefore retain the full body of raw physical evidence needed for an independent audit, not just the final verdict.

The adjudicator ultimately signs one of the three decisions summarized in table 16.4. A conditional verdict requires its own independently evidenced restricted envelope; an unresolved gap in the nominal argument cannot be relabeled as an operational constraint. No verdict ever moves the proposal boundary. Under both `UNCOND` and `COND`, learned policies only propose candidate actions while the deterministic safety enforcer independently admits or blocks every control command, as principle 3 requires. The release verdict sets the physical envelope that the permission path enforces; it never grants learned policies unchecked authority.

Table 16.4: Three signed release verdicts for the mobile manipulator: Full operation and restricted mode both retain independent per-action permission. Refusal is an actionable engineering result.

Signed verdict	Evidence required	Permission and runtime limits	Expiry or refusal trigger
`UNCOND`	Full operating-envelope claim, measured plant and timing bounds, independently validated permission and fallback	Policy proposes across full *signed* task envelope; every action passes the enforcer	Evidence, configuration, calibration, or standing premise fails

Signed verdict	Evidence required	Permission and runtime limits	Expiry or refusal trigger
`COND`	Restricted operating-envelope claim and its own evidence, limits, and fault coverage	Policy proposes only within signed reduced limits; every action passes the enforcer	Any restricted premise becomes false or unknown
`REFUSE`	Missing, contradictory, expired, or unauthenticated critical evidence	No operating permit; execute the assessed stop or hold, the fallback-ladder rung the release case validates for the plant	Re-adjudication with repaired evidence

Each verdict in table 16.4 is signed against the physical state of the machine at the moment of evaluation. The right-hand column of the table therefore pairs every operational grant with an explicit expiry or refusal trigger, because a brake lining or sensor mount that passed inspection before commissioning does not stay in its commissioning state. As the physical plant wears and drifts over time, a release verdict holds only while runtime checks, scheduled measurements, and enforced site procedures continue to verify its standing premises.

16.5 The Verdict's Standing Conditions

A signed release can lapse without any change to the underlying software. Brake linings wear down, camera brackets shift under continuous vibration, or warehouse traffic polishes concrete lanes until traction drops. When these physical premises drift, the stopping claim certified by the adjudicator no longer holds. Standing conditions bind the operational verdict to these physical baselines by defining an explicit observation cadence for each premise alongside deterministic fallback responses when a check fails. Because failure modes originate in hardware and environment, their observation schedules must follow physical degradation mechanisms rather than software sprint schedules. An assurance case maintained this way, its validity updated throughout operating life as monitored evidence shifts, is what the safety literature calls a *dynamic safety case* (Denney et al. 2015).

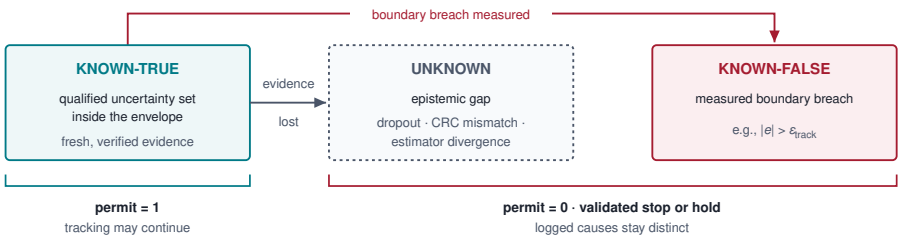
16.5.1 Degradation, drift, and observation cadence

None of the three verdicts is a permanent grant. Mechanical linkages develop backlash, friction surfaces wear, optical lenses collect dust, and operating environments change. Operating under either an unconditional (`UNCOND`) or conditional (`COND`) verdict therefore carries continuous obligations for the life of the deployment. Notebook 16.1 shows how little wear the stopping claim tolerates. A credible deceleration 31 percent below the assumed 2 m/s^2 spends the whole partial spare, and a smaller loss spends the reserve that remains once admission work is charged, leaving no allowance for perception latency or traction variation. A lining that wears that far is discovered at a rack end as an overrun unless the degradation first trips a standing condition, such as a scheduled loaded deceleration trial or an automated pre-shift brake diagnostic, before the machine is cleared to enter the aisle. Every operational obligation pairs a physical premise with an automated detector and an immediate mitigation, establishing a standing condition tied to the release verdict.

Sensor mounting drift can silently invalidate localization while every camera frame stays sharp and fresh. Daily thermal cycling and machine vibration alter extrinsic sensor geometry, and software rollback cannot realign a physically displaced bracket. The safety case must therefore require qualified online drift detection or scheduled physical recalibrations, setting inspection intervals from the underlying mechanical wear rates. A cryptographic checksum confirms only that the stored calibration file matches its build artifact; it gives no evidence that the physical camera still sits at that modeled pose.

A release verdict depends on physical premises with widely differing observation schedules. For instance, the mobile manipulator's optimistic all-weight traction screen requires a floor friction coefficient of at least 0.204; the braking claim additionally requires qualified loaded wheel forces, drive conditions, and stopping traces. Dry concrete exceeds this threshold by a wide margin, at roughly 0.60, but a baseline site survey conducted before commissioning cannot guarantee surface conditions against fluid spills or traffic polishing over time. The safety case must therefore specify routine floor maintenance schedules alongside strict exclusion rules whenever surface contamination occurs, supplemented by any onboard traction monitoring. Similarly, the arm's contact-force sensors require periodic recalibration against reference loads. Every physical premise must be rechecked

continuously or periodically at a cadence matched to how fast it degrades. This is the fourth law, *permission must be earned* (principle 4), applied over time. The verdict grants permission contingent on operating conditions, and that permission endures only while the evidence supporting each premise remains valid.



Every runtime-monitored premise requires a dedicated detector and a pre-allocated fallback response; conversely, premises governed by facility maintenance require accountable operators and enforceable exclusion rules. If a safety case credits a navigation-camera dispatch age of 51.6 ms, the runtime monitor must measure frame arrival latency against hardware clocks, accounting for sensor readout and transport delays separately. Forwarding an unverified metadata timestamp does not confirm that the frame is fresh. Without hardware-synchronized event timestamps, unverified inputs quietly turn safety premises into ungrounded assumptions. Different premises demand different sampling frequencies. The tote-rack load, bounded by its 50 kg mechanical payload limit, can be checked at each load-changing event if access controls exclude unrecorded loading and the check completes before the changed load receives motion authority. Conversely, base velocity, position tracking, and action lease validity must be evaluated deterministically on every 1 ms safety-enforcer tick.

16.5.2 The envelope trichotomy and epistemic gaps

A naive binary health check assumes normal operation whenever no explicit error flag is asserted, mistaking a dead sensor or a diverged filter for safe clearance. Checking monitored premises at runtime instead exposes three states of **envelope membership**: known-true, known-false, and unknown. Membership is *known-true* when authenticated telemetry and hardware-referenced timestamps confirm that the plant's bounded state-uncertainty set remains strictly inside certified envelope boundaries. Estimator convergence or small covariance matrices alone do not prove containment if model assumptions have broken down. When measured telemetry reveals a physical boundary violation, such as base tracking error exceeding the 40 mm bound reserved within the stopping envelope, the state is *known-false*. Finally, when an optical encoder loses serial communication, a camera frame fails its cyclic redundancy check (CRC), or an extended Kalman filter diverges, the system enters an *epistemic gap*. In this *unknown* state, the controller cannot tell whether the physical machine is safely positioned or breaching clearance margins.

When telemetry supporting active motion becomes unknown or known-false, the safety enforcer revokes trajectory tracking and executes the pre-certified fallback procedure for the plant's dynamic state. This runtime intervention differs from rejecting an invalid future trajectory proposal, because an already active trajectory chunk can continue executing only while its supporting sensor evidence, physical bounds, and lease duration remain intact. The system's flight recorder must log whether revocation stemmed from unobservable state telemetry or an active boundary breach, while the hardware supplies enough reserve energy and sensing capability to bring the plant to a controlled stop or hold.

Definition 16.3: Envelope trichotomy

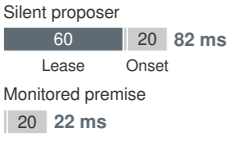
Envelope trichotomy is the three-state epistemic classification of cyber-physical system health relative to its signed operating envelope: *known-true* (qualified state-uncertainty set contained inside the supported envelope), *known-false* (verified boundary violation triggering deter-

ministic hardware refusal), and *unknown* (state uncertainty caused by sensor dropout, frame corruption, or estimator divergence).

1. **Significance**: An unknown state is not evidence of a boundary breach, yet neither condition permits continued tracking. The permission decision is refusal in both unknown and known-false states; the logged cause remains distinct and the response depends on the plant's validated stop or hold capability.
2. **Distinction**: Unlike a binary boolean status check (`is_safe == true`), the envelope trichotomy separates sensor blindness from active violations, ensuring telemetry loss is never mistaken for safe clearance.
3. **Common pitfall**: Treating a stored command as indefinitely valid after communication fails. An active chunk may continue only within its own still-valid evidence and lease; otherwise the assessed fallback must take over.

The same three-state distinction applies to verification test records. A test trial marked `UNOBSERVABLE` or `INVALID` during acceptance testing (section 15.4.1) cannot establish the claim its required witnesses or test conditions failed to resolve. It leaves a gap in that coverage; other valid records remain evidence only for the conditions and claims they establish. Verified `PASS` records support the claims covered by their conditions and witnesses. A valid `FAIL` contradicts the claim tested under those conditions and withdraws any authorization that relies on it.

16.5.3 Blind travel, kinetic consequences, and cycle limits



When telemetry fails or sensors black out, a machine traveling without sensory feedback moves blind; it must execute a deterministic fallback stop before its forward travel consumes the remaining spatial clearance. How fast that clearance vanishes depends directly on vehicle speed, contact geometry, and available actuator authority. Sizing the response therefore requires calculating the kinetic energy and blind travel accumulated during each millisecond of delay, and matching each sensor loss to a pre-certified fallback path.

How the system responds when a premise cannot be checked must follow from the physics of unmonitored motion rather than from arbitrary severity categories. When the mobile manipulator traverses an aisle at 1.3 m/s with its tote rack fully loaded, its 368 kg mass carries 311 J of kinetic energy. If its primary lidar stops updating, every millisecond of blind travel carries the base 1.3 mm closer to potential obstacles. The safety case pre-certifies three possible fallback paths, two of which apply only when the signed release names them in advance. The first is a degraded mode that permits continued motion while diverse redundant sensors keep state uncertainty bounded, for example throttling the aisle speed to 0.65 m/s (half the aisle speed, a chosen value) while secondary sensors watch the path. The second is a switch to a restricted limit set that a signed `COND` case pre-validated for that exact sensor loss, if the release includes one. The runtime only selects that profile; it does not create a new verdict. Dead reckoning and wheel odometry may retain qualified position bounds over a brief window, but cannot verify obstacle clearance on their own. The third option, the hardware STOP response, handles complete loss of observability by executing a configured drive and brake sequence. Stopping the vehicle within available clearance margins requires calibrated response timing, sufficient drive traction, and known brake deceleration.

Action leases bound how long an admitted trajectory chunk may run without renewal. Checking this lease on every controller tick does not require re-measuring every long-term site condition. Instead, the runtime permission path checks fresh local sensor telemetry alongside the signed validity windows of slower site inspections and maintenance records. If the proposer stalls or its communication drops, task throughput suffers, but safety holds as long as the enforcer and its fallback path remain decoupled, responsive, and intact.

Any standing condition governing physical motion requires an enforcement path with a measured detection and response budget. In this book's architecture, an independent safety enforcer checks trajectory proposals and monitored premises before issuing actuator permissions, re-evaluating system state on every 1 ms control tick. A subsystem failure reaches this enforcer along one of two paths: a silent proposer that stops transmitting is caught only when its existing action lease expires,

whereas an actively monitored hardware fault raises an immediate interrupt flag. Because detection delays differ between these paths, so does the distance the base travels blind (notebook 16.2).

The lease dominates: a silent proposer reaches brake onset in 82 ms, a flagged premise in 22 ms.

Napkin Math 16.2: The silent-proposer window

Problem: The base runs the aisle at 1.3 m/s. How far does it travel before brake onset when the proposer falls silent, how far when a monitored premise fails and its flag reaches the enforcer at once, and how late may that flag arrive before monitoring stops the base no sooner than the lease would?

Variables:

- Aisle speed $v = 1.3$ m/s (Chosen), so 1.3 mm of travel per millisecond
- Chunk lease 60 ms and permission tick 1 ms (Chosen); bus transfer 1 ms and brake onset 20 ms (Illustrative)
- Flag latency δ_{flag} from the physical failure to a flag the enforcer can read (Unknown; the detector's qualification must bound it)

Math:

1. **Silent proposer**: 60 ms + 1 ms + 1 ms + 20 ms = 82 ms, and 1.3 m/s × 82 ms = 106.6 mm.
2. **Monitored premise, immediate flag**: 1 ms + 1 ms + 20 ms = 22 ms, and 1.3 m/s × 22 ms = 28.6 mm.
3. **Crossover**: δ_{flag} + 22 ms = 82 ms at δ_{flag} = 60 ms, the length of the lease itself.

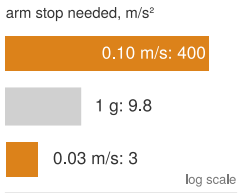
Result: Monitoring can save up to 78 mm of travel, but only for a flag that arrives within 60 ms of the failure; a slower flag stops the base no sooner than waiting out the lease.

Systems insight: The 22 ms local subtotal is not a complete detection-to-stop time; it reflects only controller cycle delay, communication transfer, and physical brake engagement. The decisive term governing whether an active monitor preserves physical clearance is δ_{flag}, the hardware detection latency. If an architectural budget fails to bound δ_{flag}, the safety case cannot claim proactive protection. Every millisecond spent detecting a fault carries the loaded vehicle another 1.3 mm toward whatever the failed premise was protecting against.

When an operating premise transitions to unknown or known-false, the enforcer revokes trajectory tracking and commands the appropriate rung of the fallback ladder, and the signed safety case must specify both this fallback selection and its measured timing. For the mobile base, the certified stopping sequence uses controlled, powered deceleration to bring the wheels to rest before applying electromechanical holding brakes. Because digital controller logic and brake-coil hold-up capacitors cannot deliver drive motor torque, the safety case must confirm drive energy, feedback sensing, and inverter continuity across every fault condition expected to use this active deceleration profile. By contrast, a raw torque-inhibit or free-wheeling cutoff is a different physical response; it cannot inherit stopping-distance guarantees calculated for controlled electrical braking.

Entering an unknown or known-false state also triggers local black-box logging. The onboard recorder must preserve the telemetry window leading up to refusal alongside the execution of the fallback trajectory, even if the initiating fault cuts external networking or primary bus power. These records are essential for root-cause investigation, but writing them to nonvolatile storage must never delay the hard real-time safety stop; section 16.9.5 sizes the capture path.

On longer timescales, even when every runtime heartbeat succeeds, the **release verdict** carries an operational cycle and inspection budget.[7] Operating hours and mechanical fatigue wear components in ways that high-frequency telemetry cannot observe directly (such as surface pitting on gear teeth, elastomer seal stiffening, or fastener preload relaxation). Once this cycle budget expires, the release case must be re-adjudicated before autonomous motion can resume. Across every timescale, a deployment verdict remains valid only while its supporting standing conditions remain demonstrably known-true, checked at intervals matched to physical wear rates and backed by pre-certified fallback stops with measured latencies. Claims, verdicts, and revocation conditions are



[7] **Mechanical Fatigue Budget**: A cumulative-damage model such as Miner's rule ($\sum_i n_i/N_i$) (Miner 1945) can organize a measured load spectrum against component-specific fatigue data; it is an approximation, not a universal failure deadline. The assessed loads, uncertainty, inspection evidence, and stopping consequences determine any signed payload derating and cycle limit. An expired limit revokes the applicable release case rather than silently extending service.

now defined. The six claims of the warehouse mobile manipulator can be adjudicated against the physical evidence assembled across this book.

16.6 Adjudicating the Safety Case

An algebraically exact stopping equation or contact-force bound still fails to protect a machine if the physical premise beneath its warrant has never been measured on hardware. Adjudicating a safety release case requires checking each warrant against the qualified measurements, justified analysis, or validated operating restrictions that support it. For the warehouse mobile manipulator, the adjudicator takes each of the six claims of table 16.2 in turn, names the physical premise under its warrant, and grades the evidence behind that premise. This isolates the exact boundary where mathematical deduction ends and physical measurement must take over.

The door-opening branch of C1 shows the procedure in full. The contact enforcement record supplies the branch's underlying mechanics (section 12.7.2). At the guarded approach velocity of 0.03 m/s, equation 12.11 yields an impact force at physical braking onset of 39 N, well below the 100 N latch limit. From there, equation 12.12 leaves the latch plate with only 0.15 mm of additional allowable compression. Bringing the arm to rest within this narrow mechanical travel requires a deceleration of approximately 3 m/s² over a brief 10 ms stopping window. By contrast, at the unconstrained approach velocity of 0.10 m/s, the force at braking onset rises to 95 N, and avoiding structural damage demands a deceleration of 400 m/s², more than an order of magnitude above standard gravity. While this kinematic calculation specifies the stopping performance required for release, mathematical derivation alone cannot prove that the physical arm actuators can deliver it. Consequently, the operating envelope (table 16.1) excludes the high-speed approach. Raising approach speeds sharply escalates contact braking demands, whereas the system's training demonstrations offer zero empirical evidence for safe high-speed contact (section 5.7.1).

Raising the approach from 0.03 m/s to 0.10 m/s multiplies the arm stop needed 136-fold.

Neither result is in doubt as arithmetic; the algebraic deduction is exact. Formal engineering release, however, cannot rest on closed-form kinematic models alone. The door branch fails authorization because its safety warrant depends on an unverified physical premise. Whether the physical manipulator, carrying its link momentum, payload mass, and reflected rotor inertia, can actually deliver 3 m/s² of deceleration within a fraction of a millimeter depends on transient joint torque limits, motor electrical time constants, and structural stiffness. Without calibrated hardware traces measuring these dynamic properties under load, this mechanical premise remains *unknown*, and the adjudicator must refuse the claim.

The remaining claim branches fail on similar grounds:

- **Base braking corridor (C1)**: The base stopping budget of 969.0 mm omits dispatch-to-admission delay and rests on illustrative values for braking deceleration, brake onset, path-tracking error, and localization uncertainty. Its remaining margin of 131.0 mm can be exhausted by the illustrative deceleration shortfall in step 4 of notebook 16.1, and step 5 leaves still less once admission work is charged.
- **Object handover (C1)**: The mug handover branch fails on three separate premises. First, the calculated contact force falls below the criterion only for an unconstrained, free-moving hand, and it comes from a standardized biomechanical body model rather than a force measurement of this contact. Second, the evidence packet does not show that the coworker's hand cannot be trapped against a rigid fixture, so the non-clamping geometry is unproven. Third, perceptual grounding remains unverified: a proposal that mistakes a clear glass jar for the target mug satisfies every geometric affordance check, and no trace in the runtime logs disambiguates the object.
- **Enforcer timing (C2)**: The timing warrant for the runtime safety enforcer assumes a worst-case execution time (WCET) of 250 µs against an unloaded baseline of 135 µs and a 400 µs deadline. The WCET is declared without architectural analysis and loaded stress evidence supporting it under peak memory bus saturation.
- **Traction and environmental state (C3)**: Claim C3 requires a qualified friction floor across every authorized aisle; 0.204 is only the optimistic all-weight traction screen, not a sufficient loaded stopping qualification. A clean concrete floor can be validated through baseline skid testing, but the onboard cameras cannot reliably distinguish dry concrete from a thin film of

transparent oil, and no sensor on the machine can exclude liquid contamination ahead of the braking contact.

- **Perception pipeline latency (C4)**: The 51.6 ms dispatch age combines nominal datasheet readout times with uncharacterized pipeline delays rather than verified end-to-end telemetry.
- **Permission independence (C5)**: The placement record's loaded test report, which would show the enforcer's maxima under the proposer's worst interference and test the common causes of section 13.2, is described in this book but not produced. Without it, the credited enforcement isolation is unsubstantiated; even supporting isolation records would not by themselves establish statistical independence of every failure event.
- **Authority transfer (C6)**: The argument cites `PASS` fault records for authority transitions A1 through A4, and no such records exist yet. Local operation could drop the remote-channel cases, but not the local ones.

Because every claim rests on at least one unverified physical premise, the adjudicator must render a verdict of `REFUSE`. This refusal does not imply that the robot is inherently dangerous. The book's supporting inputs are illustrative models rather than empirical validation logs, so the verdict is illustrative as well; it models how release is adjudicated and shows why ungrounded claims cannot license physical deployment. The fourth law, *permission must be earned*, requires an operational restriction wherever the available evidence cannot support a premise. Here, every branch contains an unverified premise. A principled refusal must therefore specify the exact measurements required to turn an unverified assumption into an accepted warrant. Table 16.5 lists these evidentiary requirements, naming the physical premise each measurement settles and the operational restriction a supporting result would lift.

↩ The four bedrock laws, the fourth of which holds that permission must be earned, are established in section 1.10.

Table 16.5: Measurements that would move the verdict toward `COND`: Each row names the premise a measurement settles on the warehouse mobile manipulator and the restriction a supporting result would lift; the inference trace bears on service availability only.

Measurement	Premise it settles (value in this book)	Claims	What a supporting result lifts
Stopping trials at the loaded mass	Low-tail credible deceleration (2 m/s^2)	C1	The base's budget and its 1.44 m/s ceiling, so an aisle speed can be signed
Brake-onset trials	Brake onset (20 ms)	C1, C2	The 82 ms bound from the last valid renewal to brake onset
End-to-end age trace	Dispatch age (51.6 ms) and subsequent evidence aging	C4	The age term of the budget and the stale-data threshold
Tracking-error and localization tails	Tracking bound (40 mm) and localization bound (50 mm)	C1	The inset and overhead terms of the budget
Site survey	Rack-end clear distance (1.10 m)	C1	A signed speed at each surveyed rack end
Floor survey	Dry-floor friction (0.60) against the 0.204 needed	C3	Assessed route only, with maintained contamination exclusion and loaded stops at the qualified friction floor; reduced speed alone cannot exclude oil
Inference trace	Chunk inference at the 99th percentile (40 ms)	None	Service availability: characterize renewal within the 60 ms lease; a percentile does not guarantee each renewal, and C2 depends on independent fallback
Loaded enforcer timing	Enforcer WCET (250 µs, declared)	C2, C5	The 400 µs deadline under the placement's worst load
Arm stopping trials	Arm deceleration from the guarded approach (about 3 m/s^2 needed)	C1	Door opening at the guarded approach
Handover force trials	Peak contact force at the handover speed (20.7 N derived for a free hand) and absence of clamping geometry	C1	Handing the mug to the coworker at 0.10 m/s under `accept_item`
Operator trials	Takeover and authority-handover timing	C6	Remote takeover, once A1–A4 each have a `PASS` record; otherwise local operation only

DRAFT

Neural network inference latency primarily governs system availability rather than baseline safety. An inference overrun will not violate physical containment so long as the independent hardware safety path and powered fallback controllers remain operational; however, repeated deadline misses will degrade throughput and stall task progress. Conversely, resource contention across shared memory, PCIe buses, or CPU caches that delays the runtime enforcer or starves its sensor feeds represents a direct safety failure under claims C2 and C5. Finally, while local autonomous operation can safely omit validation trials for unused remote teleoperation links, deployment still requires verified software placement records, comprehensive common-cause fault coverage, and passing test records for every local authority transition.

16.6.1 Worked restricted service with stipulated evidence

Without calibrated hardware measurements, the mobile manipulator remains locked out under a `REFUSE` verdict. To see how an engineering organization moves from initial refusal to conditional deployment without relaxing its structural safety limits, consider a **stipulated** release case in which an engineering packet supplies the measured traces specified below. (The uncalibrated evidence currently available in this book continues to dictate `REFUSE`.)

The target application is *restricted inspected-route mug delivery*. The robot retrieves a declared mug from a singulated feeder and traverses a designated, surveyed warehouse aisle at a velocity capped at 1 m/s. It then pauses the mobile base to open an equipment cage latch using the guarded contact trajectory and hands the mug to a consenting human coworker under the `accept_item` primitive at 0.10 m/s. Operational authority remains strictly local. The feeder mechanism physically prevents accidental object substitutions, recognizing that singulation alone cannot authenticate identity. Similarly, strict access controls prevent personnel from stepping into the robot's active stopping corridor during transit.

↪ The difference between a coworker who consents to a machine's risk, as this one does, and people who bear it without choosing, is developed in section 17.6.

For claim C1, the safety case stipulates empirical stopping traces under full payload mass, measured tracking and localization variance, dynamic latch-stopping performance, and instrumented handover contact forces that satisfy the bounded thresholds in table 16.5. For claims C2 and C5, the case stipulates independent hardware fault-injection logs and worst-case execution timing traces gathered under peak synthetic computational load. These records must account for common-cause hardware failures, support the enforcer's permission deadlines and actuator reaction latencies, separate controlled motor deceleration from passive mechanical braking at rest, and confirm isolated drive-energy cutoff and sensor integrity under all credited fault modes.

For claim C4, the case stipulates synchronized end-to-end hardware timestamp telemetry, bounded clock skew, and a verified upper bound on dispatch-to-admission latency. This latency must be deducted from the dynamic stopping distance budget so that a strictly positive safety margin remains; a theoretical kinematic velocity ceiling cannot authorize transit speeds on its own. Because sensor data ages continuously throughout execution, the chunk lease starts only when a plan is admitted, never when it is computed. The qualification packet must also check the time between admitted plans against the lease renewal deadline rather than assuming that nominal policy inference frequency guarantees admission. For claim C6, the packet stipulates verified `PASS` audit records across every state transition exercised by the local autonomous executive, while disabling the unverified remote teleoperation interface entirely.

Claim C3 requires substantially more than visual inspection or reduced transit velocity. The case stipulates a qualified site friction survey showing a friction coefficient of at least 0.12 across the surveyed transit corridor, reinforced by active cleaning protocols, chemical containment barriers, and physical access gates that maintain floor integrity throughout the authorized inspection interval. Stopping trials at maximum payload must confirm deceleration on this specific friction surface with the loaded wheel distribution and drive settings of the signed configuration. The complete restricted stopping distance, including the verified dispatch-to-admission delay bound and a positive safety margin, must fit inside the surveyed physical clearance with a positive reserve, the same accounting as step 5 of notebook 16.1. The operating velocity of 1 m/s sits below the partial ceiling of 1.23 m/s, but that comparison is only an initial feasibility filter. The active transit permit is revoked immediately upon any reported spill, expired maintenance inspection, or perimeter breach. If unmonitored oil or other fluid can enter the corridor during the deployment window, the stipulation is invalidated and the verdict reverts to `REFUSE`. A lower speed cannot repair that premise, because

the restricted speed was sized for the inspected friction floor of 0.12, not for a film near 0.05 that removes most of it.

The task capability packet is similarly stipulated. Before evaluation begins, the facility operator defines binding acceptance criteria in the verification plan: a minimum mission completion rate, an upper bound on end-to-end cycle time, and a maximum allowable operator intervention rate, accompanied by sample-size requirements, confidence intervals, and statistical decision rules. A successful mission requires maintaining object identity and physical integrity from retrieval through coworker handover. Cycle time accounting includes transient safety stops, crossing delays, and autonomous replanning; human rescues and aborted deliveries are tracked as explicit mission failures. The safety case stipulates that closed-loop trials of this exact restricted configuration satisfy all three benchmarks. The qualification dossier separates raw neural policy autonomy, system-level task success, and safety interventions into independent metrics, the separation section 7.2 drew between the policy's own completions and the completions that protection made possible. Minimal-intervention safety filtering may run during nominal task execution; its clamps are counted separately, so they neither mask the policy's shortcomings nor count as safety violations.

With these stipulated evidence packets in hand, the adjudicator can sign a verdict of `COND` (conditional release) for *restricted inspected-route mug delivery*. The physical records support claims C1 through C6 solely within the restricted operating envelope, while the task evaluation shows acceptable operational utility under identical constraints. The adjudicator binds both the physical safety dossier and the capability evaluation to the release manifest, leaving full-speed autonomous transit and remote teleoperation unauthorized. The result is a conditional safety case, not a blanket deployment permit. Invalidating any underlying assumption or breaching a boundary condition immediately returns the verdict to `REFUSE`; conversely, gathering qualified operational telemetry and physical measurements over time can justify expanding the envelope toward full-scale release.

Checkpoint 16.2: Refusal and the path to conditional release

Before approving a conditional release of the machine, verify your understanding of how a premise, rather than a calculation, decides a claim:

- ☐ **Premise vs. arithmetic**: Can you explain why the calculated latch force at physical braking onset is not in doubt while the door branch of C1 is still refused?
- ☐ **Unsupported approach**: Can you use equation 12.11 and equation 12.12 to show why the operating envelope admits only the guarded door approach?
- ☐ **Refusal as a deliverable**: Can you name, for one refused claim, the measurement that would lift it and the restriction that would remain after a supporting result?
- ☐ **Measured-deceleration estimate**: Suppose loaded stopping trials put the low tail of the deceleration at 1.6 m/s^2 under the same jerk bound. Can you rerun notebook 16.1 at 1.3 m/s and decide whether that aisle speed can still be signed once Δ_{da} is charged?

16.7 Adversarial Review

Confirmation bias steers an engineering team's data collection toward nominal conditions where learned models succeed, leaving edge-case hazards untested until live operation exposes them. Suppose the measurements listed in table 16.5 arrive and, as in the stipulated branch, appear to support a conditional (`COND`) authorization for the mobile manipulator. Before signing, the safety adjudicator submits the safety case to an independent **adversarial review** tasked with falsifying its warrants. Rather than ratifying a brief, the reviewer actively searches for unsupported warrants, uncharacterized physical transitions, and environmental edge cases that violate the release contract. If an argument collapses on paper when an adversary probes for physical violations, the machine cannot be expected to withstand the hazards of live service.

The review interrogates every evidentiary node in the argument tree using four structured probes. The first challenges **empirical sufficiency**: whether the physical trials reached the extremes of the operating envelope. Stopping trials with the loaded base on dry concrete, at a friction coefficient near 0.60, support the warrant that the base achieves its certified deceleration under ideal conditions. The

restricted operational mode, however, admits facility floors that the site's inspection regime certifies only down to 0.12, such as an aisle polished smooth by traffic. In those zones, the base may run at the restricted velocity 1 m/s, below the 1.23 m/s ceiling. If the trial set contains no loaded stops on such degraded floors at that speed, the warrant for the restricted mode is unsupported. A coverage audit finds on paper the gap that unvetted service would otherwise find against a warehouse rack. The reviewer also checks whether validation trials covered transient execution states across an A/B partition swap, when a newly flashed software bank takes over from the incumbent one (section 16.9.1). The same check applies to cold-start sensor characteristics before cameras and inertial measurement units reach thermal equilibrium. It applies as well to the operating boundaries of canary units, the small subset of the fleet that first runs a candidate policy (section 16.9.2). Finally, the reviewer asks whether site procedures actually keep fluid films out of the corridor throughout the authorized interval, since listing oil outside the envelope does not exclude it from the floor.

The second probe examines **domain transfer**, targeting claims where synthetic simulation substitutes for direct physical measurement. A vision-based human detector may achieve high recall across synthetic, ray-traced warehouse environments, yet fail on physical hardware when encountering coworkers partially obscured by stretch-wrapped pallets whose specular reflections blind the camera's auto-exposure algorithm. Benchmark recall on curated offline datasets is an indirect proxy metric that scores isolated frames rather than the closed-loop physical causal chain running from visual detection to an arrested base. Likewise, a simulation that omits linkage compliance or fieldbus jitter cannot establish tolerance to those physical mechanisms. The reviewer demands empirical evidence from paired hardware-in-the-loop (HIL) trials on target SoC devices connected to chassis dynamometers[8] and physical bus emulators under real facility illumination, dust, and reflective geometry.

The third probe attacks **structural independence**, asking whether the learned model and safety enforcer share hardware resources whose contention could delay sensor delivery or actuation cutoff. On modern robotics edge platforms where neural inference engines and real-time safety enforcers share a single system-on-chip die, internal crossbar interconnects, shared caches, and DRAM memory controllers, unconstrained direct memory access (DMA) transfers from large model forward passes can saturate memory channels. This memory contention induces tail latency spikes that starve deterministic safety enforcer execution ticks, directly invalidating the 51.6 ms observation-age chain of C4. Stress tests and hardware timing analysis under peak synthetic compute and bus loads must establish the worst-case interference bound; unit tests on an otherwise idle bus provide zero evidence of non-interference. The reviewer also checks whether writing frozen edge telemetry ring buffers to non-volatile storage competes with real-time fieldbus DMA buffers across the internal bus fabric. The reviewer inspects watchdog reset circuits for single points of failure and verifies whether the supercapacitor power hold-up circuit supplies enough energy to flush in-flight telemetry buffers to persistent flash when an emergency stop opens the main DC bus contactors.

The fourth probe identifies **unmonitored state drift**. Mechanical wear alters gearbox compliance[9] and disrupts the dynamic relationship between commanded motor torque and physical joint motion. The reviewer therefore demands paired wear-state braking and contact traces before accepting the arm-stop premise of the door branch of C1 (section 16.6). A static motor-current threshold alone cannot prove that a mechanically worn drive train remains inside certified force and stopping limits. The reviewer also checks whether over-the-air updates preserve the persistent hardware calibration partition intact across schema migrations, or whether an OS reflash can silently reset camera extrinsics and joint zeroes to unverified factory defaults. Finally, the probe checks whether thermal bracket motion stays inside the localization allowance; fresh timestamps and unchanged calibration files on disk cannot establish that physical fact.

Reviewers turn these vulnerabilities into concrete tests by constructing explicit defeaters for each warrant. The hardest failure modes to catch combine minor anomalies that each stay inside their own tolerance bands, the compound faults that section 15.6.5 derives from shared causes. Consider the mobile manipulator's navigation camera operating with three simultaneous sub-threshold degradations. A light film of dust coats its lens. A mount whose fasteners relaxed within tolerance vibrates as the base crosses floor joints. An interconnect harness flexes at those joints and elevates the bit-error rate across its serializer/deserializer (SerDes) link. Each individual check reads normal. The optical transmission score exceeds its 85 percent alarm threshold. The mount deflection

8 | **Chassis Dynamometer**: Powered rollers under the drive wheels absorb or supply torque, so the base can run at aisle speed on a bench while its drive and braking torques are measured. The rollers, not the floor, set the traction. Dynamometer stops can therefore qualify drive and brake response but say nothing about the friction premise of C3.

9 | **Strain-Wave Gear Wear**: The arm's joints use strain-wave reducers (section 2.4.4), and in service their flexspline teeth and wave-generator bearing wear. Wear raises lost motion and torsional hysteresis, which adds phase lag between motor and link, so the arm begins to decelerate later and its first contact peak rises.

registers below its 0.15-degree hardware fault limit. SerDes cyclic redundancy check error counters remain below their warning tripwire. Their timing effects remain contained only if the independent permission path strictly enforces the event-specific observation-age and clock-uncertainty checks of section 8.8 and retains its validated response time. Any hardware or bus interference that defeats that deterministic path is a safety violation under C5, not a benign availability-only event.

The same anomalies compound within spatial estimation. Dimmed contrast reduces tracked visual features, mount vibration adds motion blur and persistent pose bias, and frame drops extend intervals of uncorrected dead reckoning. A systematic pose bias can quietly erode the localization allowance without forcing estimated filter covariances or innovation residuals to breach trip thresholds. The release reviewer therefore challenges the combined error against the qualified uncertainty bound, rather than inferring containment from individually passing scalar diagnostics. A breach of the combined bound consumes part of the stopping reserve and invalidates the release warrant; exhausting the entire stopping margin requires a quantified combined-error scenario. Statistical residual monitoring protects against only the specific faults its qualification shows it can detect, leaving site operational restrictions or independent physical checks to cover the remaining biases.

The review also audits the execution integrity of the permission path, checking whether inference loops or background services can bypass, corrupt, or starve the enforcer or human overrides, the latter covered by claim C6 of table 16.2. Below the proposal boundary, both safety monitors and manual overrides maintain non-preemptible execution priority over learned models. The reviewer asks concrete systems questions: whether a runaway policy thread can exhaust shared memory channels, whether an accelerator-runtime exception can lock a kernel spinlock, and whether a telemetry logging burst can brown out a regulated power rail. The reviewer accepts **permission path** independence, and the held-up power rail that carries it on the mobile manipulator, only after reviewing physical fault-injection trials. These trials must show survival under bus saturation, active feed removal, and an abruptly killed proposer task (fault F1), and they must appear in the signed fault records, because C2 claims only the faults the permission path demonstrably survives. A user-space implementation without qualified scheduling, resource isolation, and response mechanisms cannot supply the justified execution bound and fault isolation the reviewer requires.

When an adversarial probe succeeds, the case cannot be salvaged by editing claim descriptions or inserting arbitrary safety margins. The broken warrant is traced to its root systems failure (an uncharacterized physical boundary, an inadequate dataset, or an unmodeled bus latency), and the defect returns to the owning engineering subsystem. For example, a motor-current observer that fails under gearbox compliance returns to the mechanical specification as wear limits and runtime compliance estimation, while bus contention that delays the enforcer returns to the compute architecture as memory partitioning and real-time scheduling. The case returns to the engineering team with its broken warrants named, and only updated boundaries, re-derived stopping distances, and renewed verification reopen formal adjudication.

Adversarial review must also recur periodically, because a case accepted once can erode in service without any single discrete event forcing a new audit. The *normalization of deviance* names that operational erosion, in which anomalies that cause no immediate harm come to be treated as acceptable operating noise rather than as evidence against a warrant (Leveson 2011; Vaughan 1996) (war story 16.1).[10] On the mobile manipulator, this erosion unfolds silently across months of fleet operation. Localization residuals creep toward the edge of their tolerance. Observation-age watchdog trips are dismissed as nuisance stops. Stopping distances end slightly longer than the initial trials did. Enforcer trips are cleared on the floor without a trace review. When thresholds are widened, margins trimmed for throughput, and alarms suppressed because nothing has yet gone wrong, the gap between the signed envelope and the machine's actual physical behavior widens until a routine disturbance exhausts what remains. The defense is to fix each watched quantity's threshold and response before service begins, as the safety performance indicators of section 16.9.5 do, so that a run of harmless readings cannot move it.

[10] **Normalization of Deviance**: The sociologist Diane Vaughan coined the term in her study of the Challenger launch decision (Vaughan 1996). It names a process rather than a decision, in which each anomaly that caused no harm widened what the next review accepted as normal.

DRAFT

War Story 16.1: Challenger and experience limits (1986)

Context: The Space Shuttle's solid rocket motors were assembled from cylindrical steel segments whose field joints were sealed by primary and secondary O-rings (Presidential Commission on the Space Shuttle Challenger Accident 1986). No learned model appears in this chain. The adjudication failure it records is the exact failure this chapter's verdicts exist to prevent: a launch approved for conditions that the evidence did not cover.

Mechanism: The ambient temperature at launch was 36°F, 15 degrees colder than any previous launch. O-ring resiliency falls with temperature, and a cold ring returns to shape too slowly to follow the joint gap as ignition pressure opens it. On the eve of launch, engineers at Morton Thiokol, the motor's contractor, recommended against launching below 53°F, the O-ring temperature of the coldest previous flight, whose joints had shown the worst blow-by to date. That limit was the outer edge of flight experience, not a qualified bound. NASA managers countered with a qualification temperature that applied to the propellant's bulk temperature rather than to the joint seals.

Impact: A combustion gas leak through the right booster's aft field joint, beginning at or shortly after ignition, weakened or penetrated the External Tank. The vehicle broke up about 73 seconds after launch, and all seven crew members died.

Response: The presidential Commission attributed the failure to "a faulty design unacceptably sensitive to a number of factors," and temperature heads its list of those factors. It recommended that the joint be changed and that the new design be certified by tests "over the full range of operating conditions, including temperature."

Systems lesson: Thiokol management reversed its engineers' recommendation at the urging of NASA's Marshall Space Flight Center. Thiokol's vice president of engineering testified, "We had to prove to them that we weren't ready." The burden of proof had inverted: rather than requiring proof that the joint was safe inside its evidence, adjudicators demanded proof that it was unsafe outside the evidence, where no data existed. The Commission also found that O-ring erosion had recurred on earlier flights and that NASA and Thiokol "accepted escalating risk apparently because they 'got away with it last time' " (Presidential Commission on the Space Shuttle Challenger Accident 1986), so the flight record itself had been read as evidence of safety. A release verdict keeps the burden where the envelope trichotomy puts it. A condition outside the evidence, such as a seal temperature below all flight experience, is unknown, and the verdict refuses it.

The Tempe collision analyzed in section 1.8 rested on an unmeasured premise of the same kind as Challenger's seal temperature. Its vehicle operator was the countermeasure the whole system leaned on, so the premise was that the operator was watching, and nothing measured whether that held. A release case that relies on such a premise must bind its operational response, whether an outright refusal or a restricted case, to verified physical limits, as claim C6 does for authority transfer. Even a case that survives this adversarial review has had its warrants tested only in principle while its verdict still lives on paper. The release manifest turns the surviving argument and the verdict it supports into a signed, tamper-evident record that the machine itself checks before it moves.

16.8 The Release Manifest

A safety case that lives only in static documents or procedural sign-off sheets cannot stop a robot from booting with an unverified policy checkpoint or stale sensor calibrations. To make the verdict enforceable on hardware, the adjudicator's decision is recorded in the **release manifest**, the fourteenth record in the book's record chain. This signed, tamper-evident data structure binds every upstream engineering contract, the Goal Structuring Notation argument graph, the operating envelope limits, and live standing conditions to the adjudicator's verdict by cryptographic digest. The target platform refuses physical motion whenever runtime binary images, silicon attestation measurements, or underlying qualification data diverge from these signed digests.[11]

The release manifest gathers the engineering contracts established throughout this book. Each upstream record defines an operating boundary or contributes empirical data that the safety case

↩ The operator-monitoring failures that a human-takeover premise invites, from mode confusion to authority ambiguity, are established in section 14.6.

11 **Cryptographic Manifest and Silicon Attestation**: One-time programmable electronic fuses (OTP/eFuse) store the adjudicator's public verification key in silicon, preventing unauthorized software updates from replacing the root of trust. Secure bootstrap validates each early boot stage before handing over execution control (Arbaugh et al. 1997), while measured boot extends cryptographic measurements into Trusted Platform Module Platform Configuration Registers (TPM PCRs). The hardware verifier checks these measurements against the digests specified in the signed manifest; any unsigned or modified binary image fails attestation and never receives an operational permit.

↪ The residual-claims register, the record that follows the release manifest and ties each premise it leaves open to an operational restriction, is developed in section 18.3.3.

must check; a signature on an isolated contract does not validate the system as a whole. Instead, the manifest links reviewed snapshots of these records into a single argument graph:

1. **Physical plant and timing base:** The limit record (section 2.7.3) documents torque, velocity, and thermal dissipation bounds alongside their qualification data. The proposer's payload requirements (section 3.5.4) specify candidate action horizons that feed the handoff record rather than standing as an isolated contract. The handoff record (section 4.9) establishes deterministic fieldbus jitter, cycle deadlines, and real-time communication premises.
2. **Data, policy, and behavioral bounds:** The provenance record (section 5.11) captures dataset calibrations, sensor configurations, and operating-domain coverage. The policy manifest (section 6.8) binds frozen neural network weights to the empirical behavioral bounds proven for that candidate model. The evaluation record (section 7.8) details closed-loop task success rates, human intervention tallies, and stress-tested operational conditions.
3. **Perception, belief, and planning:** The observation contract (section 8.8) enforces observation freshness and multi-sensor synchronization windows. The belief record (section 9.3) specifies geometric state estimates, state covariance, and validity domains. The intent lease (section 10.4) records task objectives, spatial tolerances, and preemption conditions. The trajectory record (section 11.8) encodes motion profiles, kinematic seam continuity, execution deadlines, and safe stopping continuations.
4. **Deterministic containment, execution, and verification:** The enforcement record (section 12.11.1) logs the command stream admitted by runtime safety filters, cleanly separated from the signed enforcement contract that specifies barrier functions and fallback triggers. The placement record (section 13.8) documents the qualified compute scheduling, memory isolation, and processor affinity. The authority record (section 14.8) documents arbitration switches and fallback outcomes. The fault records (section 15.11) index tested fault-injection scenarios alongside known coverage gaps.

Beyond linking these upstream contracts, the release manifest adds its own fields. It carries the root claim, the cryptographic digest of the Goal Structuring Notation argument graph, and binary hashes across all deployed software (spanning learned policy weights, the deterministic enforcer logic in both nominal and restricted modes, and the real-time operating system kernel). It also carries sensor calibration tables, the adjudicator's digital signature, mandatory standing operational conditions, an accumulated lifecycle wear budget of operating hours and load cycles, and a calendar expiration timestamp. All evidence links must resolve to these exact reviewed record digests, organized hierarchically beneath a single evidence root structured as a Merkle hash tree (Merkle 1988). Each parent digest is computed from its children's digests, so changing an evidence leaf changes the root that the manifest signs. Only when the hardware root of trust authenticates this complete cryptographic tree will it permit the motor power stages to energize. While traditional release notes or post hoc compliance certificates summarize safety after the fact, the release manifest is an active, machine-checked gate. The robot checks it before closed-loop control begins, and its runtime monitors revoke motor tracking within a bounded detection-and-response window if any underlying evidence or environmental condition expires.

↪ **Byte layout:** The release manifest's fields, types, and digests are given in section C.15.10.

Figure 16.3 routes every release attempt through authentication and physical standing checks before an operating permit can issue. The release gate authenticates the manifest, binary images, and complete set of fault records before verifying current sensor calibration, mechanical maintenance thresholds, and operational design domain conditions. Only an exact cryptographic and physical match enables the plant's certified startup sequence. Table 16.6 lists the gate result for each combination of signed case and standing check, including the single path by which stale calibration still reaches `COND`. A separately signed `COND` case can tolerate a named stale calibration only when its restricted envelope either locks out the motions that depend on that sensor, such as prohibiting base transit when the tote-rack scale is stale, or widens the uncertainty allowance and derates speed to cover worst-case calibration drift. During active motion, any breached condition commands an assessed safe fallback before any switch of software partition (the A/B banks of section 16.9.1) or electrical isolation.

↪ **Protocol:** The gate's step-by-step authorization protocol is given in section C.15.11.

DRAFT

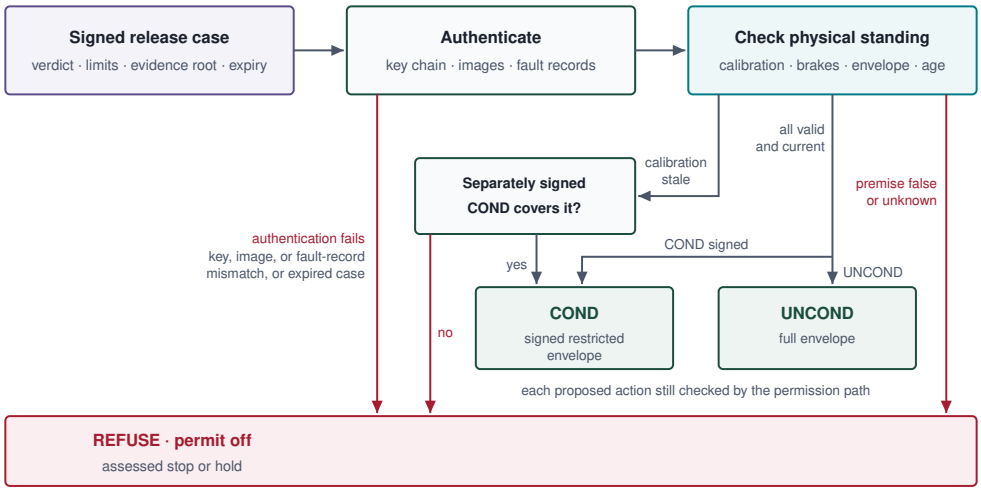


Figure 16.3: Fail-closed release pipeline: The signed verdict and evidence root pass key, image, and complete fault-record authentication, then current calibration, brake, and operating-envelope checks. Every failure path ends in REFUSE. A valid case reaches UNCOND or COND according to what was signed, and stale calibration reaches COND only through a separately signed restricted case; either way, each proposed action is still checked by the permission path. Attribution: Textbook production team (CC BY-NC-ND 4.0).

Table 16.6: Release authorization truth table: A restricted mode is a distinct authenticated claim, never an unsigned downgrade of the full case.

Signed case	Evidence and standing checks	Restricted case covering stale calibration	Gate result
`UNCOND`	All valid and current	Not needed	Full *proposal* envelope under enforcer; `UNCOND`
`COND`	All restricted evidence valid and current	Included if calibration stale	Signed restricted envelope under enforcer; `COND`
`UNCOND` or `COND`	Fault-record root/signature mismatch, expiry, image mismatch, or unknown physical premise	Any	Permit off; `REFUSE`
`UNCOND`	Calibration stale	No	Permit off; `REFUSE`
Separately signed `COND`	Only the named calibration is stale; restricted evidence and limits valid	Yes	Restricted envelope; `COND`
`REFUSE`	Any	Any	Permit off; `REFUSE`

Each empirical evidence leaf in the assurance Merkle tree must identify its raw sensor trace, instrumentation hardware, calibration log, machine configuration, and automated test harness script. Analytical leaves retain their derivations and assumptions; procedural leaves retain the accountable procedure and its validation for the signed envelope. Measured latency profiles enter the safety case as empirical percentiles, whereas deterministic real-time execution guarantees demand the analytically justified upper bounds specified in section 4.5. Similarly, collaborative object-handover criteria require load-cell time series recorded against standardized anthropomorphic surrogates across specified contact geometries. By cryptographically anchoring these primary records, an independent auditor or verification engine can reproduce the experimental test suite and pinpoint the exact operating boundaries where each safety claim ceases to hold.

The release manifest bounds the physical envelope and hardware configuration under which its verdict remains valid. Modifying a neural policy checkpoint, altering a real-time thread priority, updating a device driver, or replacing an actuator with an unverified component revision immediately invalidates the manifest, requiring a re-adjudicated safety case. On the warehouse mobile manipulator, for example, the manifest enforces signed wear thresholds on harmonic-drive backlash

and electromagnetic brake lining thickness derived from stopping-distance and payload trials. Operating envelope tripwires trigger immediate refusal: on-board load cells detect tote-rack overloading beyond rated payload capacity, while facility procedures prevent operation on unmapped or unsurveyed floor surfaces (table 16.1). The manifest also encodes the isolated, energy-buffered power rail of the permission path as a standing invariant, running a diagnostic self-test on the hold-up capacitor bank before granting boot authorization. Whenever a runtime sensor detects that a state variable has breached a signed threshold, the hardware permission path interrupts closed-loop trajectory tracking within its certified detection-and-response deadline and brings the system to an assessed fallback state.

To preserve traceability across time, the manifest binds all operational telemetry directly to the exact hardware-software revision that generated it. High-resolution local ring buffers capture boundary excursions for post-incident diagnostics, whereas fleet-wide telemetry summaries reveal systematic mechanical drift across hundreds of operating hours. The curation pipelines examined in section 16.9.5 must preserve this cryptographic lineage whenever field data is promoted to support a later release case.

During daily operation, edge telemetry logs motor torque residuals, control-loop cycle times, and safety enforcer interventions for trend analysis, while the hardware permission path checks physical invariants on every 1 ms permission tick. If a routine maintenance check measures a stopping distance exceeding the signed clearance budget, or if a camera calibration certificate expires, the release verdict is revoked automatically. Re-flashing an older firmware image cannot compensate for worn mechanical friction pads. Unless an engineer deploys a separately signed restricted case (`COND`) that explicitly accommodates that degraded physical state, the controller executes an assessed emergency stop and locks out autonomous motion until certified maintenance and re-adjudication take place (table 16.6).

Once its powered stop has brought the base to rest, the warehouse mobile manipulator can reach a quiescent state only after the arm and payload are supported and the assessed holding brakes are engaged before drive power is removed. The base rests stably on the floor, but that support alone does not secure its gravity-loaded arm. For other morphologies, severing motor power is itself the hazard, because the machine collapses under gravity once torque is removed (perspective 16.1).

Systems Perspective 16.1: When removing torque causes the harm

Question: Which verdict applies when removing torque causes the harm?

A supported wheeled base at rest eliminates its translational kinetic hazard, though its arm and payload still require qualified support. In contrast, an upright bipedal humanoid retains substantial gravitational potential energy. While resting in a support gantry before standing up, a `REFUSE` verdict safely holds the robot in its mechanically supported state. Once balanced upright, however, revoking locomotion authority cannot simply de-energize the actuators without inducing an immediate dynamic fall; safe shutdown requires an active, validated arrest or controlled descent strategy.

- **Torque removal can cause a fall.** An unsupported biped with backdrivable transmissions will collapse if motor currents drop to zero: torque removal leaves gravity-loaded joints without support (section 4.6), and an upright biped without active balance diverges like an inverted pendulum (section 4.9.1). Consequently, such physical plants cannot treat torque removal as a fail-safe stopping condition unless accompanied by certified passive catches, lock-up brakes, or an external tether.
- **The fall-arrest response is itself an actuation.** Executing a controlled squat, brace, or step-down to bring the robot to rest is itself an active trajectory that requires validated sensorimotor claims, verified timing margins, and fault-tolerance guarantees. In this regime, executing a safe `REFUSE` action depends on the very control systems maintaining upright stability.
- **Wear revokes the running permit.** Degradation in foot-sole rubber traction or increased backlash in planetary gearheads alters the dynamic margin required for emergency

balancing. When telemetry signals that physical wear has crossed the threshold certified in the safety case, the runtime supervisor must revoke high-speed dynamic locomotion well before the safety-critical arrest maneuvers degrade below their qualifying safety margins.

Checkpoint 16.3: Deriving a verdict from your own measurements

Table 16.5 lists the measurements needed to support a release case but supplies no raw trial results. Make a copy with columns for value, source, provenance, and premise status, fill those columns with empirical data from hardware trials on your own robotic platform or an illustrative benchmark scenario, and evaluate the resulting release verdict:

- ☐ **Provenance and premise status**: For each row, record measured, derived, datasheet, or illustrative provenance; label selected operating requirements as chosen. A derived result retains its inputs and assumptions and remains illustrative when those inputs are illustrative. A selected substitute for an unmeasured brake value is illustrative, whereas a chosen speed cap needs qualified evidence that it fits. A manufacturer's rating is datasheet evidence, not a measurement of this unit. Separately apply the Reader Guide's five premise statuses: established by measurement or derivation, assumed, decided by accountable judgment, unsupported, or outside the threat model. Explain why each credited assumption or restriction is warranted for the signed envelope; a status label grants no authority. Runtime known-true, known-false, and unknown describe current envelope membership, not provenance.
- ☐ **Verdict derivation**: A `COND` case requires adequate support for every relied-on premise: qualified measurements, justified analysis, or validated operating restrictions. Illustrative values alone still support only an actual `REFUSE`. Recompute the base's budget and spare margin from your values. If every relied-on premise has adequate support, name the envelope the `COND` case signs and the premise that keeps the normal mode unsigned. If a relied-on premise lacks adequate support, derive the verdict the table *would* support given the missing evidence, and label that verdict hypothetical.
- ☐ **Artifact label**: Mark the filled table as your own work, whose values license no physical machine.

A release manifest binds the verdict to an explicit, reviewed system configuration. Any later modification, whether retraining a perception head, tightening an actuator torque limit, or swapping a camera lens, breaks that closure and reopens some of the underlying claims. The question the rest of the chapter answers is which ones, and how the machine stays contained while the reopened claims are requalified.

16.9 Maintaining Release Through Updates

Continuing the stipulated warehouse branch, suppose the mobile manipulator's restricted mug-delivery policy is retrained to reduce hesitation at the controlled pick station. Pushing that updated checkpoint directly to the fleet would invalidate the signed manifest and expose the machine to unverified bus loads and contact trajectories. Before the candidate neural policy can issue commands to physical actuators, it must pass back through the release decision. A signed safety case establishes which historical evidence remains valid, which hardware-in-the-loop tests must run again, and how the machine maintains physical containment throughout the update.

16.9.1 Modular safety cases and over-the-air updates

Retraining a policy directly alters capability evidence, and neural modifications often introduce side effects across the shared hardware platform: increased neural accelerator memory bus traffic, altered sensor frame processing latency, or modified contact force trajectories. An engineer must

↩ Every updated checkpoint is a new policy whose earlier evaluations no longer apply, the rule established in section 6.6 that gives each one its own manifest and regression evidence.

trace these cross-subsystem dependencies before deciding which containment records remain valid. While **over-the-air (OTA) updates** swap out a named software payload, **modular safety cases** isolate dependencies by recording how each claim relies on specific evidence items and platform assumptions (Denney et al. 2015). Whenever an update alters an underlying dependency, the modular case shows exactly which safety claims are reopened.

The containment argument is the defense against physical harm. It binds together the plant model, physical sensor limits, worst-case execution budgets, and the independent permission path. Key engineering premises include the bounded tracking error tube ϵ_{track}, the emergency stopping budget, the passivity barrier for physical contact, and hardware watchdog timing margins. Historical verification records for these containment claims remain valid only if the proposed update preserves the exact operating conditions under which they were measured. For example, replacing a backbone network with a higher-capacity model can increase memory bus contention or cause voltage droop on the power rail even if the deterministic safety-filter binary remains byte-for-byte identical. An unchanged enforcer binary does not imply an unchanged containment argument; its guarantees remain bounded by the validated dynamic envelope $\mathcal{C}$ and the system-level timing margins established during qualification.

↩ The tracking-error tube ϵ_{track} that the containment argument consumes as an invariant is established in section 12.2.

In parallel, the capability argument shows that the robot reliably fulfills its mission within its certified operational design domain. Candidate benchmarking, passive shadow traces, and geofenced closed-loop trials test whether a retrained policy reduces hesitation or improves task throughput. While the low-level enforcer can continuously clamp or reject invalid control proposals to maintain safety, an enforcer that constantly intervenes degrades the robot into an unusable, halting machine. Release engineering therefore evaluates capability and containment together. An update qualifies for fleet dispatch only when the candidate configuration delivers acceptable task performance without undermining the empirical premises supporting its containment envelope.

Modern physical AI platforms preserve configuration integrity during deployment through **dual A/B OS partitioning**. The update agent streams the candidate image onto the inactive storage bank (Bank B) while the incumbent controller continues executing from the active bank (Bank A). Activating the newly flashed partition requires an assessed stationary update state. The robot must be parked with its payload supported. Battery reserves must exceed with margin the energy needed for re-flashing and post-boot self-tests. The independent safety supervisor must hold all motor drives unpowered or mechanically locked so the robot cannot move during bootloader cutover. Hardware watchdogs govern the runtime decision to commit or abort this cutover (section 16.9.4). A single fleetwide signing key is a single point of compromise, because an attacker who extracts that key from one compromised endpoint could sign arbitrary firmware for every robot in the field. Update architectures therefore use role-separated signing structures where distinct root, targets, and release keys live on separate, hardware-isolated machines. The Update Framework (TUF) pioneered this design, and Uptane extended it to automotive and robotics systems where heterogeneous electronic control units require independently authenticated firmware images (Samuel et al. 2010; Kuppusamy et al. 2016).

Overwriting firmware must never destroy the physical calibration history of an individual robot. **Persistent hardware calibration parameter retention** separates machine-specific measurements from generic operating system binaries, preventing a **calibration clashing failure**. Camera intrinsic matrices ($\mathbf{K}$), extrinsic sensor transformations ($[\mathbf{R} \mid \mathbf{t}]$), kinematic joint zero-point offsets, and motor torque constants (K_t) reflect the mechanical and electrical geometry of an individual machine and drift over time with vibration, thermal cycling, and wear. Storing these values in a dedicated, wear-leveled, non-volatile parameter partition keeps calibration intact when an OS image is flashed. When a firmware update introduces a revised parameter schema, the migration utility writes the transformed schema into a new record while preserving the legacy block, allowing direct rollback to the prior image-parameter pair. Cryptographic checksums verify the bit-level integrity of these stored calibration blocks, while physical self-tests at field release verify that the stored parameters still match the physical machine.

Finally, **forensic traceability** links every running OS image, policy checkpoint, and calibration partition to its training provenance, compiler flags, and reviewed HIL regression records through the signed release manifest (section 16.8). When an unexpected field intervention or trajectory excursion occurs, these links let incident investigators reconstruct the exact configuration running at

that millisecond and determine which safety warrants need re-examination. While a cryptographic digest confirms identity, isolating the physical root cause requires detailed sensor traces and causal analysis.

16.9.2 Staging candidate policies before release

Software simulation models timing and electrical behavior only to the accuracy of its mathematical approximations; it cannot catch memory-bus contention, fieldbus noise, or inverter thermal sag on the real processor and drive electronics. A candidate policy must therefore repeat the **hardware-in-the-loop (HIL) regression gates** affected by its changes on a physical test bench under full thermal and electrical load. The bench tests the specific interference and fault mechanisms on which release claims depend:

1. **Worst-case execution time (WCET) and scheduling jitter**: Profiling whether safety filter evaluations complete within their hard real-time deadlines ($T_{\text{exec}} \leq T_{\text{deadline}}$) while neural workloads drive peak memory crossbar contention and DMA transfers, the falsification campaign of section 13.7.
2. **Deterministic bus arbitration**: Measuring fieldbus communication jitter and cyclic transmission integrity across physical EtherCAT or CAN FD networks under simulated telemetry broadcast floods and electrical noise injection.
3. **Power-stage thermal dynamics and current ripple**: Verifying that high-frequency control chatter or torque ripple proposed by the candidate policy does not induce excessive inverter switching losses, DC rail voltage sag, or thermal runaway in motor windings (section 2.5).
4. **Hardware fault-injection survivability**: Validating that physical line breaks, power supply brownouts, or deserializer frame dropouts deterministically trigger the hardware watchdog and safe-stop sequence within certified timing budgets before motor power stages can be damaged.

A candidate policy advances through bench staging only when every required regression test passes and empirical records confirm that timing and physical margins remain intact. Observing zero deadline overruns during a finite bench campaign does not by itself establish a mathematical upper bound on worst-case execution time, nor does it show how the policy will behave on the warehouse floor. In cloud software engineering, blue-green deployment can reduce downtime by preparing a replacement cluster and redirecting traffic after readiness checks. In physical AI, however, blue-green cutover cannot happen mid-stride or at speed. Swapping active control authority between an incumbent controller and a candidate policy while mass is moving requires managing actuator state continuity, motor winding back-EMF, and dynamic tracking tubes (section 14.4.1). De-energizing motor windings or inducing sudden torque steps causes severe mechanical shock loads ($N_{\text{gear}}^2 J_{\text{rotor}} \ddot{\theta}_{\text{link}}$) and loss of traction. An unvalidated policy also cannot be granted partial motor authority in a populated warehouse to "canary test" edge-case performance.

Safe predeployment staging instead relies on **shadow mode deployment**, the shadow-operation evidence regime of section 7.4.1 applied to a release candidate. The incumbent controller $\pi_{\text{incumbent}}$ supplies proposals, while the independent enforcer retains sole actuator-output ownership and checks each command before fieldbus dispatch. Concurrently in the background, the candidate neural policy $\pi_{\text{candidate}}$ executes on the host compute SoC, consuming identical live sensor streams $\mathbf{o}_t$ within its qualified shared-resource budget and computing what control command $\mathbf{u}_t^{\text{cand}} \sim \pi_{\text{candidate}}(\mathbf{o}_t)$ it would have proposed. The candidate writes its outputs to an isolated telemetry buffer that grants no actuator authority. Consumers can read that record, but neither the buffer nor the candidate can bypass the enforcer. Shadow inference and recording must stay within the interference and power budgets that preserve the active case. Discrepancies between candidate proposals and the incumbent's admitted commands are logged as high-rate telemetry events without admitting any candidate command to the drives.

Shadow-mode telemetry monitors two instantaneous divergence metrics:

1. **Action discrepancy** ($\Delta \mathbf{u}_t$): The Euclidean (or angular) distance between the candidate proposal and the incumbent control action, measured here by the Euclidean norm:

$$\|\Delta \mathbf{u}_t\|_2 = \|\mathbf{u}_t^{\text{cand}} - \mathbf{u}_t^{\text{incumbent}}\|_2.$$

DRAFT

Sustained spikes in $\|\Delta \mathbf{u}_t\|_2$ identify behavioral divergence where the candidate policy introduces unmodeled bias, high-frequency control jitter, or erratic steering commands. In addition, the discrepancy analyzer monitors the command-rate norm $\|\dot{\mathbf{u}}_t^{\text{cand}}\|_2$, which is a torque-rate norm only when $\mathbf{u}$ is a torque command, to detect unmodeled control chatter that would excite mechanical resonances.

2. **Safety barrier margin discrepancy** ($\Delta \dot{h}_t$): The differential proximity to forward-invariant safety boundaries under a control barrier function $h(\mathbf{x})$ (section 12.5):

$$\Delta \dot{h}_t = \dot{h}(\hat{\mathbf{x}}_t, \mathbf{u}_t^{\text{cand}}) - \dot{h}(\hat{\mathbf{x}}_t, \mathbf{u}_t^{\text{incumbent}}),$$

where $\hat{\mathbf{x}}_t$ is the state estimated from the sensor streams $\mathbf{o}_t$. A negative $\Delta \dot{h}_t$ means the candidate has a smaller modeled barrier derivative than the incumbent. Both derivatives can still be positive, so the sign alone does not imply decreasing clearance or a violated boundary of $\mathcal{C}$ (defined by $h(\mathbf{x})$).

The two discrepancies answer different questions. A large action discrepancy $\|\Delta \mathbf{u}_t\|_2$ can reflect an alternate useful action, while $\Delta \dot{h}_t$ indicates how the proposals differ in their modeled effect on the barrier. Neither sign alone supplies a verdict; review must consider the current margin, uncertainty, and the condition that the independent enforcer would require.

Shadow mode nevertheless has a limit that more traces cannot remove, the trajectory confinement of that evidence regime, which a release reviewer encounters as **counterfactual divergence**. Because admitted incumbent proposals determine the plant trajectory, the historical state trajectory $(s_0, \mathbf{u}_0^{\text{incumbent}}, s_1, \mathbf{u}_1^{\text{incumbent}}, \dots)$ is conditioned entirely on incumbent actions, and the candidate's proposals $\mathbf{u}_t^{\text{cand}}$ never alter it. Conflating open-loop agreement with deployment safety is the **open-loop replay fallacy**: assuming that high action agreement during passive trace replay guarantees closed-loop dynamic stability. The $\mathcal{O}(S^2\epsilon)$ result in section 5.3 is an expected-cost bound under its stated imitation-learning assumptions, not a universal law for physical tracking error. A candidate that agrees on incumbent trajectories can still visit unfamiliar states or excite unmodeled dynamics when it closes the loop, the covariate shift that interactive imitation learning was designed to correct (Ross et al. 2011). Shadow mode is an essential pre-filter for gross behavioral anomalies, but never a substitute for closed-loop dynamic qualification.

Phased canary fleet rollouts[12] expose the candidate to closed-loop operation under a separately supported restricted case. Selecting fewer machines limits exposure but does not bound the consequence of any one action. The restrictions must address the physical hazard:

1. **Geofenced operational containment**: Canary units operate exclusively within dedicated, surveyed low-risk corridors, such as wide transit aisles devoid of blind rack corners, reduced pedestrian density, and high-friction surveyed concrete ($\mu \geq 0.60$).
2. **Enforced kinematic derating**: The real-time safety enforcer clamps candidate policy velocity and acceleration below nominal ratings ($v \leq v_{\text{canary}} < v_{\text{nominal}}$), expanding stopping distance margins and suppressing transient kinetic energy.
3. **Supervised human oversight**: High-readiness human supervisors equipped with wireless remote emergency-stop (tele-stop) pendants maintain line-of-sight monitoring over canary units, backed by an active-lease watchdog.
4. **Targeted regression observability**: The trial measures tracking error variance σ^2_{track}, drive torque ripple, and enforcer intervention frequency to reveal service regressions. The permission path retains only the containment claims validated for the restricted envelope.

Expansion requires predeclared acceptance criteria tied to the service and physical claims. Intervention-rate non-inferiority[13] and tracking variance $\sigma^2_{\text{track}} \leq \sigma^2_{\text{incumbent}}$ are possible capability criteria, with their comparison conditions and statistical assumptions stated. The non-inferiority margin δ is fixed before the trial, so that the upper one-sided 95 percent confidence bound on the rate ratio $\lambda_{\text{canary}}/\lambda_{\text{incumbent}}$ must fall below $1+\delta$. With a zero margin, that upper-bound criterion requires evidence that the candidate is better, which may demand more exposure than a small canary provides. The trial arithmetic of section 7.7 sets how much operation a given δ requires. A sequential test can stop expansion as soon as the evidence suffices. None of these criteria replaces the evidence for stopping, observation, or containment. An enforcer intervention also needs causal

12 **Canary** (the miners' sentinel bird): Miners carried caged canaries because the birds succumb to carbon monoxide before people do, so a bird's distress warned the crew to leave. The metaphor carries this section's warning. The canary is the unit exposed to the hazard first, so on a physical fleet its exposure must be bounded by containment, not by how few units are chosen.

13 **Non-Inferiority Testing**: The design comes from clinical trials, where failing to find a difference proves nothing, so a new treatment must instead be shown worse than the standard by no more than a margin fixed before any data arrive (Blackwelder 1982). A canary can therefore pass on modest exposure without proving the candidate better, but only if δ was not chosen after the result was seen.

DRAFT

review, because suppressing legitimate clamps to improve a rollout metric would weaken the release argument.

16.9.3 From qualification to a new manifest

Reducing a policy's hesitation rate at the pick station does not justify relaxing its contact-force limits or floor-friction restrictions. If the retrained mug-delivery candidate were promoted on task speed alone, it would bypass the containment premises that keep the restricted route safe. Instead, the reviewer repeats closed-loop capability evaluation under the restricted route and feed conditions, and repeats the loaded timing and fault tests whose dependencies changed. Unaffected plant evidence remains reusable only while configuration, calibration, wear, and site premises still match.

Assume, still within the stipulated branch, that those results satisfy the predeclared capability criteria and preserve the containment claims. The adjudicator issues a new manifest binding the candidate, retained and repeated evidence, current calibration, and the same restricted mission. At the assessed stationary cutover state, the gate authenticates that manifest and checks current standing conditions before admitting new proposals. Field monitoring then compares the running service with the same success, cycle-time, rescue, and protection criteria. Failed qualification leaves the incumbent case unchanged; a failed standing condition withdraws the affected grant.

16.9.4 Over-the-air staging and watchdog-enforced rollbacks

A candidate written to the inactive bank inherits no operating grant from its predecessor, and rolling back to the prior software image cannot repair a worn brake or a stale calibration. **Hardware watchdog rollback triggers** must therefore distinguish a failure to boot from a failure during motion. Before tracking is enabled, failed image authentication, startup tests, or fieldbus synchronization can reject the candidate and select the retained image, which must still pass current calibration and standing-condition checks before receiving a permit.

During motion, the independent supervisor first commands the assessed fallback within its measured response budget. Where that response ends in torque removal, the supervisor asserts Safe Torque Off after the required controlled stop; a plant needing a powered hold retains the authority needed for that hold. Unlike a conventional compute watchdog that resets the processor immediately upon a timeout, a missed enforcer heartbeat withdraws tracking permission and triggers the hardware-controlled stop without resetting the processor mid-motion. Only after the plant has come to rest in its validated update state may the boot selector change banks.

The image and its compatible calibration schema form the rollback unit. If either record is missing, corrupted, or physically stale, the gate selects `REFUSE` unless a separately signed restricted case covers the actual state and its limits, such as $v \le v_{\text{restricted}}$. Retaining the prior binary image provides an immediate rollback target, but operators must re-validate standing physical conditions before the recovered binary receives an operating permit.

16.9.5 Event-triggered telemetry and safety performance indicators

An enforcer trip can reveal a policy failure, a changed physical premise, or both, and the field record must let the reviewer distinguish those causes before choosing retraining, maintenance, or a narrower envelope. Because wireless summaries alone cannot reconstruct the observations and actuator response around the event, detailed traces are retained locally. **Edge event-triggered telemetry** captures the sensor, proposal, permission, actuator, and timestamp chain around an intervention or boundary excursion. A local rolling buffer preserves the lead-up, and capture continues through the physical response whenever the qualified recording power path survives. Buffer length, write bandwidth, and hold-up energy are sized from the required reconstruction window and verified under the same contention and power faults as the permission path. A logic-rail capacitor does not guarantee that the full sensor and storage path survives, and recording must never delay the stop.

UL 4600 calls the field measurements that keep a claim alive **safety performance indicators** (SPIs). Each is a metric tied to a named claim, with a threshold and a predeclared response when the threshold is crossed (UL Standards & Engagement 2023). On the running machine, every standing condition of section 16.5 has one. Measured stop distance at scheduled trials and enforcer trips per operating hour watch the base's stopping claim, age refusals per operating hour watch the

↩ The sequential probability ratio test, which stops a trial campaign as soon as the evidence crosses a precalibrated boundary, is established in section 7.7.3.

observation-age claim, and localization residuals against their allowance watch the sensor geometry. An SPI whose threshold is crossed withdraws or narrows the grant it watches; one that drifts toward its threshold triggers review before it is crossed, which is the defense against the normalization of deviance of section 16.7.

During routine operation, compact health summaries support fleet monitoring while required incident records retain full provenance locally until transfer succeeds. Learning-data filters may prioritize unfamiliar events for training, provided they never discard required safety evidence or hide repeated failures. Once the traces arrive, a reviewer distinguishes policy hesitation from calibration drift, surface contamination, and mechanism wear before assigning the repair: qualified recovery traces can enter the experience pipeline, whereas reconstructed simulations extend test coverage only over their modeled conditions. A captured event therefore changes the release argument only after its physical cause and operating conditions are established. Reconstructed scenes and retraining can improve a candidate policy, yet neither automatically repairs a physical warrant, so the revised claim must return through the relevant qualification stages before a new manifest grants authority. Because the traces the machine keeps also record the people around it, each record that identifies a person carries standing conditions of its own: a declared purpose, a retention period, and a list of readers, audited like any other premise.

↪ The declarations that govern records identifying people, and the access and retention audit that enforces them, are developed in section 17.7.1.

16.9.6 Fleet evidence and accountable release

Teams break the safety warrant when they pool dissimilar routes into a single fleet mileage total or treat an operator intervention count as a collision rate. Fleet exposure can reveal recurring failures, but interpreting it requires knowing the operating domain, the intervention definition, and the exact system configuration. The release reviewer uses fleet records to challenge the same capability and containment claims, rather than replacing them with a mileage ranking. One public fleet record shows what an interpretable version looks like. Waymo publishes its rider-only crash rates by outcome, each against a human-driven benchmark adjusted to the same locations and each with a confidence interval. It republishes them as rider-only mileage accumulates (Waymo 2026; Kusano et al. 2025). Figure 16.4 plots the latest release and the history of two of its outcomes.

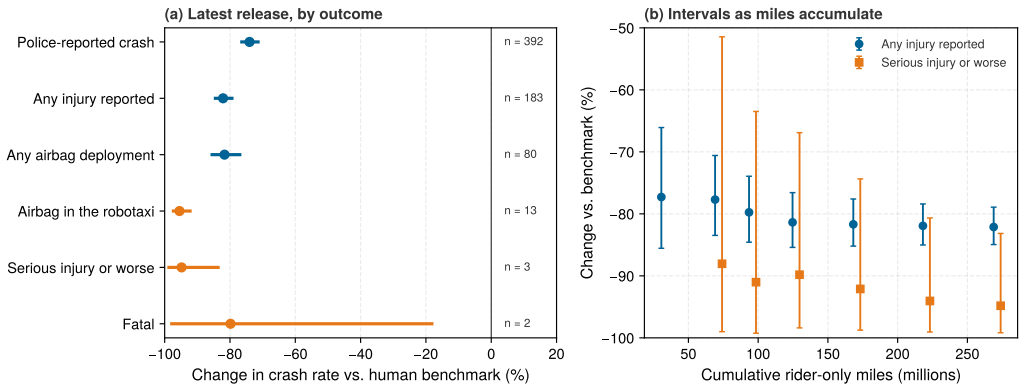

Figure 16.4: Exposure licenses claims one outcome at a time: (a) Percent change in crash rate against a location-adjusted human benchmark for each outcome in the latest public release, with 95 percent confidence intervals and the number of fleet crashes behind each estimate; orange marks outcomes with fewer than 20 crashes. (b) The same estimate and interval for two outcomes at each release, against cumulative rider-only miles. Common outcomes converge to narrow intervals; the serious-injury and fatal estimates rest on a few events, so their intervals stay wide however favorable the point estimate. Data from Waymo (2026).

In the June 2026 release, after 271 million rider-only miles, the injury estimate rests on 183 crashes and its interval spans a reduction of 79 to 85 percent. The serious-injury estimate rests on 3 crashes and spans 83 to 99 percent, and the fatal estimate rests on 2 and spans 18 to 98 percent. The same mileage therefore licenses a tight claim about common crashes and only a loose one about the outcomes a release decision cares about most, because rare events accumulate slowly however many miles the fleet drives. That is the fourth law, permission must be earned (principle 4), measured on

a real fleet. Each outcome's claim may extend only as far as its own interval, and a reviewer reads the interval before the point estimate.

The signed release manifest records the engineering decision and its accountable owner, and together with the records it binds, it lets an investigator follow one admitted action back to the person who signed for it. The enforcement record logs the admitted command. The manifest in force at that moment names by digest the policy weights, the enforcer and real-time operating system binaries, the calibration tables, and the operating envelope behind it. The signature on that manifest, made with a key held in a hardware security module, is bound to the sign-off record that names the lead systems adjudicator who accepted that configuration or the update that installed it. The manifest does not itself establish regulatory compliance or determine legal liability. Applicable requirements depend on the machine, intended use, and jurisdiction; the release manifest must preserve the evidence needed for that separate assessment. Throughout this lifecycle, release remains a decision about a named machine under named conditions. Shadow traces, staged trials, and field records can strengthen the next argument only when their operating conditions and limits are explicit, while the manifest and independent permission path retain the restrictions that the evidence supports.

↪ Who answers for each decision the manifest binds, and the duty to report an incident completely and on time, are developed in section 17.9.

16.10 Fallacies and Pitfalls

In purely digital software, a deployment bug manifests as a silent crash, a corrupted database row, or a dropped network packet; in physical AI, software decisions drive heavy actuators through real space where errors bend steel, destroy machinery, and injure coworkers. Releasing an embodied AI system therefore requires uncovering hidden assumptions before kinetic energy is coupled to physical mass. The following fallacies and pitfalls highlight recurring mistakes where teams confuse software statistical confidence with cyber-physical safety.

Fallacy: *Statistical coverage substitutes for deterministic architectural warrants.*

Engineering teams frequently present millions of simulated hours and thousands of incident-free test cycles as primary justification for deployment release. While physical and simulated exposure provides valuable empirical evidence regarding typical operating regimes, proving the ultra-low catastrophic failure rate required by a safety release claim demands far more operational hours than any physical test campaign can execute. Simulation environments also depend on idealized models, such as rigid-body dynamics, simplified Coulomb friction, and linear actuator response. Empirical performance and architectural warrants answer different questions. A large trial count cannot substitute for architectural enforcement, such as an independent permission path that revokes motion and executes a certified safe stop. The safety case must establish how deterministic runtime guards actively constrain actuator authority to provably safe physical limits when the learned policy encounters out-of-distribution inputs.

Statistical sampling bounds hazard rates only under observed operational distributions; trial volume cannot substitute for deterministic architectural mechanisms that constrain actuator authority.

Architect's countermeasure: Couple learned policy evaluation with independently qualified safety monitors. Explicitly state the hazard models, plant dynamics, execution deadlines, and safe-stop fallback conditions under which the system's safety invariants are deterministically enforced.

Fallacy: *A release verdict is a permanent certification of safety.*

A machine passes formal validation and enters production under a signed safety case. Over months of operation, brake friction material wears down and lengthens stopping distances, kinematic calibration drifts under daily thermal cycling, and dirt or optical scratches degrade sensor fidelity. Even when the deployed software binaries remain bit-for-bit identical, the physical assumptions underpinning the original release case gradually erode. A signed release verdict certifies safe operation only within a bounded maintenance window and under strict operational thresholds. To maintain safety, the release manifest must establish explicit invalidation triggers and scheduled maintenance intervals tied to hardware lifecycle counters, physical wear measurements, and calibration drift estimates. Once these operational limits are exceeded, the system must automatically restrict its capabilities or halt operation until recalibration and service occur.

Software bit-exactness cannot prevent mechanical wear, material fatigue, or sensor degradation.

DRAFT

Architect's countermeasure: Treat release manifests as perishable operational leases bounded by operating hours, calendar age, and mechanical cycle counts. Implement automated recalibration self-tests at boot, and require diagnostic verification before energizing high-power motor stages.

Pitfall: *Relying on unstated environmental assumptions to support a safety claim.*

During commissioning, a team verifies a mobile base's stopping distance in brightly lit warehouse aisles on clean concrete, documenting floor friction in the safety case while leaving ambient lighting unstated. In production, when the robot enters a dimly lit cross-aisle, longer camera exposure times increase image processing latency, which an age check flags at runtime (section 16.3). Concurrently, sparse visual feature matches degrade state estimation accuracy, introducing unmonitored localization drift that consumes the clearance buffer calculated from well-lit testing (section 16.7). The mechanical brake engages exactly as specified and low-level controller diagnostics report all systems nominal, yet the actual stopping distance margin quietly vanishes. Safety claims depend on operational surroundings. If an environmental boundary is omitted from the safety case, the deployment architecture can neither verify the operating conditions at release nor enforce them at runtime.

Unstated operating assumptions silently erode safety margins until an ordinary environmental fluctuation precipitates a collision.

Architect's countermeasure: Formally document every environmental assumption (such as ambient illuminance in lux, surface friction coefficients, and ambient thermal bounds) as an explicit premise in the release manifest. Pair each premise with a deterministic runtime detector or an enforced facility operational specification.

Fallacy: *Shadow-mode qualification guarantees closed-loop dynamic stability.*

An engineering team evaluates a candidate neural policy in shadow mode across thousands of fleet operating hours, recording near-zero action discrepancy ($\|\Delta \mathbf{u}_t\|_2 \approx 0$) between the candidate policy and the certified incumbent controller. The team infers that high behavioral fidelity during open-loop playback proves the candidate policy is ready for autonomous deployment. However, because the incumbent controller retains active authority over the plant, the state distribution is entirely dictated by the incumbent's dynamics. The candidate policy never experiences the compounding physical consequences of its own commands. Even minor discrepancies in control output can excite unmodeled mechanical resonances, induce severe actuator chattering, or generate phase lag that destabilizes the physical plant the moment control authority is transferred to the closed loop.

Open-loop trace replay conceals covariate shift, compounding autoregressive errors, and unmodeled plant resonances.

Architect's countermeasure: Treat shadow mode strictly as an initial filter to catch gross algorithmic discrepancies, never as proof of dynamic stability. Require closed-loop Monte Carlo sweeps across perturbed plant models, followed by supervised canary execution in isolated physical test facilities, before granting live actuation authority.

Fallacy: *Web-style canary traffic routing is directly applicable to physical machines.*

In cloud engineering, canary deployments safely route a small fraction of live network traffic to a newly deployed service, rolling back the deployment if error rates exceed a set threshold. Attempting to mirror this practice by assigning a percentage of live operational missions to an unvetted neural policy overlooks the physical reality of mass and momentum. A 368 kg vehicle moving at 1.3 m/s carries 311 J of kinetic energy. If an unverified model issues an erratic actuation command near an operator, the resulting collision cannot be mitigated by rolling back a container image or tearing down a replica set.

Kinetic energy and physical momentum render live production canary routing hazardous without deterministic architectural containment.

Architect's countermeasure: Restrict canary deployments to physically geofenced zones devoid of human personnel. If testing in active production environments is necessary, encapsulate the unvetted policy within an independent, non-preemptible runtime safety enforcer. This permission path must deterministically maintain the vehicle within its certified viable state space across all

declared sensing, plant, timing, and fault models, relying on hardware watchdog leases and certified safe-stop drive functions to override invalid actions.

Fallacy: *Over-the-air updates can be treated as stateless software deployments.*

In web architectures, stateless services restart cleanly from immutable container images. Treating OTA updates on physical robots as simple container replacements ignores the reality of hardware-bound state. Every physical machine possesses unique hardware calibrations: camera extrinsic matrices, joint zero-position encoder offsets, and load-cell tare values, alongside individual mechanical wear profiles. If an OTA update overwrites non-volatile storage or fails to migrate calibration schemas, the updated model executes with distorted sensor transformations. Even minor coordinate offsets introduce spatial localization errors that rapidly deplete geometric clearance budgets and invalidate the stopping guarantees established in the safety case.

Embodied systems are stateful; software updates cannot be decoupled from machine-specific physical calibration.

Architect's countermeasure: Decouple machine-specific calibrations into an isolated, schema-versioned non-volatile partition (such as EEPROM or write-protected flash) that persists across operating system bank swaps. Use dual A/B system partitions paired with hardware watchdogs that transition the plant into a safe, depowered, or mechanically locked state before changing the active bank. Require automated calibration validation and power-on self-tests before transferring motion authority to the updated partition.

Fallacy: *Continuous high-bandwidth wireless telemetry streaming is superior to edge event-triggered buffering.*

To achieve comprehensive operational visibility, an engineering team attempts to stream raw multimodal sensor data (high-resolution video, dense lidar point clouds, and 1 kHz motor current logs) continuously over facility Wi-Fi or cellular networks to cloud dashboards. In dense fleet deployments, wireless channel contention, radio frequency (RF) shadowing in industrial bays, and access-point roaming cause severe packet loss and queue bloat precisely during rapid, safety-critical dynamic events. Continuous network serialization also consumes substantial CPU time, DMA channels, and memory bus bandwidth, creating bus contention that can starve real-time safety controllers of deterministic execution guarantees.

Wireless bandwidth is physically constrained and vulnerable to RF fading; continuous raw streaming alone cannot guarantee preservation of telemetry during critical dynamic anomalies.

Architect's countermeasure: Transmit only compact, low-bandwidth health heartbeats and summary metrics over wireless networks during routine operation. Maintain continuous, high-rate circular telemetry buffers in local non-volatile storage. When a safety fault, anomalous dynamic event, or emergency stop occurs, latch the pre-trigger and post-trigger event windows locally. Size storage write bandwidth and write endurance to prevent memory bus interference with real-time safety enforcers, and offload event packages once the machine establishes a dedicated, high-bandwidth maintenance link.

16.11 Summary

A deployment release formalizes which physical claims the empirical evidence licenses for a specific physical machine, under what operating conditions, and for how long. For the warehouse mobile manipulator examined across these chapters, release resolves to three concrete physical inequalities. The mobile base stops within surveyed clearance. The manipulator unlatches the cage door below the latch's mechanical force limit. A mug handover remains strictly below the contact criterion for an unconstrained human hand. A formal claim-argument-evidence safety case links each inequality to its supporting premises and experimental evidence within a clearly demarcated operating envelope. Because required premises combine conjunctively, an argument is no stronger than its least supported premise; empirical confidence cannot be averaged across heterogeneous requirements. Independent sufficient legs strengthen support in the stipulated probability model, which estimates neither this robot's hazard rate nor calibrated assurance confidence. In the physical argument, a policy error cannot breach a monitored invariant only while the qualified enforcement, plant, sensing, timing, and fault premises hold; C5 isolation evidence does not by itself establish statistical independence.

Recognized machinery safety standards govern this argumentation structure. Within the permission path, only the safety microcontroller's lease-expiry timer and heartbeat watchdog are rated safety functions; the other formal protective claims rest on the certified drive, scanner, and arm safety functions beneath it.

An adjudicator evaluates the safety case to deliver one of three definitive verdicts: unconditional release (`UNCOND`), conditional release (`COND`), or refusal (`REFUSE`). If release is granted, standing conditions enforce operational boundaries in real time, automatically withdrawing authorization whenever any relied-upon premise becomes false or unobservable. Records that identify people carry standing conditions of their own, declared and audited like the physical premises (section 17.7.1). Against this book's illustrative input datasets, every primary claim contains at least one ungrounded premise, compelling a verdict of `REFUSE`. A separately stipulated branch illustrates the empirical evidence that would justify restricted conditional service (`COND`). Before final authorization, an adversarial review must try to break the entire argument, and that scrutiny must recur throughout the operational lifespan. A cryptographically signed manifest binds the release verdict to reviewed software and calibration artifacts by cryptographic digest, failing closed if any binary or configuration changes. Any subsequent model or firmware update must return through the same safety case, because open-loop shadow operation cannot evaluate the physical consequences of unexecuted closed-loop control actions. Table 16.7 collects the load-bearing equations governing deployment release, detailing the physical or statistical boundary each expression establishes and noting where each was derived in earlier chapters.

Table 16.7: Key equations of deployment release: Each load-bearing equation of the chapter, the physical boundary it bounds or decision it settles, and the equation where it is derived. Stopping, contact, latch, and exposure relationships originate in preceding chapters; the release case incorporates their mathematical guarantees as foundational premises.

Equation	What it bounds or decides	Derived in
$d_{\text{stop}} \le D_{\text{clear}},\ F_{\text{contact}} \le F_{\text{limit}},\ T_{\text{exec}} \le T_{\text{deadline}}$	The three physical criteria every release claim must evidence: stopping clearance, contact force, and execution timing	equation 16.1
$v\,\tau_{\text{delay}} + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} \le D_{\text{clear}}$	The mobile base stopping budget, whose unspent margin every premise of the stopping claim draws on	equation 12.1
$F_{\text{unbraked}} = v\sqrt{k_H\, m_{\text{red}}}$	The peak transient handover force (m_{red} is the hand-arm reduced mass), establishing the maximum approach speed permitted by the contact criterion	equation 12.13
$F_{\text{cmd}} = F_{\text{trip}} + k_{\text{latch}}\, v_{\text{latch}}\, T_c$	The contact force developed against a door latch before arm braking begins	equation 12.11
$F_{\text{cmd}}/k_{\text{latch}} + v_{\text{latch}}^2/(2a_{\text{arm}}) \le F_{\text{lim}}/k_{\text{latch}}$	The arm deceleration the door-opening branch must guarantee, bounding admissible approach velocity	equation 12.12
$T \ge 3.0/\lambda$	The failure-free testing exposure required, at 95% confidence, to demonstrate a failure rate λ per operating hour, showing why empirical exposure alone cannot validate catastrophic risk claims	equation 7.9
$\Pr(C) = \prod_i p_i$	Probability of an exact conjunction in the stipulated independent-premise model; not measured robot hazard or calibrated assurance confidence	equation 16.2
$\Pr(C) = 1 - \prod_j (1 - r_j)$	Probability of an exact union in the stipulated independent-leg model; C5 isolation alone does not establish statistical independence	equation 16.3

DRAFT

Key Takeaways: Deployment release and safety cases

- **The envelope bounds the claim:** A release claim covers only the speeds, payloads, surface friction coefficients, clearances, and contact scenarios for which empirical evidence was systematically collected. Every dimension of the operational design domain requires an active runtime monitor or a strictly enforced site procedure.
- **Doubt accumulates along required premises:** A conjunctive argument ($\bigwedge_i P_i$) is no stronger than its weakest required premise and is often strictly weaker; confidence cannot be averaged across premises. High empirical accuracy in perception cannot offset an unmonitored braking margin or an uncharacterized tail latency. Independent sufficient legs reduce doubt under the stipulated probability model. Policy validation and an isolated permission path do not automatically constitute such legs; the physical containment claim still requires qualified plant, sensing, timing, and fault premises.
- **Standing conditions make release revocable:** Every relied-upon premise requires an active detector or operational procedure, an explicit checking cadence, and a validated safety action triggered whenever the premise evaluates to false or unknown. The signed safety case binds these obligations directly to the machine across its operational life.
- **Updates return through the release argument:** Shadow deployment reveals policy divergence without testing the closed-loop physical consequences of those divergent actions. Rigorous closed-loop qualification and a re-evaluated manifest still govern deployment authorization; every update must preserve machine-specific calibration and execute a validated stop or hold during software cutover.
- **An unknown premise refuses, and refusal names the next work:** In safety argumentation, unknown envelope membership refuses exactly as a measured violation does, while its cause is logged separately. On this book's illustrative walkthrough, the mobile manipulator receives an explicit verdict of `REFUSE`. A structured refusal is productive: it isolates the missing measurements, identifies the claims they would ground, and defines the residual operational envelope that remains once those gaps are closed.
- **Useful service needs its own evidence:** The stipulated restricted mug-delivery workflow achieves `COND` only by satisfying concrete task-success, cycle-time, and human-intervention criteria alongside safety claims C1–C6. Safety filtering can preserve high task completion rates even when raw proposer policy autonomy is comparatively modest.
- **No verdict moves the proposal boundary:** Under both `UNCOND` and `COND`, learned policies merely propose actions while the hardware permission path decides physical admission. Within that permission path, only the safety MCU's lease-expiry and heartbeat watchdog is a rated safety function; the admission checks are not rated. Entering a restricted operational mode requires its own signed release case, never an informal or ad hoc runtime downgrade.

The fourth law, *permission must be earned* (principle 4), establishes that permission to operate must derive strictly from recorded evidence and expire whenever that evidence lapses. Standing conditions transform this principle into an active software and hardware mechanism. Each condition couples a required premise with a dedicated detector, a monitoring cadence, and an enforced safety response. Consequently, the loaded stopping trials that would support a conditional release for the warehouse mobile manipulator become binding empirical warrants whose invalidation immediately terminates authorization. Under this book's illustrative records, that grant is never issued, because each of the six primary claims relies on at least one premise that remains ungrounded or unknown. The stipulated delivery branch demonstrates how empirical field trials could substantiate useful restricted service and specifies the runtime conditions necessary to sustain that grant. Just as a manual lease restricts human or teleoperation authority to the validity window of its evidence, and precommitment binds test evaluation to rules established before observations occur, deployment release binds fleet deployment to verifiable physical limits. Release is the widest operational authority

granted in this book, and even it never reaches the actuators directly. Every motion it licenses still crosses the causal boundary only through the permission path and the rated functions beneath it.

↩ The manual lease that bounds human authority to the validity window of its evidence is established in section 14.3.4.

16.12 Historical Perspective and Further Reading

Long before it became an engineering artifact, the modern safety case originated in the philosophy of practical reasoning. Toulmin (1958) decomposed argument structures into concrete elements: an explicit claim, the ground data offered to support it, an inferential warrant that licenses the logical step from data to claim, and the rebuttals that identify conditions under which the warrant fails. That structural anatomy survives almost unchanged in modern deployment release arguments. In the late 1990s, safety engineers translated these philosophical foundations into auditable systems practices. The Claim-Argument-Evidence (CAE) methodology introduced by Bishop and Bloomfield (1998) and the Goal Structuring Notation (GSN) formalized by Kelly (1998) transformed implicit engineering convictions into graph-structured arguments that an independent reviewer can inspect link by link. Later, the autonomous vehicle community adapted this goal-based assurance framework in ANSI/UL 4600 (UL Standards & Engagement 2023), requiring explicit argumentation over positive and negative evidence, concrete safety performance indicators, and rigorous independent assessment.

Two foundational results established the statistical limits of empirical testing, shaping what a release argument can claim. First, Butler and Finelli (1993) proved that the ultra-low failure rates demanded of life-critical software cannot be validated through testing alone; verifying a rate of 10^{-9} failures per operational hour demands on the order of 10^{9} failure-free test hours. Decades later, Kalra and Paddock (2016a) applied that same arithmetic to embodied autonomy, showing that an autonomous fleet would have to drive billions of operational miles to establish statistical parity with human drivers. A hazard mitigation claim therefore cannot rest solely on driving miles; it requires an architectural warrant, such as formally verified runtime safety envelopes and deterministic interlocks, alongside empirical testing. Second, redundancy cannot be assumed to yield statistical independence. The classic empirical study by Knight and Leveson (1986) demonstrated that independently written software implementations suffer correlated failures far more often than independent probability models predict. As a result, a multi-legged safety argument (Bloomfield and Littlewood 2003) must provide empirical and architectural evidence for the independence of its redundant legs rather than treating diversity as an axiom. On the running machine, claim C5 carries that burden.

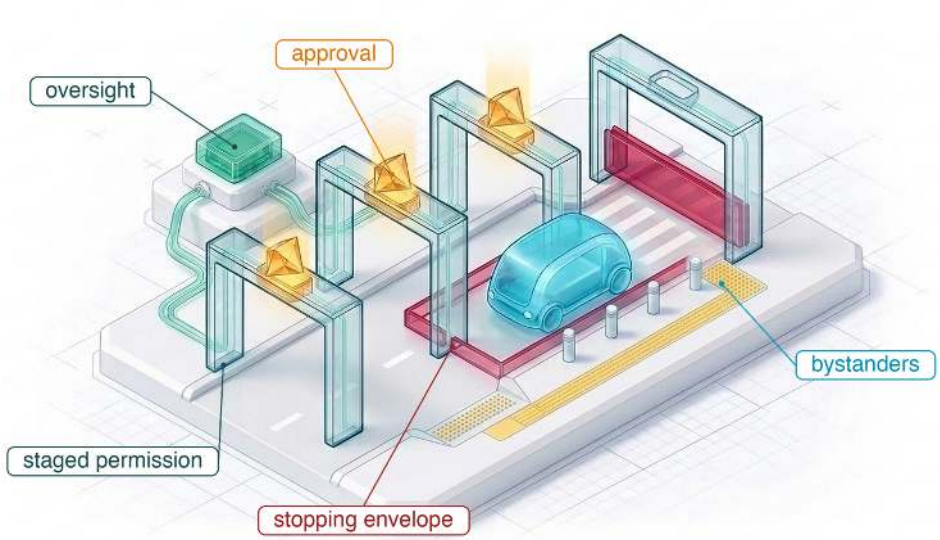
The final historical lesson concerns the temporal fragility of assurance. The Rogers Commission report on the Space Shuttle Challenger disaster (Presidential Commission on the Space Shuttle Challenger Accident 1986) and Diane Vaughan's subsequent sociological analysis (Vaughan 1996) revealed that safety cases rarely collapse from an isolated blunder. Instead, arguments degrade through the "normalization of deviance," a slow organizational erosion in which unexplained anomalies are repeatedly rationalized until a catastrophic threshold is breached. Dynamic safety cases (Denney et al. 2015) counter this failure mode by maintaining the argument as an active runtime process, continually validating underlying assumptions against operational telemetry. Because embodied systems require continuous post-deployment evolution, compromise-resilient update frameworks such as TUF (Samuel et al. 2010) and Uptane (Kuppusamy et al. 2016) established that the software delivery channel is itself a primary attack surface. The release architecture developed here joins these lines of work. The deployment verdict is cryptographically bound to a signed manifest validated by the target controller before motion begins, and every environmental assumption remains a standing operational condition whose violation revokes execution authority within the qualified detection-and-response bound.

Six foundational works reward careful study, each anchoring a distinct dimension of the release argument:

- Toulmin (1958) introduces the claim, warrant, backing, and rebuttal framework that underpins modern structured argumentation, establishing why inferential warrants must be scrutinized independently from raw empirical data.
- Bishop and Bloomfield (1998) articulates the Claim-Argument-Evidence (CAE) framework for critical software systems, providing the structural basis for the assurance scorecard in table 16.2.

- Kelly (1998) introduces Goal Structuring Notation (GSN) and formalizes pattern-based approaches for managing safety cases across system lifecycles, establishing the graphical formalism illustrated in figure 16.1.
- Knight and Leveson (1986) provides empirical evidence of correlated failures in diverse redundant software, demonstrating why claims of subsystem independence must be actively verified rather than taken as an architectural postulate.
- Vaughan (1996) reconstructs the organizational and technical breakdown of the Challenger launch decision, defining the concept of normalization of deviance that runtime safety performance indicators are designed to detect and arrest.
- Koopman and Wagner (2016) identifies inductive machine learning among the core challenges confronting autonomous vehicle validation, proposing phased operational envelope expansion, hardware-isolated runtime monitors, and systematic fault injection, the triad that this chapter's release protocol builds on.

What's Next: From release to responsibility



Who answers for the decisions behind a signed manifest? The manifest names the adjudicator who accepted the configuration and its operating envelope. Yet the crossing rule, the staffing of the remote assistant, the permit under which the machine runs, and the uses of the records it keeps were each decided by someone else, and none of them appears in a per-tick log. Chapter 17 traces those decisions to named owners. It tests whether each human role the safety argument relies on is one a person can perform. It converts gaps in how well the machine detects different groups of people into gaps in stopping distance. It collects all of it in an approval record that the release gate reads, so that a decision with no owner refuses operation the way an unknown premise does.

Purpose

Who answers for a machine that moves on its own when its motion harms someone?

A machine's logs can show, tick by tick, what it sensed, proposed, and admitted, and still not show who decided that it could travel at that speed, among those people, with that person as its only backup. When harm arrives, blame settles on whoever stood closest to the event, often an operator handed a duty no person could have carried out, while the decisions that set the machine's limits stay spread across engineering teams, suppliers, site managers, and regulators. The machine's effects also reach people who never chose it: pedestrians and coworkers whose detection rate was never measured for people like them, workers whose jobs shift to rescuing and watching it, and bystanders whose faces fill the records kept to explain its mistakes. A machine is fit to be given authority only when each decision behind its actions names the person who answers for it, each human role it relies on is one a person can actually perform, and each group that bears its risk or its recording has been counted. Assigning responsibility after a collision cannot take back the energy the machine has already delivered across the causal boundary, so it has to be assigned before the machine moves.

Learning Objectives

- Explain why reconstructing what a machine did does not establish who answers for it, and trace an admitted action back to the decisions that allowed it
- Evaluate whether a human role gives its holder the time, information, and authority to act, using the takeover budget and supervisor utilization
- Specify the stages of operating permission, what each stage allows and must report, and what withdraws it
- Calculate how a gap in per-frame detection between groups of people becomes a gap in stopping distance and impact energy
- Size a per-group evaluation whose confidence interval can resolve a detection gap of a stated size
- Distinguish risk borne by people who chose the machine from risk borne by people who did not, and specify exposure reporting for each group
- Design an approval record that names an owner for every decision behind an admitted action, so that a missing owner blocks release

17.1 Who Answered for the Cruise Collision

Release left the running machine with a signed manifest: a verdict, the records it binds by digest, and the standing conditions that withdraw it. The manifest names the lead systems adjudicator who signed it. It does not name who decided the aisle speed the warehouse would accept, who decided that one remote assistant would serve every machine on the floor, or who would report an incident, to whom, and how fast, if the machine hurt someone. Those decisions shape what the machine does once a command crosses the causal boundary as surely as the enforcer's thresholds do, and none of them appears in a per-tick log.

The Cruise collision in San Francisco on the night of October 2, 2023 shows what happens when they are left unassigned. A human-driven car struck a pedestrian in a crosswalk and threw her into the path of a driverless Cruise robotaxi, which braked hard, ran over her, and stopped. With her still beneath it, the vehicle then began a pullover toward the curb and moved about 20 ft (6.1 m) at up to 7.7 mph before it stopped (Quinn Emanuel Urquhart and Sullivan, LLP 2024). The engineering failure belongs to the permission path. A post-collision classifier placed the pedestrian at the side of the vehicle rather than in front of it, and the fallback it selected moved the vehicle without any evidence that the space beneath it was clear.

↩ The fallback rule that forbids renewed motion while the space beneath a vehicle is unverified is established in section 12.9.1.

The machine's own records were enough to reconstruct that motion. The engineers who analyzed the event for the company's boards rebuilt it from the vehicle's logs and video, including the dropped pedestrian track before impact and the pullover after it (Quinn Emanuel Urquhart and Sullivan, LLP 2024). What failed after the collision was the account given to the people who had licensed the vehicle. On October 3, a Cruise representative told an analyst at the California Public Utilities Commission (CPUC) by telephone that the vehicle had stopped on impact and contacted remote assistance; the description left out the pullover and the dragging. The commission later counted 15 days, October 3 through 18, in which Cruise withheld a full account, and it received the full video on October 19 (California Public Utilities Commission 2024). Cruise's crash reports to the National Highway Traffic Safety Administration (NHTSA) also omitted the dragging (U.S. Attorney's Office, Northern District of California 2024). On October 24, the California Department of Motor Vehicles (DMV) suspended Cruise's permits for driverless testing and driverless deployment, citing among its grounds that the company had misrepresented information related to the safety of its autonomous technology (California Department of Motor Vehicles 2023). A review commissioned by Cruise's boards found no evidence that anyone intended to mislead regulators, but it described a "passive, non-transparent approach" to disclosure and a leadership focused on correcting media coverage of the crash (Quinn Emanuel Urquhart and Sullivan, LLP 2024).

Each group involved held one piece of the outcome: the engineers who designed the classifier and the fallback, the remote-assistance staff, the people who drafted the reports, and the executives who managed the response. Each could describe its own piece truthfully, and none of those descriptions

said who had decided the whole. The CPUC had granted Cruise commercial driverless service in San Francisco at any hour seven weeks earlier (California Public Utilities Commission 2023). The logs answered what the vehicle did. They did not answer who had decided that a driverless vehicle should pull over after a side impact without checking beneath itself, who decided what regulators would be told, or who answered for either decision. Five years earlier, after the Uber test vehicle killed a pedestrian in Tempe, the person who answered in court was the vehicle's backup operator, who pleaded guilty to endangerment in 2023 (Maricopa County Attorney's Office 2023).

Responsibility for a physical machine therefore has to be engineered like any other premise of its authority: written down before the machine moves, attached to the decisions that set its limits, and checked when it is released. The same questions arise on the warehouse machine without a public road in sight. A remote assistant answers for takeovers, facility management for the crossing rule that keeps people out of the aisle, a data team for the camera traces the black box keeps, and someone, so far unnamed, for the decision that one person can watch every machine on the floor. The sections that follow take these decisions in turn: the links behind one admitted action, the human roles the design relies on, the stages of permission to operate, the detection of different groups of people, the people who bear the machine's risk and appear in its records, and the labor it moves rather than removes. The approval record collects these decisions in one place that the release gate reads, so that a decision with no named owner blocks operation the way an unknown premise does.

17.2 Decisions Behind an Admitted Action

Consider one command the enforcer admitted in the aisle: a base velocity of 1.3 m/s toward a rack end. The enforcement record shows that it passed the stopping check at that tick, under the thresholds in force, yet behind that single log line stand at least six decisions made by different people at different times. Four of them leave traces in the engineering records built in earlier chapters. The learning team trained and approved the policy weights that proposed the command. The safety engineering team built and signed the enforcer and its thresholds. The intervention design and the remote assistant on shift set the authority state at that tick. The lead systems adjudicator signed the operating envelope into the release manifest, including the aisle speed and the floor-friction premise beneath it. The other two decisions govern the site rather than the machine: facility management wrote the crossing rule that lets people enter the aisle only at marked points, while operations decided how many machines one remote assistant would serve. Figure 17.1 draws the six links and the record, if any, that holds each one.

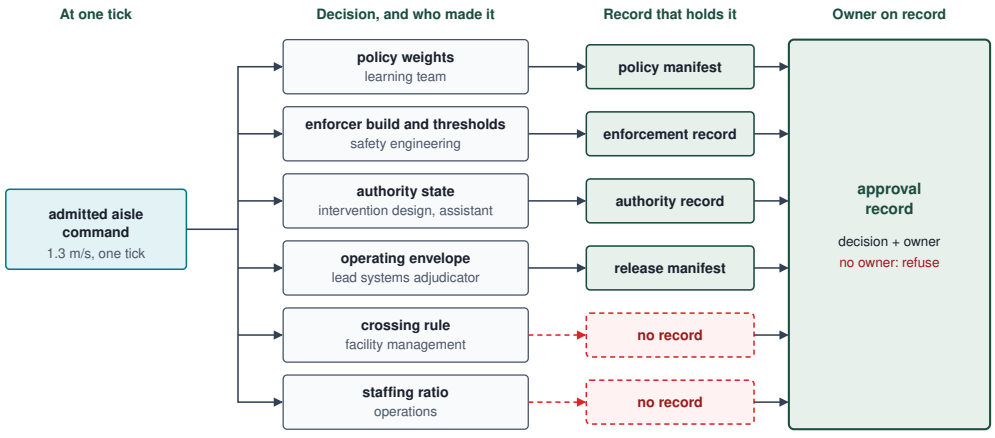

Figure 17.1: Six decisions behind one admitted command: An aisle command admitted at one tick traces back to decisions made weeks earlier by six different parties. Four of them land in a record the book has built (the policy manifest, the enforcement record, the authority record, and the release manifest); the crossing rule and the staffing ratio land in none, so no log can name who made them. The approval record lists each decision with its owner and refuses operation while any link has no owner.

↩ The lead systems adjudicator, whose signature binds the release verdict to a named person, is established in section 16.4.

When each of these decisions belongs to a different party, every party can truthfully say that the harm came from someone else's part. Thompson called this the **problem of many hands** in his study of public officials, where responsibility for a policy that many people shaped ends up resting on no one (Thompson 1980). Nissenbaum showed that computer systems make it worse: they are built by many people, they fail in ways no single person caused, and their failures are easily excused as bugs that no one could have prevented (Nissenbaum 1996). A learned proposer adds a further excuse. Its behavior was learned rather than written, so no engineer wrote the rule it followed, and Matthias argued that machines which learn create a real gap in who can be held responsible for what they do (Matthias 2004). The architecture of this book closes that gap at the point where it matters. The model proposes and never admits (principle 3), so every admitted action passed a check that someone designed, under an envelope that someone signed, and "the model did it" is never a complete answer.

17.2.1 Decisions that leave no trace in a log

When an incident investigator opens a machine's runtime logs, the decisions that made the incident possible are missing because those logs capture only runtime events: an observation and its age, a proposal, an admission, a change of authority, or a fault trial. The choices that shaped those events happened weeks or months earlier in meetings and documents, long before a command crossed the causal boundary. A safety engineer approves an operating envelope, an operations manager sets a staffing ratio, a team disables a protective function, a company applies for a permit, and a data team declares what its camera traces may be used for. In the Cruise case, the rule that a side impact should trigger a pullover was a design decision made long before October 2, and the choices about what to tell regulators were made in the days after. Neither could appear in the vehicle's log, because the vehicle did not make them.

Such decisions have to be recorded on purpose, and a chain of them is less complete than any one of its links. Suppose each of the 6 links behind the aisle command can be retrieved when an investigator asks with probability 0.99, independently of the others. The whole chain then resolves with probability $0.99^6 = 0.94$. At 0.95 per link it resolves with probability 0.74, and at 0.90, roughly what a decision held only in memory and email achieves once its author has changed jobs, with probability 0.53. An investigator would then find the full chain in about 53 percent of incidents. The same arithmetic makes a conjunctive release argument weaker than any one of its premises, and the remedy is also the same: each link has to be written down as part of the design, not left to accumulate.

↩ The conjunctive arithmetic that makes an argument no stronger than its weakest premise is established in section 16.3.2.

These links are held in the decision block of the approval record (section 17.9). For each decision it names the type of decision, the role that owns it, the signed approval, the evidence it relied on, and the date after which it must be made again. A link with no owner is not a gap in paperwork; it is a premise of the machine's authority that no one has accepted. Even when every link has a named owner, however, many of those approvals rest on a further premise: that a human operator in the loop can step in when the machine's own case runs out.

17.3 Oversight a Person Can Perform

Naming a human operator in that decision chain, whether a safety driver behind the wheel, a remote assistant at a console, or a spotter walking beside a robot during commissioning, often shifts blame onto that person without adding any real protection. A person in the loop provides genuine oversight only if three conditions hold: the person must have the time to act before the hazard arrives, the information to understand what the machine is doing, and the authority to change what it does, not only to report it. Santoni de Sio and van den Hoven state the same requirement in two parts: the system must respond to the reasons of the people meant to control it, and every outcome must trace back to someone who understood both the system and their own role in it (Santoni de Sio and Hoven 2018).

DRAFT

Definition 17.1: Human oversight role

A ***human oversight role*** is a duty that a design assigns to a person, such as stopping the machine, taking over a channel, or approving a motion, and that the safety argument relies on. The role counts as a countermeasure only if its holder has the time, the information, and the authority to carry it out within the time the hazard leaves.

1. **Significance**: A role that fails any of the three conditions adds no protection, yet it moves blame onto the person who holds it, so every role the safety case cites must be tested like any other premise.
2. **Distinction**: The takeover budget measures how long a person needs; the oversight role asks whether the design leaves that much time, gives that person what they need to see, and lets them act on it.
3. **Common pitfall**: A frequent misconception is that adding a person to the loop makes a design responsible. A person who cannot act in time is a place to put blame, not a safety layer.

When a role fails any of these conditions, the person in it absorbs responsibility for control they never had. Elish calls the person in that position a **moral crumple zone**. Like the crumple zone of a car, the person absorbs the impact, except that here the impact is blame, and what the crumpling protects is the reputation of the system rather than the person (Elish 2019). The three conditions give a design team a test it can apply before the machine moves.

17.3.1 Time to act

Time is the condition most often violated, and it is the easiest to check. At the 1.3 m/s aisle speed, a person who steps out 1.10 m ahead of the machine leaves 0.85 s before the rack end. A remote assistant who has been monitoring rather than driving needs about 4.5 s to take over, the design out-of-loop takeover time, during which the machine travels 5.8 m. The person needs about 5× the time the hazard leaves. No training, attention, or diligence closes a gap of that size, so a design that names the remote assistant as the countermeasure for a person stepping out at a rack end has not added a layer of protection. It has recorded in advance who will be blamed.

The engineering consequence is already in the book's design. The machine stops itself first and asks for help from standstill, where waiting costs time but not clearance. What the time test adds is the duty to write that choice down. For every human role the safety case relies on, the approval record lists the response time the role requires, the time the hazard leaves, and a verdict of `FEASIBLE`, `INFEASIBLE`, or `UNKNOWN`. A role marked `INFEASIBLE` may stay in the design as a productivity resource; it may not appear in the safety argument as a countermeasure.

↩ The out-of-loop takeover time and its price in the stopping budget are established in section 14.2.2.

17.3.2 One person, many machines

A remote assistant who serves many machines is a server in a queue, and queueing theory says how busy that person is. If help requests arrive from the whole fleet at rate λ_{arr} and each holds the assistant for a mean time $\bar{T}$, the share of time the assistant is busy, the utilization, is

$$\rho_{\text{serv}} = \lambda_{\text{arr}} \bar{T}. \tag{17.1}$$

A request that arrives while the assistant is busy waits. Under the simplest queueing model, with random arrivals and random service times, the mean wait before service begins is

$$W_q = \frac{\rho_{\text{serv}} \bar{T}}{1 - \rho_{\text{serv}}}. \tag{17.2}$$

The wait grows without bound as ρ_{serv} approaches one. Moreover, a request arriving while the assistant is busy, which happens with probability ρ_{serv} in this model, gets no human attention at all until the request ahead of it is finished.

Napkin Math 17.1: One assistant, twenty machines

Problem: A site plans to run 20 mobile manipulators with one remote assistant. Each machine asks for help 0.5 times per operating hour, and each request holds the assistant for 3 min on average. How busy is the assistant, and how long does a request wait?

Variables:

- Requests per machine: 0.5 per operating hour (Illustrative); mean service time $\bar{T} = 180$ s (Illustrative).
- Machines served: 10, 20, or 32 (Illustrative).

Math: By equation 17.1, 20 machines give $\rho_{\text{serv}} = 0.50$, and equation 17.2 gives a mean wait $W_q = 180$ s. One request in a hundred waits longer than 23 min. With 10 machines the figures are 0.25 and 60 s; with 32 they are 0.80 and 720 s, about 12 min.

Result: The assistant is busy 50 percent of the time, and a typical request waits minutes. Adding machines past that point makes the wait grow much faster than the fleet.

Systems insight: Every one of these waits is longer than the 0.85 s a person stepping out at a rack end leaves. The ratio of machines to assistants is therefore a productivity budget and never a safety layer. A staffing plan that caps utilization at 0.5 limits this assistant to 20 machines, and the approval record lists that cap as the decision of whoever set it.

↩ Admitting a remote-assistant session only when the machine is in a state where waiting costs no clearance is established in section 14.4.6.

The queue shows why the staffing ratio is a decision someone must own. A manager who adds machines to one assistant's load is not changing a number in a spreadsheet; that manager is deciding how long a stranded machine, and the people working around it, will wait for a person. If that decision is written down with the utilization it implies and an owner, it can be reviewed when the fleet grows. If it is not, it changes silently every time a machine is added.

17.3.3 Information and authority

Time is necessary but not enough. A person with time to act must also know what the machine is doing and be able to change it. A console that shows the camera feed but not which channel the machine still owns leaves the operator guessing about the most important fact of a handover, and an operator who believes they hold a channel they do not hold can make a takeover worse. A role whose only output is a report, a flag raised to a supervisor or a note in a log, gives its holder no authority over the motion at all. The test for authority is mechanical. The person must be able to stop the machine, through a channel the permission path honors within the time the hazard leaves, without asking anyone else.

↩ Mode confusion, and the per-channel annunciation that keeps an operator's picture of who owns each channel current, are established in section 14.6.

For each human role, the approval record therefore holds three fields beside the timing verdict: the information channel the person reads, the authority channel the person can act through, and whether that channel reaches the permission path. A remote assistant on the running machine passes the information and authority tests for a stranded machine at standstill and fails the time test for a person stepping out at a rack end. Both facts belong in the record, because they assign that one person two different duties.

Checkpoint 17.1: Oversight a person can perform

A design names three people in its safety argument: the remote assistant, a teach-pendant operator during commissioning, and a floor supervisor who watches the fleet dashboard.

- ☐ **Time**: Can you state, for each role, the time the role requires and the time the relevant hazard leaves, and mark the role `FEASIBLE`, `INFEASIBLE`, or `UNKNOWN`?
- ☐ **Load**: A site runs 24 machines with one assistant; requests arrive at 0.8 per machine-hour and take 75 s. Can you compute the assistant's utilization and mean wait, and say whether the assistant may be listed as a countermeasure for any hazard faster than a minute?

☐ **Authority**: Can you say which of the three roles can stop the machine through a channel the permission path honors, and which can only report?

17.4 Permission in Stages

Granting a machine full operating permission on day one exposes the public or the workforce before the configuration has accumulated the field evidence needed to support that exposure. Regulators of driverless vehicles therefore grant permission in stages. California's rules separate testing with a safety driver, testing without one, and deployment to the public, each under its own permit and conditions (California Department of Motor Vehicles 2018a, 2018b). The CPUC adds a second ladder for carrying passengers. Before August 2023, Cruise could carry paying passengers without a safety driver only in limited areas of San Francisco between 10 p.m. and 6 a.m., could carry paying passengers anywhere in the city at any hour only with a safety driver present, and could give free driverless rides anywhere at any hour. On August 10, 2023, the commission removed the time limit on driverless fared service (California Public Utilities Commission 2023). Each rung named a configuration, a place, a time, and who could be aboard.

Definition 17.2: Permission stage

A ***permission stage*** is a grant, made by the party entitled to grant it, that allows a named configuration of a machine to operate in a named domain, among named groups of people, on named evidence, and under named reporting duties. A machine moves to the next stage only on evidence gathered at the current one, and a stage can be withdrawn for a configuration change, an incident, or a withheld record.

1. **Significance**: Exposure grows one stage at a time, so the evidence for the next stage is gathered under the protection of the current one, and a failure at one stage costs only what that stage exposes.
2. **Distinction**: A release verdict is the engineering decision about whether a configuration's claims are supported; a permission stage is the grant that decides who may be exposed to that configuration and what must be reported about it.
3. **Common pitfall**: A frequent misconception is that a stage, once reached, belongs to the company. It belongs to a configuration, and it carries duties that, if broken, withdraw it.

Each stage carries reporting duties, and the duties grow with the stage. California requires a manufacturer testing on public roads to report, within ten days and on a set form, any collision that causes damage, injury, or death, and to file an annual report of every disengagement, each transfer of control from the automation to the safety driver (California Department of Motor Vehicles 2018a). Since 2021, a federal order has required companies operating automated driving systems to report crashes to NHTSA. Under the version in force in 2023, a crash that involved a death, an injury treated at a hospital, or a pedestrian or other vulnerable road user had to be reported within one day, with an update at ten days (National Highway Traffic Safety Administration 2021). The disengagement reports are the data behind figure 14.1, whose two series come from two different stages, testing with a driver and testing without one.

A warehouse has no public permit office, but the same ladder exists. The machine is commissioned with a spotter walking beside it, then allowed to run unattended in a zone people cannot enter while it operates, and only then released onto an open floor among workers. The facility owner, the integrator, and the workers' representatives grant these stages, and the approval record names who granted each one, for which configuration, on what evidence, and with which reporting duties. The stage and the verdict are recorded separately. A `COND` verdict for restricted inspected-route delivery says which claims the evidence supports; the stage says whether that restricted service may run on the open floor yet.

17.4.1 Leaving a stage on evidence

A stage is left on evidence, not on a calendar date, and the evidence a lower stage produces is partly hidden by the protection that stage provides. A safety driver or a spotter masks failures: when the person intervenes, the machine's own error never reaches its consequence, and the stage records an intervention rather than a collision. Counting failures at the supervised stage therefore means reconstructing, for each intervention, whether the machine would have failed without it, which is why the disengagement reports matter and why they must say why control was transferred.

↩ Interventions that end a trial before its outcome is known, and how they are counted, are established in section 7.6.

The exposure arithmetic sets how long a stage must run. Under the zero-failure Poisson exposure bound of section 7.9, ruling out an intervention rate at 95 percent confidence with zero observed events requires an exposure of $\ln(1/0.05)$, or nearly three times the target mean interval between interventions, so claiming fewer than one safety-relevant intervention per 1,000 operating hours after observing none requires the machines to accumulate about 2,996 failure-free operating hours. A fleet of 10 machines running 16 hours a day reaches that in 19 days. Those hours support the claim only for the configuration that ran them. A new policy, a new enforcer build, or a new site layout starts its own count, because the evidence belongs to a configuration, and so does the stage it supports.

17.4.2 Withdrawal and disclosure

Permission is withdrawn the way it is granted, one stage at a time. The DMV's October 2023 order suspended Cruise's driverless testing and deployment permits but left in place its permit to test with a safety driver (California Department of Motor Vehicles 2023), stepping the company back down the ladder rather than off it. The grounds the DMV cited show what a permit protects. One was that the vehicles were not safe for public operation, a finding about the motion. Another was that the company had misrepresented information related to the safety of its technology, a finding about the record.

The regulatory fines that followed were for the record. The CPUC counted the 15 days in which it lacked a full account, applied its daily maximum of $7,500 to each, and fined Cruise $112,500 (California Public Utilities Commission 2024). In September 2024, NHTSA imposed a consent order with a $1.5 million penalty for crash reports that omitted the dragging (National Highway Traffic Safety Administration 2024b). In November 2024, Cruise entered a deferred prosecution agreement and paid a $500,000 criminal fine for submitting a false record to influence the federal investigation (U.S. Attorney's Office, Northern District of California 2024). Regulators withdrew authority from the company because of what its vehicle did and because of what the company did not tell them about it.

The **incident disclosure duty** is the obligation, attached to an operating permit, to report an incident completely and on time to the parties the permit names. It is a decision with an owner like any other: someone decides what an incident report contains, someone signs it, and someone decides when a record has been withheld long enough to break the permit. The permit block of the approval record therefore lists, for each stage, the regulator or grantor, the configuration the stage covers, the reporting duties with their deadlines, and a disclosure log of every report sent, with its author and the evidence attached. A release manifest that binds raw traces to the configuration that produced them, and that an assessor can open, is the engineering half of that duty. The disclosure log is the other half, because it shows what was actually sent, to whom, and when. Once a machine enters an open-floor stage among coworkers or pedestrians, however, its safety case rests on a sensor premise that aggregate stage-exit hours can hide: whether its detectors see every group of people in its path equally well.

↩ The release manifest that binds raw traces to the configuration that produced them is established in section 16.8.

17.5 When Detection Depends on Who Is Detected

A machine that earns open-floor permission on aggregate obstacle-detection metrics can still fail systematically on specific groups of people sharing the aisle or roadway. Buolamwini and Gebru found that commercial face-analysis systems misclassified darker-skinned women far more often than lighter-skinned men, and that the benchmarks used to evaluate them contained few of the people they failed on (Buolamwini and Gebru 2018). Pedestrian detection shows the same pattern. Wilson, Hoffman, and Morgenstern annotated pedestrians in a driving dataset by skin type and found that standard detectors reached an average precision of 67.1 percent on lighter-skinned

pedestrians and 55.9 percent on darker-skinned ones under a strict overlap criterion. Time of day and occlusion did not explain the gap (Wilson et al. 2019). Testing widely used pedestrian detectors, Li and colleagues found the proportion of children left undetected 20.14 percent higher than that of adults, and significant gender bias at night (X. Li et al. 2025).

A warehouse has its own groups. A detector trained mostly on people walking upright may see a kneeling worker, a person carrying a carton that hides the torso, a wheelchair user, or a worker without a high-visibility vest later or less often. Where the machine relies only on its certified safety scanner, which stops for any object above its resolution without deciding what it is, these differences do not matter. They matter wherever the design relies on a learned detector to recognize a person: to slow down when a person is near, to keep a wider separation from people than from pallets, or to predict where a person will walk. In those places, a difference in detection becomes a difference in how close the machine comes to each group before it begins to brake.

17.5.1 From a detection gap to a stopping gap

When a detector sees one group of people less reliably than another, the machine travels farther before braking begins and can strike a person in the less-detected group even when the stop was sized to clear the best-detected group. The conversion from a detection rate to a stopping shortfall runs through the camera's frames. Suppose a design requires that the chance of missing a person in every frame of a window be no more than p_{miss}, and that a detector reports a person in view in each frame with probability p_{frame}, independently from frame to frame. Because independent misses multiply across frames so the probability of missing the person in all N_{frames} frames is $(1-p_{\text{frame}})^{N_{\text{frames}}} \le p_{\text{miss}}$, the number of consecutive frames the person must be in view before the design may count on detection is

$$N_{\text{frames}} = \left\lceil \frac{\ln p_{\text{miss}}}{\ln (1-p_{\text{frame}})} \right\rceil . \tag{17.3}$$

A group the detector sees less often needs more frames, and each extra frame is travel before the machine can count on knowing the person is there. If the stop was sized for the best-detected group, a group that needs ΔN_{frames} more frames, at camera frame period T_{sample} and speed v, loses a distance

$$\Delta d_{\text{detect}} = v\, T_{\text{sample}}\, \Delta N_{\text{frames}} \tag{17.4}$$

before braking begins. A stop that would have ended just short of a person in the reference group now ends at the person, and the machine is still moving when it gets there. Because the reference braking distance $v^2/(2\,a_{\text{brake}})$ was sized to shed all of the initial squared speed v^2 just as the machine reaches the person, losing a distance Δd_{detect} before braking begins leaves that final Δd_{detect} of braking uncompleted. While the shortfall is smaller than the braking distance, braking at a_{brake} over the remaining distance therefore leaves an impact speed and an impact energy of

$$v_{\text{impact}} = \sqrt{2\, a_{\text{brake}}\, \Delta d_{\text{detect}}}, \qquad E_k = \tfrac{1}{2} m v_{\text{impact}}^2 = m\, a_{\text{brake}}\, \Delta d_{\text{detect}}. \tag{17.5}$$

The last form says that the energy delivered to the person grows in direct proportion to the distance lost to late detection. Fairness for a moving machine is therefore measured in meters and joules, not only in percentage points of recall.

> Napkin Math 17.2: Two frames late
>
> **Problem**: The running machine slows near people only after its learned detector reports a person. Its stop is sized for a group the detector sees in 95 percent of frames. A second group, kneeling workers, is seen in 75 percent of frames. At the aisle speed, what impact speed and energy does the second group receive from a stop that would have just cleared the first?
>
> **Variables**:
>
> - $p_{\text{miss}} = 10^{-3}$ (Chosen); $p_{\text{frame}} = 0.95$ and 0.75 (Illustrative).
> - $T_{\text{sample}} = 16.7$ ms (Datasheet, navigation camera); $v = 1.3$ m/s (Chosen); $a_{\text{brake}} = 2$ m/s² (Illustrative); $m = 368$ kg (Derived, loaded).

DRAFT

Math: By equation 17.3, the first group needs 3 frames and the second 5, so $\Delta N_{\text{frames}} = 2$, or 33.3 ms. By equation 17.4, $\Delta d_{\text{detect}} = 43$ mm, well inside the 0.42 m braking distance. By equation 17.5, $v_{\text{impact}} = 0.42$ m/s and $E_k = 32$ J.

Result: A stop designed to end short of a standing worker ends in contact with a kneeling one at 0.42 m/s.

Systems insight: A few centimeters of late detection become a collision because the stop was sized with no margin for the slower group. The result also assumes the detector's misses are independent from frame to frame; a detector that systematically fails on a pose misses it in many frames in a row, and the shortfall grows well beyond this best case.

Table 17.1 repeats the calculation for three lower-detection groups. The relationship is steep at the low end: a group seen in 60 percent of frames needs 5 extra frames and receives a 0.66 m/s impact carrying 80 J. Figure 17.2 plots the speed of the machine against distance for the reference group and for that group.

Table 17.1: A detection gap measured in meters and joules: Each row is a group of people the detector reports with the given probability per frame. The stop is sized for the reference group at the running machine's aisle speed, loaded mass, and credible deceleration, with an allowed all-frames miss probability of one in a thousand and independent frames. Groups seen less often need more frames, lose the distance shown before braking can begin, and are struck at the speed and energy shown.

Per-frame detection	Frames needed	Extra frames	Distance lost	Impact speed	Impact energy
0.95 (reference)	3	0	0 mm	0 m/s	0 J
0.85	4	1	22 mm	0.29 m/s	16 J
0.75	5	2	43 mm	0.42 m/s	32 J
0.60	8	5	108 mm	0.66 m/s	80 J

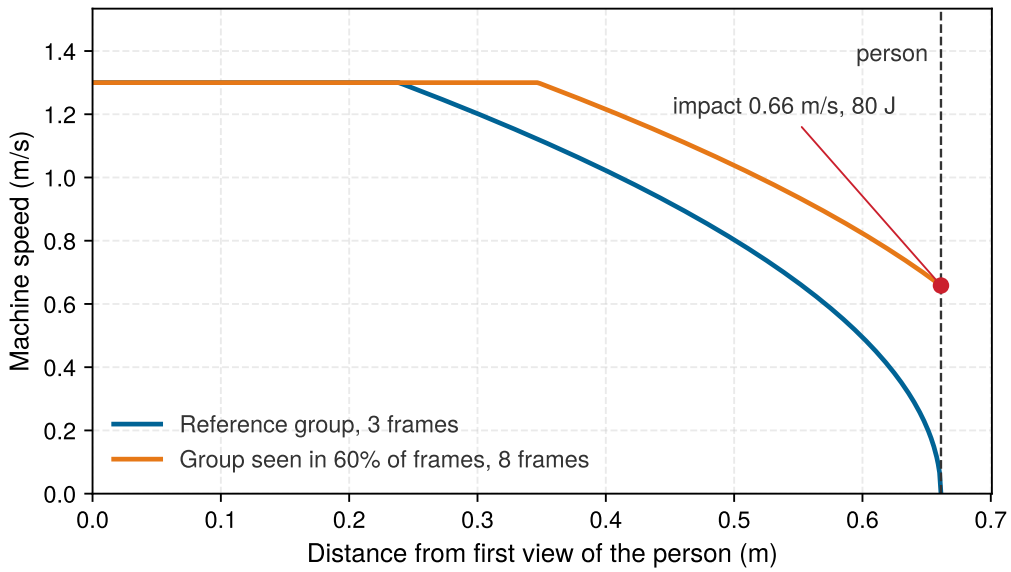

Figure 17.2: One stop, two groups of people: Speed of the running machine against distance traveled from the moment a person enters the detector's view, for a stop sized so that it ends just short of a person in the best-detected group. That group is detected after 3 frames; a group seen in 60 percent of frames is detected after 8, so braking begins later and the same deceleration leaves the machine still moving when it reaches the person. The impact speed and energy follow from the distance lost, not from the recall gap alone.

17.5.2 Sample sizes for each group

A detection gap can be managed only if it can be measured, and measuring it per group takes more data than measuring it overall. Suppose an evaluation set holds 10,000 people, of whom 2 percent belong to a smaller group, 200 people, and the detector finds 0.95 of both groups. The exact 95 percent interval for the larger group runs from 0.945 to 0.954. For the smaller group it runs from 0.910 to 0.976, about 8× wider, too wide to tell a detection rate of 0.95 from one of 0.92. A pooled detection rate reported for "pedestrians" or "workers" hides exactly the group the machine serves worst.

Telling a detection rate of 0.95 from one of 0.92 with 80 percent power takes about 1,059 people in each group, about 11 percent of the whole evaluation set for every group the evaluation must resolve. A group that makes up a few percent of the people a site employs will not reach that count by chance; the evaluation has to recruit it deliberately. The same arithmetic sets how long field monitoring must run before a per-group detection rate can be trusted, and it is why the sample size for each group belongs in the plan before data collection begins, not in the report after it.

↩ The exact binomial bound, and why a few observed failures drop it sharply, are established in section 7.6.1.

17.5.3 Where the measurement lives

If per-group detection rates live only in a research benchmark report, the release gate cannot check them before admitting the machine to an open floor. Tracking them does not need a new pipeline; it needs a new dimension in records the book already keeps. The observation contract states its detection qualification for each group the machine must slow down for. The fault list adds a coverage dimension that seeds kneeling, carrying, and seated people as deliberately as it seeds stale frames. The evaluation record reports detection per group with its confidence interval rather than only in aggregate. From those qualified measurements, the exposure block of the approval record stores, for each group the machine relies on detecting, the sample size, the rate, its interval, and the distance shortfall it implies at the operating speed. A group with no entry is an unknown premise, and the release gate treats it as one.

↩ The observation contract, which states what each measurement may be relied on for, is established in section 8.8.

Checkpoint 17.2: Detection gaps and sample sizes

- ☐ **Conversion**: A detector reaches a person kneeling between racks two frames later than a standing person. Can you compute, at the running machine's aisle speed, loaded mass, and credible deceleration, the impact speed and energy if the stop was sized for standing workers?
- ☐ **Remedy**: Can you compare three remedies (a lower speed near racks, a sensor that does not depend on the person's pose, and a zone rule that keeps the machine out while people kneel there) by what each costs and what evidence each needs?
- ☐ **Sample**: Can you size an evaluation that distinguishes 0.95 from 0.92 detection at 80 percent power, and say what share of a 10,000-person test set each group must be?

17.6 Who Bears the Risk

The people a machine puts at risk are not only the people who chose it. The facility operator chose to buy the machine and the integrator chose how to configure it; a rider chooses to take a robotaxi. The pedestrian in the crosswalk, the coworker at an aisle crossing, and the visitor walking through a loading area made no such choice. An aggregate comparison, such as a fleet's injury rate against a human benchmark, can improve while the remaining risk concentrates on people who never agreed to carry it. The risk such people carry without having chosen it is **unconsented risk**, and it has to be counted separately because no aggregate figure reveals it.

Choices that look purely operational move that risk around. The site crossing rule, which lets people enter the aisle only at marked points, buys the machine its speed by asking pedestrians to wait and to comply. Suppose 80 percent of the encounters between machines and people happen at three crossings used by 10 percent of the workforce. Those workers then carry 8× the site's average exposure per person, while everyone else carries 22 percent of it, and the site-wide encounter rate looks the same either way. Routing, the boundaries of the operating domain, and the hours a machine runs all shift exposure among groups in the same way.

↩ Fleet crash rates reported outcome by outcome, each with its own interval, are established in section 16.9.6.

↩ The site crossing rule, and the access restriction it places on pedestrians, are established in section 16.4.1.

The requirement that follows is a reporting one. The exposure block of the approval record lists each group exposed to the machine, whether its members chose that exposure, how their exposure is measured (encounters per person-hour, near misses, close passes), and the routing and domain decisions that changed it. A group that bears risk it did not choose is owed two things a fleet-wide statistic cannot give it: a measurement of its own exposure, and a way to see the machine coming.

17.6.1 Legible intent

People protect themselves from a moving machine by predicting where it will go and getting out of the way. Yet a machine that follows an efficient path until the last moment leaves nearby coworkers unable to tell whether it will continue straight or turn across their path. Dragan, Lee, and Srinivasa distinguish two properties of robot motion: motion is predictable when it matches what an observer who knows the goal expects, and **legible** when it lets an observer who does not know the goal infer it quickly (Dragan et al. 2013). A mobile base that drifts toward the side of the aisle it will turn into, or an arm that moves toward the shelf it will reach before it reaches, is legible. A machine that moves along the efficient path until the last moment is predictable only to someone who already knows its plan.

Explicit signals add to legible motion. A light that projects the planned path on the floor, a sound before a reversing move, or a display that shows which way the machine will turn at a crossing lets a coworker begin to yield earlier. A person who yields earlier approaches the machine more slowly, which shrinks the approach-speed term of the separation the enforcer must keep. Signals help only if people's trust follows what the machine can actually do. Lee and See showed that people rely on automation in proportion to their trust in it. Trust miscalibrated in either direction causes harm: too much leads to people stepping in front of a machine that will not stop for them, too little to people ignoring a machine that would (Lee and See 2004). A signal that the machine slows for people should therefore be shown only where the machine's detection of people has been measured, group by group, to support it. Physical motion in the aisle is not the only burden the machine places on the people around it; the cameras and logs that verify that motion also record everyone who shares the floor.

↩ The human separation distance, whose approach-speed term a person who yields earlier reduces, is established in section 12.3.

17.7 Data About People

When the warehouse machine logs a near miss at a rack end, its sensors and audit trails capture the people in and behind the cell alongside the telemetry of the base and arm. The records that make a machine answerable are also records about people, and the same evidence that settles who answers for an incident can, if kept forever and read by anyone, become a tool for watching the people it was meant to protect. How those records are declared, kept, and read is therefore part of the design, not an afterthought to it.

17.7.1 Recorded people as a standing condition

Three of the release records carry personal data directly: the authority record of section 14.8 names the operator behind each takeover tick by tick, the event-triggered traces of the black box hold camera frames of whoever stood in the aisle (including coworkers who never touched the console), and the demonstration archive of section 5.11 binds each episode to the operator who produced it. If those traces are retained indefinitely or opened to unrestricted browsing, the safety evidence store turns into continuous workplace surveillance. A release must retain the evidence needed for incident reconstruction while keeping identifying data to a minimum and within justified retention limits. The release therefore carries one more premise, and it is administrative rather than physical: each record that identifies a person declares its purpose, its retention period, and who may read it, and the site operates within those declarations.

Where the machine runs in the European Union, the General Data Protection Regulation makes that premise law (European Parliament and Council of the European Union 2016). Article 5(1) requires personal data to be collected for specified, explicit, and legitimate purposes and not further processed in a manner incompatible with them (point b), to be limited to what those purposes need (point c), and to be kept in identifiable form no longer than they require (point e). Article 25(2) makes the minimum the default, in the amount collected, the extent of processing, the storage period, and accessibility. Article 35 requires a data protection impact assessment before processing that is

likely to result in a high risk to the people concerned. Article 88 lets member states and collective agreements set more specific rules for employee data, naming monitoring systems at the workplace among the safeguards those rules must address. Other jurisdictions differ in detail; the engineering premise does not.

Each declaration becomes a standing condition of the kind section 16.5 defines, with a detector and a response. Incident reconstruction sets the retention of the black-box and authority logs: the traces around an intervention are kept for a declared, justified review period, with any extension documented under the applicable retention rules, and routine ticks with no event roll off the ring buffer as they already do. Access follows the purpose, so an incident reviewer may read a trace and an operator's supervisor may not score from it. A trace promoted into the experience pipeline carries its purpose and retention with it, which is what the consent and retention field of table 5.6 records. The detector is an access and retention audit on the evidence store. Its response follows from the rule that a verdict stands only while its premises are known-true, so a record used outside its declared purpose, or held past its period, suspends that use and returns the premise to the adjudicator. Stated this way, the premise keeps the traces an investigator needs to reconstruct a stop and bars their use for watching workers.

17.7.2 Keeping less

Continuous video recording keeps every frame of every worker's shift, creating a permanent surveillance archive when an incident investigation needs only the seconds around a fault. The first way to protect recorded people is therefore to record less of them. Event-triggered retention keeps only the window around an intervention or a boundary excursion: the 5 s before the trigger that the authority record needs to reconstruct a takeover, and the response after it, 30 s in all. At 20 such events per machine over a 16-hour operating day, the machine keeps about 1 percent of its footage, a 96× reduction, and everything else rolls off the ring buffer within seconds.

↩ The pre-trigger window the black box must hold to reconstruct a takeover is established in section 14.7.

The event window and the records retained from it have different lifetimes. Figure 17.3 follows the bounded capture history into incident review and separates that use from a possible training use.

Retention limits apply to each copy, including a copy admitted to training. Deleting a routine capture frame does not remove a retained incident record, and approving incident access does not approve every later use of that record.

Two further steps reduce what the kept footage reveals. Faces and badge numbers can be blurred on the machine before a frame is stored, provided the investigation does not need them. The declaration then records which fields stay identifiable and why, for example that the operator's identity is kept in the authority record but not in the camera trace. People whose demonstrations train the policy are a separate case: they are recorded on purpose and at length, so their consent, what their episodes may be used for, and how long those episodes are kept travel with the data from the moment of collection. The data block of the approval record lists each record class, the people it records, its purpose, its retention, what is removed before storage, who may read it, and the result of the last access and retention audit.

17.7.3 When safety records become performance scores

The records most likely to be misused are the ones that measure workers. The machine's authority logs and black-box recorders capture the identity of every operator who initiates a manual takeover, how long each takeover took, and how often each operator intervened. If an employer uses those records to score employee performance, the records have crossed from safety into monitoring. Conformity assessment under the European Union Machinery Regulation addresses the machinery safety requirements for the declared use; it does not govern every later use of the machine's records. One such use falls under a different law, the European Union Artificial Intelligence Act. Its Annex III lists AI systems intended to monitor and evaluate the performance and behavior of people at work among the employment uses subject to the high-risk classification rules of Article 6. Article 26(7) requires an employer deploying a high-risk system in the workplace to inform workers' representatives and the affected workers before putting it into use (European Parliament and Council of the European Union 2024a).

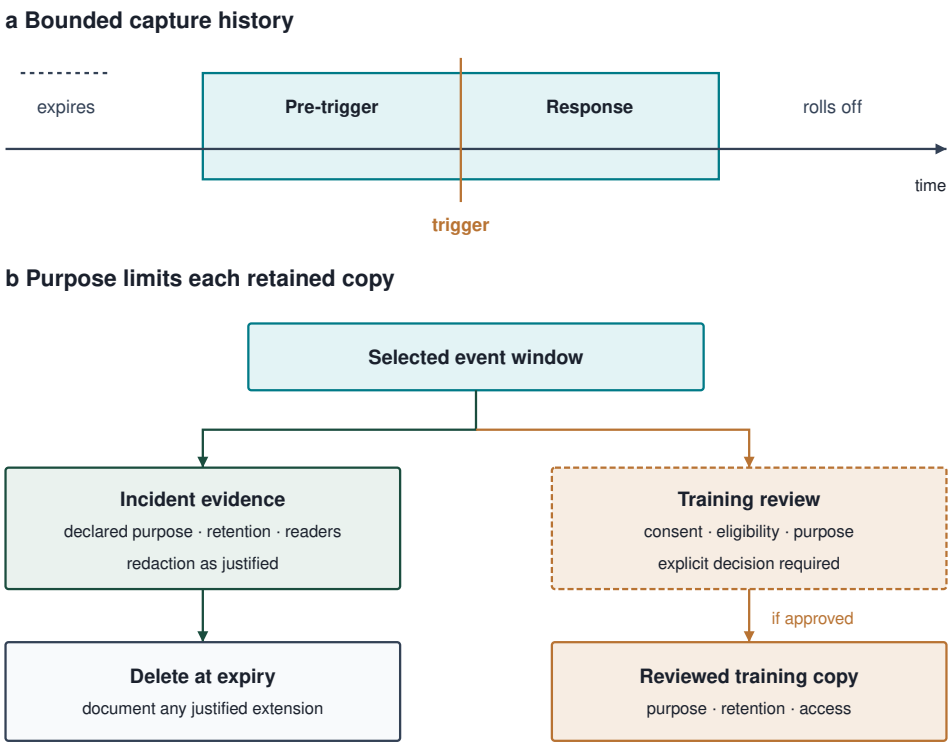

Figure 17.3: The Lifetime of Incident Evidence: A trigger selects the declared pre-trigger and response window while routine frames roll off the capture buffer. The incident record carries its purpose, retention, and readers. A training copy requires a separate review of consent, eligibility, and purpose; selection as incident evidence does not itself authorize training. The window and retention periods are those declared for the deployment, not universal durations.

The declarations of section 17.7.1 are where the line is drawn. A record declared for incident reconstruction may not be read to rank operators, and an access audit that finds such a read suspends that use and returns the premise to the adjudicator. If a site does want to evaluate workers, that is a separate system with its own declaration, its own legal classification, and its own owner, and the approval record lists it as a separate decision rather than letting it grow out of the safety records. Protecting workers in the machine's records still leaves the physical work the machine shifts onto them during daily operation.

17.8 The Labor the Machine Moves

Automating a task does not remove the labor the task needs. It moves that labor to the people who take over a machine when its planner stalls, the technicians who sweep and inspect the corridors the machine's restrictions depend on, the crews who keep the floor in the state the release assumed, and the operators who record demonstrations for the next policy. The intervention frequency logged during release testing defines the human work the deployment creates: how often a technician is dispatched, how fast that person must arrive, and where on the floor that person must be stationed.

↩ The authority record that logs each takeover, its actor, and its timing is established in section 14.8.

Napkin Math 17.3: Where the tote's labor went

Problem: The site of notebook 17.1 runs 20 machines for 16 hours a day with one remote assistant, and sweeps the restricted corridors 4 times a day. How many person-hours of work does the fleet create each day?

Variables:

- Assistant utilization: 50 percent (Derived, notebook 17.1); operating day: 16 hours (Illustrative).
- Corridor sweeps: 4 per day of 20 min each (Illustrative).

Math: The assistant must be staffed for all 16 h of operation, of which 8 h go to requests and 8 h to watching and waiting. Sweeps add 1.3 h. The fleet creates 17.3 person-hours of work a day, about 2.2 full-time shifts.

Result: The fleet needs more than two people's working days of human labor every day it runs, before counting maintenance, charging, or the collection of new demonstrations.

Systems insight: The waiting hours are labor too. A person paid to watch a console for half of every shift, ready to act within seconds, does a job that monitoring research has long shown people perform poorly (Bainbridge 1983), and the design that creates the job owns its conditions.

The burden is not only hours. Across United States local labor markets, greater exposure to industrial robots between 1990 and 2007 lowered both employment and wages (Acemoglu and Restrepo 2020). Inside warehouses, the effect on safety cuts both ways. Burtch, Greenwood, and Ravindran found warehouse robotics associated with a 40 percent decrease in severe injuries and a 77 percent increase in non-severe ones, an increase they attribute at least partly to the faster pace of work at robotic facilities (Burtch et al. 2025). Across United States commuting zones, Gihleb and colleagues found that greater exposure to industrial robots lowered work-related injury rates while raising other harms, including drug- and alcohol-related deaths (Gihleb et al. 2022). A deployment can make the most dangerous injuries rarer and the work around the machine harder at the same time. Whether mobile manipulators in logistics follow either pattern has not yet been measured at scale. The task, takeover, and technician-hour records built in the book can inform that measurement; estimating causal effects on workers also requires comparison sites and labor-market data that no single deployment holds.

The labor block of the approval record therefore lists the work a deployment moves: takeover hours, technician dispatches, sweep hours, staffed monitoring hours, and the pace targets set for workers who share the floor. It also states the uses of worker data that the deployment bars, so that the labor the machine creates is not measured with records collected for safety. A site that cannot fill these fields does not know what its machine costs the people who work beside it.

17.9 The Approval Record

↪ The cost of an operating restriction in throughput, against the cost of the test campaign that would lift it, is developed in section 18.4.2.

Left scattered across emails, slide decks, and meeting notes, the human and organizational premises behind a machine can lapse without blocking release: a staffing ratio changes on the night shift, a subgroup detection test is deferred, or a data-retention declaration expires while the robot keeps running. The **approval record** collects these premises in a single gate-checked artifact: it binds by digest the authority record, the enforcement record, the fault records, and the release manifest, and it adds the decisions behind them, each with a named owner.

Definition 17.3: Approval record

The ***approval record*** is the signed record that names, for each decision behind a machine's admitted actions, the person who approved it and answers for it, and that declares the human roles the design relies on, the permission stage and its reporting duties, the groups exposed to the machine, the records kept about people, and the labor the deployment moves.

1. **Significance**: The release gate reads the approval record as a standing condition, so a decision with no named owner refuses operation exactly as an unknown physical premise does.
2. **Distinction**: The authority record shows who held each channel at each tick; the approval record shows who decided that the machine could be in that situation at all.

3. **Common pitfall**: A frequent misconception is that a complete runtime log makes someone answerable. A log reconstructs events; only a record of decisions and their owners says who answers for them.

The approval record has seven blocks, a header that binds it to the release and one block for each kind of decision this chapter has set out (table 17.2). Each block names the decision owner alongside the specific evidence, bounds, or reporting duties that keep the release valid.

Table 17.2: The approval record: Each block holds a kind of decision the runtime records cannot hold, and each entry names an owner. The header binds the record to the release it governs by digest, so a new release requires a new approval record.

Block	What it holds	Set in
Header	Record identifier; digests of the release manifest, authority record, enforcement record, and fault records; the permission stage; the validity window	section 17.9
Decisions	For each decision behind an admitted action: its type (envelope sign-off, configuration approval, update approval, staffing, protective-function change, permit application, data use), owner, signed approval, evidence, date, and expiry	section 17.2
Human roles	For each role the safety argument cites: the duty, the response time it requires, the time the hazard leaves, the utilization bound, the information and authority channels, and a verdict of `FEASIBLE`, `INFEASIBLE`, or `UNKNOWN`	section 17.3
Permit and reporting	For each stage: the grantor, the configuration digest, the operating domain, the reporting duties and deadlines, and the disclosure log	section 17.4
Exposure	For each group exposed: whether it chose the exposure, how its exposure is measured, its per-group detection (sample size, rate, interval, distance shortfall), and the routing and domain choices that change it	section 17.5, section 17.6
Records about people	For each record class: the people recorded, the purpose, the retention, what is removed before storage, the readers, and the last audit result	section 17.7
Labor	Takeover hours, technician dispatches, sweep hours, staffed monitoring hours, pace targets, and the uses of worker data the deployment bars	section 17.8

↪ **Byte layout:** The approval record's fields, their encodings, and the check the release gate applies to each are given in section C.15.12.

The approval record gates release because the release gate reads it as a standing condition of the manifest. Four findings refuse operation the way an unknown premise does: an admitted action class has a decision link with no named owner, a human role cited as a countermeasure carries a verdict of `INFEASIBLE` or `UNKNOWN`, an exposed group the machine relies on detecting lacks a per-group entry, or a declaration about recorded people has expired or failed its audit. Each finding returns the premise to the adjudicator with its cause logged. A decision whose owner leaves the organization expires with that person's role, so the approval record is kept current the same way the standing conditions are: by checking, on a declared schedule, that every premise still holds.

↩ Standing conditions, each with a detector, a cadence, and a response that withdraws the grant, are established in section 16.5.

Not every open entry can be closed before release. A decision may wait on a regulator, a per-group sample may still be filling, a staffing plan may depend on a hire. Those entries do not vanish into a footnote. Each one leaves the approval record with an operating restriction that holds until it closes, such as a lower speed near the group not yet measured or a zone the machine may not enter. It also enters the residual-claims register with an owner and a closure test, alongside the physical premises no sensor can check.

↪ The residual-claims register, which carries each open premise with its restriction, owner, and closure test, is developed in section 18.3.3.

Checkpoint 17.3: An approval record for the Cruise configuration

- ☐ **Decisions**: Using section 17.1, can you list the decisions behind the October 2023 pullover (the post-collision response rule, the operating domain, the commercial stage, the reporting duties) and name the role that should own each?
- ☐ **Unknown fields**: Which of those fields could have been marked `UNKNOWN` before the collision, and which would have refused operation under the gate rule of this section?

DRAFT

- ☐ **Disclosure**: Can you write the disclosure-log entry that the permit block requires for the first report after the collision: who sends it, to whom, by when, and with what evidence attached?

17.10 Fallacies and Pitfalls

Responsibility for a machine fails in predictable ways, and most of them come from treating it as something settled after an incident rather than designed before one. Each misconception below assumes that a record, a person, or an average carries a responsibility that no one has actually accepted.

Fallacy: *A complete runtime log makes someone answerable for what the machine did.*

The logs of the Cruise vehicle were complete enough for engineers to rebuild the pullover in detail, and still the question of who had decided the vehicle should pull over, and who decided what regulators would hear, took months and an outside investigation to answer. A log records events. The decisions that made an event possible (the operating envelope, the response rule, the staffing ratio, the permit application) were made earlier, by people who appear in no tick. Six such links, each retrievable with probability 0.90, form a chain an investigator can follow to the end only 53 percent of the time.

Reconstruction is not attribution: only a record of decisions and their owners says who answers for an admitted action.

Pitfall: *Naming a person as the countermeasure for a hazard faster than a person can act.*

A design that lists the remote assistant as the response to a person stepping out at a rack end asks for a takeover that needs about 4.5 s when the hazard leaves 0.85 s. The person in that role adds no protection and absorbs the blame for an outcome the design controlled. Utilization makes it worse: at 20 machines per assistant, a request waits 180 s on average before anyone looks at it.

Architect's countermeasure: Test every human role the safety argument cites for time, information, and authority, mark it `FEASIBLE`, `INFEASIBLE`, or `UNKNOWN`, and let only feasible roles count as countermeasures.

Fallacy: *One detection rate for "people" describes how safe the machine is for everyone.*

A pooled rate is dominated by the largest group. At 200 people, a smaller group's exact interval is about 8× wider than the rest of the set's, too wide to resolve a gap of three points in detection. A group detected two frames later at the aisle speed loses 43 mm of clearance and is struck at 0.42 m/s.

Detection must be reported per group, with a sample large enough for its interval to resolve the gap that matters, and converted into meters and joules.

Pitfall: *Justifying a deployment for everyone exposed with a favorable fleet-wide comparison.*

An aggregate injury rate can fall while risk concentrates on the people who never chose the machine. When 80 percent of encounters happen at crossings used by 10 percent of workers, those workers carry 8× the average exposure, and the site-wide rate does not show it.

Architect's countermeasure: Report exposure per group and per location, record whether each group chose it, and treat routing and operating-domain choices as decisions about who bears the risk.

Fallacy: *Keeping every recording is the safe choice, because an investigation might need it.*

Continuous recording keeps every frame of every worker for as long as the storage lasts. Event-triggered retention keeps the windows an investigation actually uses, about 1 percent of the day, and lets the rest roll off within seconds. Records kept without a declared purpose and period drift into uses no one approved, such as ranking operators by their takeovers.

Each record about people is kept only for a declared purpose and period, and read only by the readers that purpose names.

DRAFT

Pitfall: *Carrying a permission stage across a configuration change.*

A stage authorizes a configuration in a domain under reporting duties. A new policy, a new enforcer build, or an expanded operating domain is a different configuration, and the failure-free hours that supported the old stage, about 2,996 for the claim in section 17.4.1, do not transfer to it. A withheld or incomplete incident report breaks the stage as surely as the motion does.

Architect's countermeasure: Bind each stage to a configuration digest in the permit block of the approval record, so an update reopens the stage along with the release claims it touches.

Fallacy: *Automation removes the work it automates.*

A fleet of 20 machines with one remote assistant creates about 17.3 person-hours of rescue, sweeping, and monitoring every operating day, and warehouse robotics has been associated with more minor injuries even as severe ones fell. The work moves to fewer, different people, often under a faster pace.

A deployment accounts for the labor it moves and bars the use of its safety records to measure the people who do it.

17.11 Summary

A machine's records can reconstruct every admitted action and still leave open who decided that the machine could be in that situation at all. The decisions that set a machine's limits (the operating envelope, the response rules, the staffing ratio, the permission stage, the uses of its data) are made by different people, before any command crosses the causal boundary, and they appear in no runtime log. Each party can truthfully point to another. The Cruise collision showed the consequence: a record good enough to rebuild the motion, an account to regulators that left out the part that mattered, and penalties imposed for the record rather than the motion. Responsibility therefore has to be designed like any other premise of the machine's authority, written into a record before the machine moves and checked when it is released.

The same discipline applies to the people around the machine. A human role counts as a countermeasure only if its holder has the time, information, and authority to act; a remote assistant whose takeover needs several times the time the hazard leaves, or whose queue makes requests wait minutes, adds blame rather than protection. Permission to operate is granted in stages, each for a configuration, a domain, and reporting duties, and is withdrawn for a withheld record as well as for unsafe motion. A gap in detection between groups of people becomes a gap in stopping distance and impact energy, and it can be managed only with per-group samples large enough to resolve it. Risk falls on people who did not choose the machine, records about people must be declared and kept no longer than their purpose needs, and the labor a machine moves must be counted. The approval record collects all of these with named owners, and the release gate refuses operation while any of them is missing.

Table 17.3 collects the chapter's equations.

Table 17.3: Key equations of responsibility for physical AI: Each equation, what it bounds or decides about a person's role or a group's exposure, and where it is derived.

Equation	What it bounds or decides	Derived in
$\rho_{\text{serv}} = \lambda_{\text{arr}} \bar{T}$	The share of time one remote assistant is busy, which caps how many machines that person can serve	equation 17.1
$W_q = \rho_{\text{serv}} \bar{T}/(1-\rho_{\text{serv}})$	The mean wait before a help request receives a person's attention, which no hazard faster than minutes can rely on	equation 17.2
$N_{\text{frames}} = \lceil \ln p_{\text{miss}} / \ln(1-p_{\text{frame}}) \rceil$	The frames a person must stay in view before the design may count on detecting them, for one group	equation 17.3
$\Delta d_{\text{detect}} = v\, T_{\text{sample}}\, \Delta N_{\text{frames}}$	The clearance a less-detected group loses before braking begins	equation 17.4

Equation	What it bounds or decides	Derived in
$v_{\text{impact}} = \sqrt{2\, a_{\text{brake}}\, \Delta d_{\text{detect}}},\ E_k = m\, a_{\text{brake}}\, \Delta d_{\text{detect}}$	The impact speed and energy a stop sized for the best-detected group delivers to a less-detected one	equation 17.5

Key Takeaways: Responsibility for a machine that acts

- **Reconstruction is not attribution:** A log shows what was admitted. Only a record of decisions, each with a named owner, shows who made the admission possible, and those decisions must be recorded on purpose because the machine does not make them.
- **A role no person can perform assigns blame, not protection:** Test every human role the safety argument cites for time, information, and authority, including the queue one person serves, and let only feasible roles count as countermeasures.
- **Permission is staged and can be withdrawn:** Each stage covers a configuration, a domain, and reporting duties. It is left on evidence gathered at that stage and withdrawn for a configuration change, an incident, or a withheld record.
- **Measure fairness in meters and joules:** Convert per-group detection into the distance lost before braking and the impact it causes, and size each group's sample so its interval can resolve the gap.
- **Count the people who did not choose the machine:** Report exposure per group and per location, and give the people who bear the risk legible motion and signals backed by measured detection.
- **Records and labor about people carry their own premises:** Declare each record's purpose, retention, and readers, and account for the work a deployment moves onto people and the uses of their data it bars.
- **A missing owner refuses like an unknown premise:** The approval record is a standing condition of release; entries that cannot close go to the residual-claims register with a restriction and an owner.

The fourth law, permission must be earned (principle 4), lets a machine operate only as far as its evidence supports, and the earlier chapters of this part applied it to channels, faults, and claims. Responsibility applies it to the decisions behind them: an envelope is supported only if someone accepted it, a human safeguard only if a person can perform it, and a detection claim only if it holds for each group the machine meets. The approval record makes those conditions checkable by the same gate that checks friction and timing, so the release that admits the running machine to an open floor also names who answers for each of its decisions. No assignment of responsibility after a collision returns the energy the machine has already delivered across the causal boundary, which is why every one of these decisions has an owner before the first command is admitted.

17.12 Historical Perspective and Further Reading

The question of who answers for an outcome that many people produced is older than computing. Thompson (1980) named the problem of many hands in public administration, where officials who each contribute a small part to a harmful policy can each disclaim it. Nissenbaum (1996) carried the problem into computing and identified the barriers specific to software: the many hands that build it, the treatment of failures as unavoidable bugs, the use of the computer as a scapegoat, and the ownership of software without liability for it. Matthias (2004) argued that machines which learn make the gap wider, because their behavior is not fully determined by any rule their makers wrote. The field's founding case remains Therac-25, the radiation therapy machine whose software removed the hardware interlocks that had protected patients (Leveson and Turner 1993).

A second line of work asked when a person placed in the loop actually controls the outcome. Sheridan (1992) laid out supervisory control, in which a person sets goals and monitors while the machine acts, and Bainbridge (1983) showed why the person left to handle only the rare emergency

is the one least prepared to handle it. Santoni de Sio and Hoven (2018) turned the debate over autonomous weapons into general conditions for meaningful human control, and Elish (2019) named the moral crumple zone after tracing how blame was assigned in accidents from aviation to nuclear power.

A third line measured who the machine serves well. Buolamwini and Gebru (2018) showed that the benchmarks used to evaluate face analysis left out the people the systems failed on, Wilson et al. (2019) and X. Li et al. (2025) found the same pattern in pedestrian detection. Nissenbaum (2009) recast privacy as the question of whether information flows in the way its context expects, which is the question a declaration about recorded people answers. Regulation followed the same arc, from the General Data Protection Regulation (European Parliament and Council of the European Union 2016) to the European Union Artificial Intelligence Act (European Parliament and Council of the European Union 2024a) and the state and federal reporting duties for driverless vehicles (California Department of Motor Vehicles 2018a; National Highway Traffic Safety Administration 2021).

Six works reward careful study:

- Thompson (1980) defines the problem of many hands and the forms of responsibility that survive it, the starting point for recording decisions with their owners.
- Nissenbaum (1996) names the four barriers to answering for computer systems, each of which reappears in a physical machine's chain of decisions.
- Elish (2019) introduces the moral crumple zone and shows, case by case, how blame settles on the person nearest the event.
- Santoni de Sio and Hoven (2018) states the conditions under which human control of an autonomous system is real rather than nominal.
- Wilson et al. (2019) measures how pedestrian detection differs across skin types, the evidence behind measuring detection per group.
- Nissenbaum (2009) explains privacy as appropriate flow, the frame for declaring what each record about people may be used for.

What's Next: From responsibility to engineering judgment

What do the release verdict and its approval record say about the question this book opened with? On the book's own records, the warehouse mobile manipulator is refused. The stipulated branch earns it only a restricted mission, and the approval record adds entries that cannot close before release: a per-group detection sample that is still filling, a staffing plan that depends on a hire, and a crossing rule that no sensor checks. Chapter 18 reads this verdict as the answer to why a better prediction can still produce a worse physical action. It transfers the same four-law method to an unfamiliar machine. It also gives each premise left open, whether physical or human, an owner, a restriction, and a closure test in the residual-claims register.

Engineering Physical AI

18.1 From a Better Prediction to Useful Service
18.2 Generalizing to Unfamiliar Systems
18.3 The Epistemic Frontier
18.4 Choosing the Next Capability
18.5 Fallacies and Pitfalls
18.6 Summary

Purpose

Why does a better model not, by itself, make a better machine?

The learned model is the part of a physical machine that is easiest to improve and easiest to score, so it attracts most of the effort. Useful service depends on everything around it as well. The body must sustain the task across loads, surfaces, and hours of duty. The learned behavior must hold in the states its own actions create. Each proposal must be admitted, corrected, or refused before the motion it asks for is already under way. The evidence for all of it must match the conditions of operation and stay true as the machine and its site change. Each of these can be engineered well in isolation while the machine as a whole remains unjustified, because doubt accumulates across every premise a physical claim depends on, and a premise that no one names or owns is assumed silently. A team that cannot join these parts into one argument keeps improving the model while an unmeasured floor, an unqualified detector, or an unowned restriction decides what the machine actually does. The same joined argument also chooses what to build next, since the most valuable measurement, experience, or design change is the one that retires the weakest open premise. At the causal boundary, irreversibility makes that weakest premise, not the best prediction, the measure of what a machine may be trusted to do.

Brain
1–50 Hz
perception, memory, intent, planning

above: propose; below: command

Nervous System
1 kHz (one implementation)
permission path, lease, fallback

Body
10–25 kHz current loop
drives, transmission, windings

Boundary
event-timed
register write, sensor capture

Physical World
continuous
contact, friction, payload, people

Learning Objectives

- Explain why a better prediction can still produce a worse physical action, and synthesize the four laws into the design argument that answers it
- Distinguish an unobserved premise from a monitored unknown, and explain why only a standing restriction can contain an unobserved premise
- Apply the four laws to select and evaluate a candidate operating mode for an unfamiliar machine
- Construct residual-claims entries with supported restrictions, accountable owners, and predeclared closure tests
- Evaluate the throughput cost of an operating restriction against the cost of the closure campaign that would retire it
- Select the next measurement, learning experiment, or design change needed to extend a machine's capability

18.1 From a Better Prediction to Useful Service

On this book's own release and approval records (chapter 16 and chapter 17), the warehouse mobile manipulator is refused. Even the stipulated evidence branch earns it only conditional service, held in place by premises that no sensor on the machine reports, such as the friction of the aisle floor. Improving its learned models alone would not change that verdict while the supporting physical and timing premises remain unqualified. That refusal is the engineering form of the answer to the question chapter 1 opened with: why a better prediction can still produce a worse physical action, and what the rest of the machine must supply so that a model's proposals become useful work within justified limits.

The question began with a contrast. Traditional machine learning evaluated advisory predictions against static datasets, and agentic machine learning could run iterative reasoning loops inside controlled digital sandboxes, behind glass, with elastic time, transactional rollback, and symbolic interfaces. Those privileges depended on the sandbox; external calls could already produce irreversible effects. Physical AI stepped through that glass into the continuous world, where computation commands actuators across the causal boundary. That step exposed computation to continuous time, in which delay becomes distance traveled, and to mechanical and thermodynamic irreversibility, which forbids undo. The illustrated feedback workload also required one action at a time under a real-time deadline, a batch size of one ($B = 1$). This scheduling constraint does not prohibit coordinated axes or batching elsewhere in the system. These constraints forced an architectural response, the separation of speculative proposals from deterministic permission, which is a design choice rather than a fact of physics.

One reference platform carried the argument: a warehouse mobile manipulator that picks an object from a moving conveyor, opens a spring-latched cage door, and carries the payload down an aisle shared with people. That mission exercised every capability the book develops (sizing the physical and computational dynamics, teaching learned policies, integrating a real-time runtime, evaluating closed-loop behavior, and maintaining the operating envelope as the machine and its site degrade). Each design choice constrained the next.

Predictive accuracy alone does not establish the operating premises on which physical success depends. What an actuator command does once it crosses the causal boundary depends on the distance a mobile base travels while a neural network runs its forward pass, the friction available at the tire-floor interface during hard braking, the states into which the robot's own prior actions drive it, and the gaps between demonstration datasets and live site conditions. Improving a model's statistical accuracy can refine the proposed trajectory, and shortening inference can recover timing margin, but neither result by itself qualifies traction, closed-loop competence, or the complete stopping budget.

The second half of the question, what the surrounding machine must supply, resolves into the four-step argument of section 1.3, pairing one engineering discipline with each of the four laws. Under the first law (*irreversibility*), the body's mechanical and thermal limits bound what any proposal

may request. Part I translated payload capacity, surface traction, contact forces, motor heating, and energy reserves into strict operating budgets that govern proposal horizons, execution cadence, and deterministic fallback paths. Under the second law (*endogenous data*), policy competence holds only over the states induced by closed-loop interaction. Part II tied proposer evaluation directly to the states the physical machine actually visits, turning recovery failures into targeted data-collection runs rather than unhandled anomalies. Under the third law (*proposal is not permission*), execution authority resides in an independent permission path rather than the learned model. Part III joined observation freshness contracts, grounded geometric targets, timed trajectories, and real-time admission filters onto a compute layout built to meet hard deadlines under load. Under the fourth law (*permission must be earned*), deployment scope extends only as far as qualified system-wide evidence supports it. Part IV structured physical operation as a governed service contract that separates proposer autonomy, whole-system task success, and protective intervention. A least-change speed filter, for example, can preserve an in-flight delivery even when a raw proposal requires intervention, whereas an emergency stop protects physical hardware without fulfilling the promised service.

The release verdict is where the four laws meet. In the baseline audit of section 16.6, the book's illustrative records yield `REFUSE`, because tail risks and fault margins remain unverified. The stipulated branch of section 16.6.1 shows which evidence would raise that verdict to conditional authorization (`COND`). Under those stipulated performance and fault records, the machine may run inspected-route transport, guarded door approaches, and close-proximity handovers, provided that standing conditions on floor traction, pedestrian crossings, feeder alignment, and sensor calibration stay verified. Each condition traces back through the record chain to a measured limit, an evaluated behavior, or a timed check, which is what separates a result stated under premises from a deployment claim.

Assembled, these parts close one causal loop through the physical world (figure 18.1). The loop runs at rates four orders of magnitude apart: the Brain proposes at 2 Hz, the permission path on the discrete safety microcontroller admits, corrects, or refuses at 1 kHz, and the drives close their current loops at 20 kHz. The loop closes only through the World, and the World returns only what its sensors capture, with capture times, to the permission path and to the Brain. A state the sensors never carry, such as the friction under a clear film, is invisible to every level at once. Governance surrounds all five levels and changes on the timescale of releases, so it sets the budgets and standing conditions that the fast loop enforces without taking part in any single control cycle.

The records summarized in table 18.1 bring the four laws into one engineering workflow. Rather than treating safety as an abstract property of a model, each part of the architecture leaves behind durable, auditable records that preserve the evidence and operating intent when tasks, payloads, or site conditions change.

DRAFT

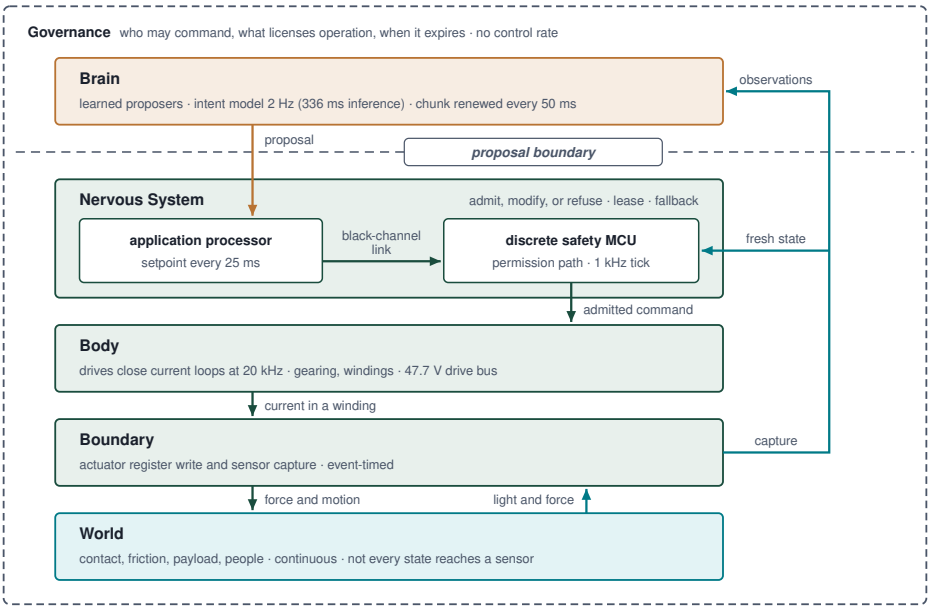

Figure 18.1: Closed causal loop: The Brain proposes across the proposal boundary, and the permission path in the Nervous System admits, modifies, or refuses each proposal before the Body acts. The Body's current becomes force and motion at the Boundary, the World evolves, and the Boundary returns measurements with capture times to the permission path and the Brain. Not every state of the World reaches a sensor. The governance envelope surrounds all five levels and changes on the timescale of releases rather than control cycles. The labels are this machine's values: the intent model proposes at 2 Hz, the chunk is renewed every 50 ms, the application processor sends a setpoint every 25 ms over a black-channel link to a discrete safety microcontroller unit (MCU) whose permission path ticks at 1 kHz, and the drives close their current loops at 20 kHz from a 47.7 V bus. Another machine sets its own rates.

Table 18.1: The four laws as engineering competence: Each part produces records that support the next design decision. The conditions and results belong to the particular machine and its evidence; they are not universal hardware requirements.

Law	Part	Records that carry it	Condition to maintain	Engineering result
Irreversibility	I (chapter 2, chapter 3, chapter 4)	Limit records; the proposer's limits, which enter the handoff record	Each measured limit, such as floor friction, payload, brake onset, or observation age, still holds under present conditions	A feasible speed or force envelope, a timed proposal interface, and a reachable fallback
Endogenous data	II (chapter 5, chapter 6, chapter 7)	Provenance record, policy manifest, evaluation record	The states the machine enters lie inside the target operational design domain (ODD, section 5.7.1) that closed-loop evaluation represents	A learned behavior evaluated in its closed loop; new qualified experience can expand its supported task population
Proposal is not permission	III (chapter 8, chapter 9, chapter 10, chapter 11, chapter 12, chapter 13)	Observation contract, belief record, intent lease, trajectory record, enforcement record, placement record	The permission path sees fresh, distinguishable state and meets its deadline under load	Useful motion admitted or minimally corrected within current limits; invalid active authority invokes a state-matched fallback
Permission must be earned	IV (chapter 14, chapter 15, chapter 16, chapter 17)	Authority record, fault record, release manifest, approval record, and the residual-claims register of this chapter	The premises of the release claim still hold after release	A named service authorized under standing conditions, with tested intervention and update procedures

The synthesis also completes the history traced in section 1.2. Over eight decades, learning moved from the machine's periphery toward its actuators. Deterministic mechanisms gave way to learned perception feeding analytical planners, then to end-to-end motor policies, and now to foundation models that propose action chunks across many robot bodies. At each step, a guarantee that physical separation or a watchful person once supplied had to move inside the machine.

The warehouse platform shows where that history now stands. Its split between an intent model proposing at 2 Hz and a chunk policy renewed every 50 ms mirrors current vision-language-action pipelines, and the guarantees those statistical models displaced survive in the deterministic architecture around them. The reflex halt beneath Shakey's STRIPS planner and the lower layers of Brooks's subsumption architecture, which kept running while higher layers were busy or wrong, have become the discrete permission path, enforcing signed kinematic and dynamic envelopes sized for this body. The remote operators who stayed close to the loop at the DARPA Robotics Challenge have become a formal intervention authority with timed handover budgets, and the environmental oversight a person once supplied has become explicit standing conditions of release.

The next phase, taken up in section 18.4.3, brings foundation models that control many bodies while learning continuously from fleet deployments. Cross-embodiment pretraining broadens what a model can propose, and it also carries the model further from the empirical distribution of any single site. Wider proposing latitude therefore makes the independent permission path more necessary, not less. It demands stronger checks at runtime and more defensible evidence at release, an architectural response to the safety-limit and conformity requirements of European machinery law (section 16.3.4).

The architecture is a method meant to carry across platforms. Its transferable core consists of the foundational questions, dynamic budgets, test protocols, and interface boundaries; the platform-specific elements are the calibrated numerical thresholds, kinematic envelopes, and actuator limits. The rest of this chapter tests how that core transfers to an unfamiliar packaging cell (section 18.2), tracks the premises no runtime sensor can check in a residual-claims register (section 18.3), and uses those open premises to select the next capability to build (section 18.4).

18.2 Generalizing to Unfamiliar Systems

An automated packaging cell that shuttles containers, seats closure tabs, and repeats high-rate cycles across a full shift can ram a closing gate, crush a carton wall, or bake its motor windings if its learned proposers outrun its physical limits. Building it requires the same pairing as the warehouse machine: a capable learned proposer with an execution pipeline whose runtime authority respects kinematic reach, contact force, and thermal buildup in the drive motors. The four bedrock laws trace one chain through such a machine. The chain runs from the task's irreversible consequences to measurable physical envelopes, through the closed-loop data that trains and validates its policies, to the real-time runtime that gates motor commands, and finally to the operating envelope certified for deployment. Auditing a machine the book has not yet studied tests whether that chain is a transferable method or only a description of one robot.

18.2.1 Auditing a new machine with the four laws

↩ The four bedrock laws, from irreversibility to permission must be earned, are established in section 1.10.

Auditing an unfamiliar machine out of order (evaluating a learned policy before the stopping budget fixes the speed ceiling, for example) wastes the evaluation on states the permission path will never admit. The audit therefore asks one question per law, in the order the laws constrain one another, and each answer leaves a record behind:

1. **Irreversibility.** What can the task do that no later command can undo, and what measured bound keeps it from happening? The answer names the collisions, plastic deformations, and thermal overloads of the task and sizes the envelope that excludes them, such as a speed ceiling from the stopping budget. It produces the machine's limit records.
2. **Endogenous data.** Do the demonstrations and the closed-loop evaluation cover the states the machine will enter once that envelope is enforced? A limit added in step 1 changes the states the proposer sees, so the evaluation must be run inside the envelope, not before it. It produces the provenance record and the evaluation record.

DRAFT

3. **Proposal is not permission.** Which independent path admits, corrects, or refuses each proposal, on which sensors, within which timing budget, and with which fallback when permission lapses? It produces the enforcement record and the timing budget the permission path must meet.
4. **Permission must be earned.** Which operating claims does the assembled evidence support, under which standing conditions, who answers for each decision behind them, and which premises remain open? It produces the release manifest, the approval record, and the residual-claims register entries for every premise left open.

Because each step constrains the next, adjustments ripple back up the list. Reducing the permitted transit speed to satisfy a stopping budget in step 1 alters the visual flow and dynamic states that step 2 must evaluate. Tracing those four steps on a high-rate packaging cell shows how a single limit in step 1 reshapes the data, runtime checks, and release claims that follow.

18.2.2 A packaging cell across the three machine classes

Consider a packaging cell in a logistics hub, laid out as in figure 18.2 (panel a). A carriage carrying one carton runs along a straight track, driven by a linear servo drive at the track's near end. Partway along, an insertion head presses down on the carton's flaps to seat its retention tabs. At the far end, a gate closes across the track whenever the next station cannot accept a carton, and a carriage still moving when the gate closes drives its carton into the gate and the frame. The cell is laid out tightly for cycle rate, so the carriage is only a few centimeters from its stop line when a closure can begin. This single cell couples all three machine classes within one enclosure: the carriage as moving mass, the insertion head as contact force, and the drive as thermal dissipation, because it cycles the carriage through rapid accelerations all shift.

↩ The three machine classes (mass-dominated mobility, contact-dominated manipulation, and energy- and thermal-dominated operation) are established in section 1.5.

The first law asks what the machine cannot undo, so the audit begins by cataloging the cell's irreversible state changes alongside the governing physical bounds. A loaded parcel container moving along a linear transfer rail carries momentum. When a carriage strikes an obstruction, kinetic energy dissipates through plastic deformation of the container and structural deflection of the frame, and commanding the drive motor in reverse cannot undo that damage. The insertion head introduces a second irreversible boundary: an actuator drives a tool head against package tabs to lock retaining clips. If the actuator pushes harder than the carton wall can support in compression, the container buckles and crushes its contents. The high-duty drive introduces a third irreversible boundary through Joule heating ($P_{\text{loss}} = i_q^2 R(T_{\text{winding}})$). Continuous high-acceleration cycles pump heat into sealed motor windings. Winding insulation does not need to melt to fail; elevated temperatures speed up chemical degradation over time, shortening insulation life rapidly (International Electrotechnical Commission 2007). Cooling the housing afterward cannot restore the dielectric strength already lost. Because insulation damage accumulates across duty cycles, an instantaneous temperature trip threshold alone cannot bound lifetime wear.

Because the carriage's momentum is already committed, the permission path must act before the carriage consumes its clearance. The stop modeled next is the cell's application-level path: a camera watches the gate, a learned model recognizes that a closure has begun, and the admitted stop command goes to the carriage brake. That path keeps normal operation clear of the gate, but it is not the cell's certified protective function, which the third-law discussion below and Problem 1 take up. The constant-deceleration stopping relation of section 2.3.1 tests a candidate design for it, here on hypothetical scenario inputs rather than measurements from a commissioned cell.

> Napkin Math 18.1: The delay wall
>
> **Problem**: The loaded carriage travels at 1.50 m/s toward a gate whose fixed stop line is 60 mm away when the hazardous closure begins, maintaining constant speed until braking begins. Can it stop short of the line, and if not, what is the fastest speed whose stop fits once a 15 mm reserve is held back?
>
> **Variables**:

DRAFT

- Moving mass of carriage and loaded tray m = 12 kg and nominal speed v = 1.50 m/s (Illustrative)
- Clearance 60 mm, less 15 mm reserved for uncertainty and residual clearance, leaves a stopping budget d_{budget} = 45 mm (Illustrative)
- Braking lower bound a_{brake} = 15 m/s² after the delay, for whichever brake the stop command engages (Illustrative; a bound to qualify under load, pad wear, and rail conditions, not a motor's peak rating)
- Delay from closure to full braking τ_{delay}: 16 ms to a usable image, including frame phase and exposure, 36 ms for transfer, inference, scheduling, and admission, 2 ms for command delivery, and 10 ms for brake buildup, in all 64 ms (Illustrative upper bounds)

Math:

1. **Nominal stop** (equation 2.2, margins held in the reserve): $d_{\text{stop}} = v\tau_{\text{delay}} + v^2/2a_{\text{brake}}$ = 1.50 m/s × 64 ms + (1.50 m/s)²/(2× 15 m/s²) = 96 mm + 75 mm = 171 mm, a deficit of 111 mm.
2. **Speed ceiling** (equation 2.3 with d_{budget} as the available distance): $a_{\text{brake}}\tau_{\text{delay}}$ = 0.96 m/s and $2a_{\text{brake}}d_{\text{budget}}$ = 1.35 m²/s², and the square root of (0.96 m/s)² + 1.35 m²/s² is 1.51 m/s. The positive root is v_{max} = 1.51 m/s − 0.96 m/s = 0.55 m/s.
3. **Candidate mode** at 0.50 m/s, below the ceiling: 32 mm of delay travel + 8.3 mm of braking = 40.3 mm, leaving 19.7 mm before the stop line. Translational energy $E_k = mv^2/2$ falls from 13.5 J to 1.5 J, a reduction of 88.9 percent.

Result: At nominal speed the carriage reaches the gate before braking even begins. The budget admits at most 0.55 m/s, and the 0.50 m/s candidate keeps more than the allocated reserve.

Systems insight: At these speeds delay travel, not braking, exhausts the clearance. The 64 ms chain alone carries the nominal carriage 96 mm, farther than the stop line, so the condition $d_{\text{stop}} \leq D_{\text{clear}}$ of principle 1 is met first by lowering speed or shortening the chain from closure to braking. The carriage's speed limit belongs to that whole chain, not to its brake alone.

The slower mode is therefore worth qualifying. Cutting speed to a third shrinks the two terms of the stop unequally (figure 18.2). Delay travel is linear in speed and falls threefold, from 96 mm to 32 mm; braking distance is quadratic and falls ninefold, to 8.3 mm. At the restricted speed the delay chain, not the brake, therefore sets most of the stop, which is why the next question is which premise moves the ceiling most.

The positive root also shows how the ceiling responds to each premise. Halving the processing allocation to 18 ms raises the ceiling to 0.66 m/s; because delay travel dominates this stop, reducing that allocation recovers substantial speed margin. Halving the qualified braking bound to 7.5 m/s² lowers the ceiling to 0.47 m/s, below the candidate 0.50 m/s mode, which then no longer fits. The two premises play different roles. Shorter latency is an opportunity for throughput, whereas a braking shortfall invalidates the mode outright, which is why the loaded deceleration must be qualified under worst-case conditions before the cell is commissioned. The stopping equation fixes the relationship; only measurements on the assembled cell can establish that the latency budget, the deceleration bound, and the reserve hold.

The second law evaluates the competence of the cell's learned proposers in the closed loop. This packaging cell runs three distinct learned proposers. A vision model infers container contents to propose carriage transit speeds (fragile or liquid contents tolerate gentler accelerations and stops than solid goods). A multimodal network estimates cardboard thickness to propose insertion forces and dwell durations. An electro-thermal estimator proposes acceleration profiles to manage motor winding temperatures. Each proposer's actions alter what it observes next. Throttling carriage speed changes camera frame timing and motion blur, extending tool dwell changes the material deformation that later thickness estimates read, and reshaping acceleration profiles changes the temperature trajectory the thermal estimator measures. Evidence of proposer competence therefore holds only for the state distribution sampled during closed-loop evaluation, and the question is

↩ This speed ceiling, the positive root of the stopping equation, is established for the mobile base in section 2.3.2.

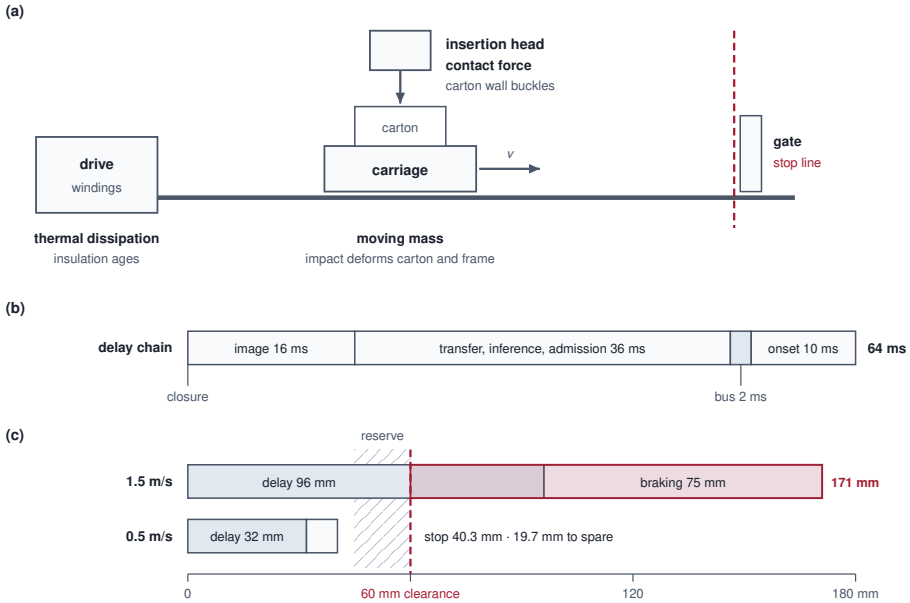

Figure 18.2: Three machine classes in one packaging cell: (a) The carriage is the moving mass whose impact deforms carton and frame, the insertion head applies the contact force that can buckle a carton wall, and the drive dissipates heat that ages winding insulation. (b) The assumed delay chain from gate closure to full braking totals 64 ms. (c) At 1.50 m/s the carriage travels 96 mm before braking begins and stops after 171 mm, far beyond the 60 mm stop line; at the restricted 0.50 m/s it stops in 40.3 mm, clear of the 15 mm reserve. All inputs are hypothetical design allocations, not measurements.

whether that distribution matches the conditions admitted at runtime. A safety restriction imposed after training shifts that distribution. If closed-loop evaluation sampled only the nominal transit speed of 1.50 m/s, clamping speed to 0.50 m/s pushes the vision model into visual dynamics it never encountered during evaluation, so the restriction that secures the stopping distance also opens a regime without evidence. The engineering team must either evaluate the policy under derated conditions before release or record the unverified regime as an open premise in the release sign-off.

↩ A policy whose actions choose its next observations drives the endogenous covariate shift established in section 5.2.

Closing this gap requires matching the data-collection and evaluation campaign to the restricted operating envelope. Expert demonstrations must span the admitted transport velocities, insertion forces, and thermal regimes, preserving complete site metadata in the provenance record. Once trained, the candidate proposer must undergo closed-loop trials on the physical cell to confirm that it completes the packaging task under those conditions, including during interventions by the permission path. If the cell cannot maintain acceptable task performance within its physical bounds, engineers must revise the task specification, the proposer architecture, or the mechanical plant before re-evaluating the modified system. Calculating a speed ceiling tests the transport stopping budget under its stated premises; qualifying those premises and demonstrating closed-loop task performance are both required for a viable packaging cell.

↩ Why proposer evidence must come from the closed loop the machine will actually run is established in section 7.3.

The third law places these proposed actions beneath an architectural authority split that the proposers cannot bypass, delay, or corrupt. The permission path prevents unverified neural proposals from reaching physical actuators directly. In this packaging cell, an independent kinematic monitor runs at 1 kHz, reading the carriage's optical encoders and a rangefinder aimed at the gate, and admits a carriage motion command only when the measured clearance supports the qualified stopping distance. This monitor is the admission stage of the camera path in notebook 18.1: the camera reports that a closure has begun, and the monitor admits the stop. Its work is therefore part of the 36 ms processing allocation, and a 1 kHz tick bounds only how long a command waits for the next check, not the transfer, inference, and scheduling that come before it.

While the software kinematic check confines normal operation to the derated velocity mode, it does not carry the cell's formal protection claims. In an industrial deployment, harm-prevention

claims rest on hardware-certified drive safety functions codified under IEC 61800-5-2 (International Electrotechnical Commission 2016b) and mapped for warehouse automation in table 12.4. The restricted transport mode maps to safely limited speed (SLS) on the carriage drive, an independent hardware function that continuously monitors motor velocity and triggers an emergency stop if the limit is exceeded. The emergency response executes as a ramp-monitored safe stop 1 (SS1) terminating in safe torque off (STO), with safe brake control (SBC) engaging mechanical holding brakes at rest. Each safety function requires a validated timing budget and an integrity metric. Under ISO 13849-1 (International Organization for Standardization 2023a), safety functions are classified by performance level (PL), which bounds their average probability of dangerous failure per hour according to the cell's risk assessment. The camera-triggered stop budgeted in notebook 18.1 is the application-level path announced before it, not a protective safety function. A safety-rated optical gate sensor feeding the drive's SS1 input directly replaces the frame-exposure and neural-inference allocations with its certified hardware response time, while command delivery and brake onset still contribute to τ_{delay} in the physical stopping model.

Physical safety limits must govern the insertion tool and actuator drives just as strictly as carriage motion. Setting a mechanical force limiter to 220 N is a nominal design choice rather than proof that every parcel resists crushing. Physical tests must verify that peak transmitted forces, including dynamic overshoot during contact impact, stay below the yield strength of the weakest admitted carton and tab geometry. Similarly, setting a winding thermistor trip threshold at 105 °C and a stall detection timeout of 400 ms provides basic supervisory cutoffs rather than a certified thermal envelope. Safe continuous operation depends on drive current profiles, winding resistance, heat capacity, cooling airflow, and sensor thermal lag. Because internal winding temperatures can surge before external housing sensors register the heat, as modeled in section 2.5.1, engineers cannot validate a sustained duty cycle from trip thresholds alone without measuring the thermal response under load.

High-rate deceleration also transfers mechanical kinetic energy back into the electrical drive system. During regenerative braking, the decelerating motor returns power to the inverter DC bus. A dynamic brake chopper and power resistor must absorb this energy before bus voltage exceeds the inverter trip threshold of 60 V, following the bus energy balance in section 2.6.3. The energy sink must handle repeated stops across a full shift rather than an isolated emergency event. Furthermore, regenerative braking requires an energized inverter stage throughout deceleration, whereas the carriage's electromechanical track brake relies on its own spring-actuated mechanism. Logic power hold-up alone supplies neither regenerative braking torque nor friction-brake clamping force. A thermal fault or electrical shutdown that cuts drive power disables regenerative braking, leaving deceleration entirely to the mechanical brake. The notebook's 15 m/s^2 bound therefore holds after a power cut only if the spring-applied track brake is itself qualified to it. Otherwise the power-cut case has a lower deceleration, a longer stop, and a lower speed ceiling of its own. System designers must ensure that safety-directed power cuts preserve a qualified deceleration and holding response across the declared operating states and fault conditions.

The fourth law synthesizes these engineering decisions into a release argument. The cell's release manifest must validate rangefinder coverage, gate clearance margins, braking deceleration, and sustained task throughput as one connected system. Equally important, the manifest explicitly records any claims that physical evidence cannot support. To check whether the tabs have latched, the engineering team evaluates a vision model that inspects surface reflections for container tab engagement. Under industrial overhead lighting, glare from tape and crinkled plastic packaging produces bright reflections that mimic latch defects while hiding genuine tab misalignments. Because the cell lacks an independent physical measurement, such as a tactile switch or a laser profile scanner, that separates engaged tabs from misaligned flaps under glare, the sign-off claim lacks a qualified detector. Recording this limitation as detectorless and unsupported in the residual-claims register (section 18.3.3) is not a documentation failure but an accurate statement of what the physical evidence justifies.

The stopping analysis therefore supports a *candidate restricted mode* for carriage transit at 0.50 m/s, provided that the 64 ms end-to-end latency, 15 m/s^2 braking deceleration, 60 mm physical clearance, and uncertainty reserve are validated together on the physical cell. Insertion forces and thermal duty cycles remain restricted until physical testing confirms material crush limits, sensor thermal

lag, and independent fault paths. Autonomous package sign-off is refused because glare hides tab engagement from the vision system and the cell lacks an independent verification sensor. A qualified tactile or laser engagement sensor could support autonomous sign-off; mandatory downstream manual inspection instead supports a commercial deployment that makes no autonomous sign-off claim. An analytical throughput model cannot substitute for that physical evidence. Each law's answer constrains the next. The stopping mechanics fix a transport envelope, the envelope fixes the regime that data collection and evaluation must cover, the runtime monitors enforce that envelope, and the release argument restricts the cell wherever a claim lacks support.

The same audit extends beyond the three machine classes of the packaging cell into fluid and chemical process systems, where the irreversible consequence may be reagent already delivered or heat already transferred rather than damage from a moving mass. Consider a learned proposer that sets the opening of a dosing valve feeding a reaction tank, with a high-level trip that commands the valve shut before the tank overfills. The first law asks what reagent has already been committed. If the shutoff command arrives after a delay τ_{delay} at a volumetric flow rate $\dot{V}$, fluid continues to discharge. The discharge adds roughly $\dot{V}\tau_{\text{delay}}$ to the volume delivered before the valve even begins to move, the fluidic analog of the delay travel $v\tau_{\text{delay}}$ in the stopping distance. The valve's closing stroke then adds the fluidic analog of braking distance, and both must fit within the headroom above the trip level, as the clearance did for the carriage. Stored thermodynamic and hydraulic energy also complicates the fallback. A pressurized accumulator, a cryogenic transfer line, or a heated pressure vessel retains stored energy after electronic control power is cut. As with a balancing biped, whose fall begins the moment its torque is removed, de-energizing the controller does not by itself produce a safe state. The design must therefore name a qualified physical sink, such as a spring-loaded pressure relief bypass, to dissipate that energy. The remaining laws apply in the same way. Policy evaluation must sample the throttled flow regimes that the safety limits enforce, the permission path must guarantee valve closure within the allowable volume tolerance, and sign-off must rest on measured valve slew rates and sensor response times. In every case the machine's operating claims hold only as far as its physical evidence reaches, and a physical state that stays unobserved until the execution deadline marks where that evidence ends.

Checkpoint 18.1: Transferring the four-law audit

The packaging cell demonstrates how the four-law audit organizes system design for an entirely novel machine, anchoring every operational claim to physical bounds and empirical measurements.

- ☐ **Speed-ceiling estimate**: Suppose physical load testing qualifies the carriage's braking bound at only 12 m/s², assuming the same 64 ms total delay and 45 mm stopping budget. Estimate the updated velocity ceiling from the positive root of the stopping equation, and determine whether the candidate 0.50 m/s mode still fits within the updated stopping budget under the remaining assumed inputs.
- ☐ **Machine classes**: For the carriage, the insertion head, and the linear drive motors, identify each component's physical machine class, the irreversible physical state transition it can produce, and the governing physical boundary.
- ☐ **Derated evaluation**: Explain why imposing a runtime velocity restriction after training induces an endogenous covariate shift for the vision proposer. What two engineering options can close this evaluation gap before operational sign-off?
- ☐ **Sign-off verdict**: What specific physical sensing evidence would be required to transition autonomous package sign-off from refused to supported, and why does expanding the training dataset with more glare-corrupted images fail to resolve the underlying detector deficiency?

18.3 The Epistemic Frontier

A packaging cell's camera can confirm an arm's position and approve a transport motion without verifying that a hidden mechanical tab has engaged. Similarly, a warehouse robot's lidar and cameras

can clear a navigation path across an aisle without determining whether the concrete floor provides enough traction to brake. These gaps are epistemic limits: boundaries on what the available sensors and analytical arguments can justify. Additional training can improve a policy's action proposals, but machine learning cannot manufacture an unmeasured physical state. Systems engineers must therefore determine whether justifying the next operating claim requires broader training experience or a physical measurement absent from the existing sensor suite.

Consider an aisle where a pallet jack with a leaking hydraulic line has just crossed, leaving a thin, clear film of fluid on polished concrete. The mobile manipulator's stopping budget assumes the floor supplies enough surface friction for credible deceleration, which dry industrial concrete reliably does. Under an oil film, however, available traction collapses, yet neither standard navigation cameras nor time-of-flight lidars can tell the clear fluid apart from dry concrete. In this failure mode the safety architecture runs exactly as specified. The software permission path meets every deadline, chunk leases expire on schedule, and the drive controller applies braking torque right on time. Even so, the robot slides past its stop line and collides at the rack end. The failure comes not from software latency or actuator lag, but from an unmonitored premise, the local wheel-floor friction coefficient before braking, and the stopping budget prices that premise.

The claim adjudication in section 16.3.3 already encountered this premise: claim C3 (braking traction) was refused on this book's own evidence and deferred to this chapter as an unresolved premise. The credible deceleration a_{brake} that chapter 2 credited to the brakes was always conditional on the floor. Made explicit, that condition says the deceleration a machine actually has available is the smaller of what its brakes can deliver and what tire-floor traction can transmit:[1]

$$a = \min(a_{\text{brake}}, \mu g). \tag{18.1}$$

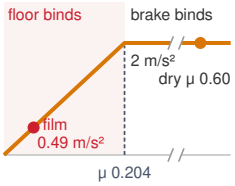
The friction term is the traction ceiling of chapter 2 (figure 2.1 and section 2.4.2), $\mu\phi_{\text{drive}}g$, taken with all of the weight on the driven wheels ($\phi_{\text{drive}} = 1$). That is the case that sets the friction floor, the same optimistic all-weight screen that claim C3 was adjudicated against. At the drive wheels' rated load share the floor is higher, as that notebook computes, so every friction margin below is the optimistic one. On an oily surface, interface friction rather than motor torque becomes the binding constraint.

1 **Amontons-Coulomb Friction**: The classical laws of sliding friction make the friction force proportional to the normal load and independent of the apparent contact area, which is what lets a single coefficient μ describe a contact. Bowden and Tabor (1950) traced the law to the small true area of contact, whose shear strength sets μ, and showed that a lubricant film only molecules thick can lower it several-fold. The coefficient therefore belongs to the pair of surfaces and whatever lies between them, not to the floor alone, and the braking premise needs a measurement at the tire-floor interface that no camera viewing the floor supplies.

Napkin Math 18.2: The friction floor

Problem: A clear hydraulic film lies across the aisle. Does the known-component stop from the candidate 1.3 m/s aisle speed still fit the rack end's 1.10 m clear distance?

Variables:



- Credible deceleration a_{brake} = 2 m/s² (Illustrative, section 2.3) and g = 9.81 m/s² (Defined standard-gravity constant)
- Floor friction μ = 0.60 on dry industrial concrete and 0.05 under the film (both Illustrative; see the Reader Guide)
- Aisle speed v = 1.3 m/s (Chosen) and clear distance D_{clear} = 1.10 m (Illustrative)
- Known-component budget, the seven rows of table 12.1, which leave out the dispatch-to-admission interval Δ_{da} that is allocated but not yet measured: pre-brake delay τ_{delay} = 133.6 ms, jerk bound j_{max} = 7.11 m/s³, and fixed overheads of 190 mm (all Derived)

Math:

1. **Friction floor** (equation 18.1): The brake binds only while $\mu \geq a_{\text{brake}}/g$ = 2 m/s² / 9.81 m/s² = 0.204. Dry concrete clears it; the film does not, so $a = \mu g$ = 0.05 × 9.81 m/s² = 0.49 m/s².
2. **Dry-floor budget**: Delay travel $v\tau_{\text{delay}}$ + braking $v^2/2a$ + jerk-ramp travel $va/2j_{\text{max}}$ (the S-curve term of row 6, valid in the trapezoidal regime because $v > a^2/j_{\text{max}}$) + overheads = 173.7 mm + 422.5 mm + 182.8 mm + 190 mm = 969.0 mm.
3. **Film budget**: The same terms at a = 0.49 m/s² give 173.7 mm + 1,723.3 mm + 44.8 mm + 190 mm = 2.13 m.

Result: On the film the stop grows from 969.0 mm to 2.13 m, far past the 1.10 m clear distance, before the dispatch-to-admission interval is even added.

Systems insight: Below $\mu = 0.204$ the floor, not the brake or the timing, sets the deceleration, and the braking term grows as $1/\mu$. Faster admission can recover only the 173.7 mm of delay travel, so no improvement in the permission path restores the dry-floor mode on the film. Only a restriction or a measurement at the tire-floor interface can keep $d_{\text{stop}} \leq D_{\text{clear}}$.

Below $\mu = 0.204$, the floor, not the brake, sets the deceleration.

The calculation omits the dispatch-to-admission interval, which the discrete placement of section 13.6.2 allocates but no loaded measurement yet confirms. That interval adds travel and reduces every derived speed ceiling, yet even the known-component budget already excludes the film. Moreover, the friction premise did not appear only when fluid leaked onto the concrete. The candidate normal operating mode of section 12.3.1 always assumed that unmeasured friction floor across every aisle, dry or wet. Software timing and physical traction are independent requirements, since bounding scheduling delays does not guarantee floor grip and confirming floor grip does not remove scheduling delays. On the oil film, the drive electronics continue to regulate motor current and commanded torque within milliseconds, yet that torque slows the base only through tire-floor contact. Neither a faster enforcer nor another layer of neural inference therefore replaces the interface measurement or the speed restriction the notebook calls for.

↩ Current regulation within milliseconds through electrical time constants and current clamping is established in section 2.4.2.

The manipulator arm's contact limit at the door latch has the same structure. Safety depends on a latch that holds under any force below the arm's contact ceiling. Mechanical wear, material fatigue, or corrosion can silently lower the latch's yield force below that ceiling, even while joint torque sensors report readings identical to those against a sound strike plate. A wrist force-torque sensor whose zero-point calibration has drifted creates the same hazard for every contact threshold that depends on its signal (section 18.3.4.2).

In each case, a machine can leave its safe operating envelope while internal telemetry stays completely nominal. Successful test runs under nominal conditions provide no safety guarantee once an underlying physical premise fails. A safety case must explicitly list each unobserved premise, restrict operating authority while that premise remains unverified, and state the physical evidence required to close it. For every open entry, the engineer must determine what the machine can physically measure, what actuator limits can still prevent, and which operating claims must remain refused.

18.3.1 What the release claim rests on

Extensive testing of one link in a safety case cannot compensate for an unmeasured premise in another: a thousand hours of fault-free perception trials will not stop a base whose tires lose traction on an oily floor.[2] A mobile manipulator's release claim forms a chain of dependent arguments tied to its operating hazards and chosen mitigations. The complete safety case must establish the operational design domain, measured actuator performance, stopping bounds, component interface contracts, and independent permission filtering for learned proposals. Hazards managed by runtime detection require verified detector coverage and bounded monitoring latency, whereas hazards managed through passive compliance or operating restrictions require physical evidence that those safeguards hold across declared payloads, component wear, and site conditions.

[2] **Popperian Falsification**: The asymmetry holds for universal hypotheses (Popper 1959). No finite run of safe stops proves that every aisle floor supplies the friction floor, and one measured film below it refutes that premise. A rate claim, such as a hazard rate per hour, is neither refuted by one incident nor proved by many incident-free hours, so it is bounded statistically and revised as exposure accumulates. This chapter therefore holds deterministic premises in register entries and rate claims in confidence bounds.

Each premise in a safety case carries one of five statuses: established by measurement or derivation, assumed, decided by accountable judgment, unsupported, or outside the threat model. (The Reader Guide lists the same five with examples; the audits of this chapter and its problems use these exact labels.) The envelope trichotomy (definition 16.3) classifies an actively monitored runtime condition as known-true, known-false, or unknown. That trichotomy presupposes a monitor. "Unknown" marks a monitored condition whose evidence has lapsed, and the permission path answers it at once with a validated stop or hold until fresh evidence returns. An unobserved premise has no runtime monitor whose report can trigger that transition; its missing evidence must instead be recorded in the release argument. Telemetry stays nominal while the premise fails, and holding the machine until a report arrives would hold it forever, because no report will come. Such premises require standing restrictions decided before operation; a fallback cannot be triggered by evidence the machine never receives. Release certification must therefore either validate and maintain these

premises through external physical evidence or restrict operating authority accordingly. For the mobile base, stopping-distance guarantees rest on an assumed wheel-floor friction coefficient that cannot be observed before braking. For the manipulator arm, contact safety assumes a minimum yield strength for the door latch and the objects it handles, a threshold set by engineering judgment rather than real-time measurement. For the wrist sensor, force-limiting safety functions assume zero-point calibration stability, a condition internal telemetry cannot verify without an unloaded physical tare. Recording these premises explicitly does not weaken a release case; it marks the exact boundary where system guarantees hold and beyond which operating authority must be withdrawn.

Separating physical measurement from accountable judgment is essential to systems engineering. Testing and statistical analysis can estimate physical exposure, quantify sensor noise, and bound parameter uncertainty, but test data cannot choose an acceptable residual risk or decide which people in a facility must bear that risk. Those choices are accountable engineering decisions that must be recorded as explicit judgments rather than presented as empirical facts. Similarly, the verification campaign's threat model bounds where the safety record holds. Field trials across normal fleet workflows and random component faults do not by themselves support claims about deliberate attacks outside the tested conditions. A test campaign showing that a vision pipeline tolerates lens flare, sensor noise, and partial occlusions provides no evidence that it resists adversarial optical projections, tampered policy weights, or deliberate denial-of-service flooding on the internal communication bus.

↩ The fault list that bounds what verification tests, including transduction-layer attacks on sensors and on the proposer, is established in section 15.6.

18.3.2 Conditional shield credit and common-cause bounds

Treating an independent permission path as a substitute for a missing floor-friction measurement asks the safety shield to stop a hazard it cannot sense. Even for hazards within its view, a shield reduces the failure rate only in proportion to its own tested coverage. Pricing what the permission path actually contributes to a hazard-rate claim separates the hazards a shield can attenuate from the register entries it can never close. Section 12.7 established deterministic guarantees for each command a safety shield checks, but turning those per-command guarantees into a system-level hazard rate requires statistical accounting. Because a shield acts as a conditional filter, the resulting hazard rate depends on how often the policy proposes hazardous actions, how reliably the shield intercepts them in those exact states, and how often failures occur outside the shield's sensing domain. Notebook 18.3 prices these terms in an illustrative deployment.

Consider an illustrative system target of $1 \times 10^{9}\,\mathrm{h}^{-1}$. This number comes from civil aviation certification, where catastrophic failure conditions must be shown to be "extremely improbable," on the order of 10^{-9} per flight hour[3] (Federal Aviation Administration 1988). While no industrial robotics standard requires this threshold, examining it shows the statistical burden a borrowed safety target imposes. As the exposure wall established, physical operating hours alone cannot certify failure rates of this scale.[4] The practical engineering question is what safety margin a runtime shield genuinely contributes against that target, and what supporting evidence its own operation requires.

A safety shield argument is inherently *conditional*. Observed incident rates across an operating fleet already include the protective interventions of runtime filters and human supervisors, so multiplying an observed incident rate by a shield's interception factor double-counts that protection. For a defined hazard class h, let $\lambda_{\text{proposal},h}$ denote the arrival rate of unshielded, hazardous action proposals emitted by the policy before the permission layer. Let $c_h = \Pr(\text{intercept} \mid \text{hazardous proposal}, h)$ denote the verified interception coverage for that hazard class. Including an independently bounded hardware fault and common-cause arrival rate λ_{other}, the conditional hazard rate obeys equation 18.2:

$$\lambda_{\text{system},h} \leq \lambda_{\text{proposal},h}(1 - c_h) + \lambda_{\text{other}} \tag{18.2}$$

Here, $\lambda_{\text{system},h}$, $\lambda_{\text{proposal},h}$, and λ_{other} are rates per operating hour, while c_h is a unitless conditional probability. The limiting cases make the shield's role plain. With perfect detection and interception ($c_h = 1$), the upper bound reduces to the hardware and common-cause term λ_{other}, a residual no coverage removes. Conversely, if the shield has zero coverage ($c_h = 0$), the raw proposal hazard rate passes straight to the actuators. This relation turns the runtime assurance architecture, which

3 | **Extremely Improbable Band**: The advisory circular offers its probability bands as aids to engineering judgment, expressed per flight hour of a mean-duration flight and applied to each failure condition separately, and it grounds such criteria in historical accident data (Federal Aviation Administration 1988). The 10^{-9} figure is therefore one catastrophic condition's share of a certified design's risk, not a rate for a whole aircraft, let alone for another kind of machine. Applying it elsewhere without the allocation argument that set its share leaves the number without its basis.

4 | **Pooling Evidence Across Updates**: An updated model may alter the proposal distribution. Earlier data can be pooled only with a justified configuration-equivalence and exposure argument; an update does not automatically erase every observation. The exposure wall's constant-rate model also requires a defensible treatment of shared fleet conditions and correlated faults.

↩ The exposure wall, the event-free operating hours needed to bound a rare hazard rate, is established in section 7.9.

pairs an unverified primary controller with a verified safety filter (Sha 2001; Hsu et al. 2024), into a checkable hazard-rate claim.

↩ The Simplex architecture, which pairs a capable unverified proposer with a verified protective controller, is established in section 12.1.

Using equation 18.2 requires four premises. The first is a verified **counterfactual oracle**: an evaluation harness that determines whether an unshielded action proposal would have caused a safety violation. Without this oracle or another justified way to identify or conservatively bound hazardous proposals, the raw proposal error rate $\lambda_{\text{proposal},h}$ has no supporting evidence. The remaining requirements are timely hazard detection, adequate braking authority, and a careful accounting of correlated failures. Designers frequently overlook this final common-cause term. Release claim C5 required physical testing rather than a theoretical independence assumption because separate implementations of the same specification fail together far more often than statistical independence predicts (section 16.3.2). The product $\lambda_{\text{proposal},h}(1-c_h)$ uses interception coverage conditional on hazardous proposals; substituting coverage measured on unrelated states erases that conditioning. An occluded camera frame that causes the neural policy to propose a bad trajectory can corrupt the safety shield's state estimator at the same moment. That shared failure does not merely add an independent background term to λ_{other}; it lowers c_h in the same states where policy errors happen. Interception coverage c_h must therefore be measured across the actual states where the policy fails rather than on an idealized set of synthetic test cases. The equation gives no credit for hazards the shield cannot sense, such as oil films or fatigue-weakened latches, and no credit for the shield at all until each of the four premises is supported. Until then the release must restrict operation instead.

Bounding the system hazard rate requires bounding the raw proposal rate $\lambda_{\text{proposal},h}$ from an adjudicated execution log before crediting shield attenuation. Under a stationary Poisson arrival model with zero observed hazardous proposals, this upper bound follows the rule of three (Hanley and Lippman-Hand 1983) from equation 7.4, with proposal operating hours in place of discrete trials. For an adjudicated log spanning T operating hours at significance level α_{sig}, the one-sided upper confidence bound is $-\ln\alpha_{\text{sig}}/T$, or roughly $3/T$ at 95 percent confidence. When the interception coverage c_h is also estimated empirically from zero-miss seeded trials rather than given as a known constant, the product $\lambda_{\text{proposal},h}(1-c_h)$ rests on two separate confidence bounds that can each fail. Guaranteeing that both bounds hold simultaneously at overall significance α_{sig} requires splitting the error budget across the continuous proposal-log test and the discrete coverage-trial test via the union bound, testing each factor at significance $\alpha_{\text{sig}}/2$:

Napkin Math 18.3: The coverage bill

Problem: In an illustrative scenario, a fleet keeps a fully adjudicated proposal log for one release cycle, judged by a validated counterfactual oracle, and the log records no hazardous proposal. If a named shield's interception coverage for that hazard class were independently established, would the modeled residual of equation 18.2 meet the system target, and what evidence would it take to show that it does?

Variables:

- System target $\lambda_{\text{target}} = 1 \times 10^{-9}\ \text{h}^{-1}$ (Illustrative)
- Proposal log $T = 100$ units $\times$ 90 days $\times$ 24 h $= 2.16 \times 10^5$ proposal-hours with zero hazardous proposals (Illustrative)
- Class-specific coverage $c_h = 0.9999$ and $\lambda_{\text{other}} = 0$ (Illustrative; the hardware and common-cause term is set to zero for this calculation)
- Confidence 95 percent, significance $\alpha_{\text{sig}} = 0.05$ (Chosen)

Math:

1. **Proposal bound** (rule of three with hours in place of trials): $-\ln\alpha_{\text{sig}}/T = 2.996 \,/\, 2.16 \times 10^5\ \text{h} = 1.387 \times 10^{-5}\ \text{h}^{-1}$.
2. **Residual**: $1.387 \times 10^{-5} \times 1 \times 10^{-4} + 0 = 1.387 \times 10^{-9}\ \text{h}^{-1}$, **above** the target. Meeting it at this bound needs $c_h \geq 1 - 1 \times 10^{-9} \,/\, 1.387 \times 10^{-5} = 0.9999279$.

3. **Proposal evidence at the assumed coverage**: The bound must fall to $1 \times 10^{9} / 1 \times 10^{4} = 1 \times 10^{5}\ \mathrm{h}^{-1}$, which takes $2.996 / 1 \times 10^{5} = 3.00 \times 10^{5}$ proposal-hours, or 124.8 days for the fleet, 34.8 days beyond the cycle.
4. **Coverage evidence**: Bounding c_h itself takes $\ln 0.05 / \ln 0.9999 = 29{,}956$ seeded hazardous proposals of that class with no miss, drawn from the states in which the policy errs.
5. **Joint confidence**: The probability that at least one of two bounds fails is at most the sum of their failure probabilities, so a joint 95 percent statement needs each bound at 97.5 percent (the Bonferroni split). The proposal bound becomes $3.689 / 2.16 \times 10^{5}\ \mathrm{h} = 1.708 \times 10^{5}\ \mathrm{h}^{-1}$, the coverage campaign 36,887 trials, and the residual $1.708 \times 10^{9}\ \mathrm{h}^{-1}$.

Result: The modeled residual misses the target even with the common-cause term set to zero. Supporting the claim takes both a proposal log longer than the release cycle and tens of thousands of seeded interceptions, and the confidence of the combined claim must be budgeted across them.

Systems insight: A shield changes the system claim only for hazard classes it can detect and intercept in time. Proposal frequency, conditional interception coverage, hardware faults, and common-cause failures need separate evidence. Oil or material failure outside the shield's sensing coverage stays in the residual-claims register.

The notebook prices what evidence the exposure model and the safety filter would need; it supplies none for either. Formal verification carries the same scoping requirement, since any mathematical proof applies only to the declared kinematic model, sensor observations, disturbance bounds, and timing guarantees. Whenever a physical premise lacks empirical proof, the release argument must substitute an operating restriction assigned to an accountable owner.

↩ The scoping limits of formal certificates to their declared plant, observations, and disturbances are established in section 15.7.3.

18.3.3 A residual-claims register

Refusing claim C3 in the safety case did not remove the floor-friction premise behind it. Without a durable record tying that open premise to an operating restriction, a later model update could restore normal aisle speed while the floor remains unmeasured. The **residual-claims register** is the sixteenth and closing record in the systems record chain. Taking in the upstream release manifest and approval record, the register binds every unresolved physical premise directly to an operating restriction.

↪ The sixteen-record chain, which the residual-claims register closes, is developed in section C.14.2.

Each register entry names four required elements: the missing physical observable, the active containment mechanism or operating restriction, the accountable owner, and a predeclared closure test. Together they give principle 4 direct operational force. Unlike a software defect log or issue tracker, the register is a machine-readable deployment record with a fixed schema. Its parameters set runtime enforcer bounds, and its standing conditions bind facility operations. Operating authority stays derated until test evidence passes the predeclared closure test. Writing a warning note in documentation, or deferring an open premise to a future release without lowering speed or narrowing the operational design domain, provides zero physical protection.

↪ **Byte layout:** Wire formats, data fields, and structural invariants for register entries are documented in section C.15.13.

Not every open premise is physical. Entries that the approval record of section 17.9 cannot close before release, such as a human role whose feasibility is still `UNKNOWN`, a decision waiting for an owner, or a group of people whose detection has not yet been measured, enter the register in the same form. Each carries the restriction that holds meanwhile, such as a lower speed wherever the unmeasured group works, an owner, and the test that would close it.

Engineers must state each **missing observable** in concrete physical quantities rather than modeling jargon. Calling a failure an "out-of-distribution latent state" does not say what physical sensor must measure it or when an enforcer must intervene. Naming an unmeasured friction coefficient or latch yield force, by contrast, makes the engineering choices concrete. The team can weigh adding a sensor, adding a passive mechanical limit, or narrowing the operational design domain, and everyone can see what test evidence is needed to retire the restriction.

The undetected oil film forms the first register entry for the mobile manipulator. Its premise is that every aisle floor supplies a friction coefficient of at least $\mu \geq 0.204$, the floor needed for credible deceleration. The missing observable is the local friction coefficient under a clear fluid film, which

neither onboard cameras nor lidars can tell apart from clean concrete. Because a stop sized for dry concrete overruns the available clearance on an oily floor, the normal speed limit is justified only on surfaces where friction is verified or actively controlled.

An open premise requires an immediate **operational response**. For warehouse aisles, release sign-off can authorize a derated speed of 1 m/s on designated routes maintained under a facility inspection procedure. In this restricted-service mode, scheduled floor scrubbing, spill isolation, and controlled access must maintain a friction coefficient of at least $\mu \geq 0.12$. That friction level gives an available deceleration of 1.18 m/s² and a known-component speed ceiling of 1.23 m/s. This is the inspected-floor ceiling that the release envelope carries (table 16.1), drawn as the dashed envelope in the stopping distance analysis of chapter 12 (figure 12.3). The restricted mode sits below that ceiling rather than at it, because the ceiling, like the budget it comes from, still leaves out Δ_{da} and any reserve for it. This inspected level is an illustrative baseline chosen below dry concrete to tolerate light surface contamination. A production deployment must set this value from friction surveys across the designated routes and show how spill prevention or bounded cleanup maintains it between inspections. In the illustrative project records, restricted-mode operation remains provisional until the full timing budget, including dispatch-to-admission latency and the required reserves, is verified under load. Routes outside the facility inspection program are excluded from automated navigation.

Restricted operation requires an accountable owner who can keep the underlying physical premise true. Facility operations owns this entry through its maintenance and spill-response procedures along pallet-jack routes, setting inspection intervals and specifying the site conditions that pause automated traffic. While the signed speed ceiling in the onboard permission path enforces the motion limit, a software speed setting alone cannot keep the floor dry.

Every register entry must also state a **closure test** before data collection begins. To detect surface films online, the closure test must qualify an independent physical sensor, since standard visual cameras and lidars cannot resolve clear fluids on concrete. Alternatively, higher-traction floor coatings or physical barriers separating leaky equipment could support a revised claim through facility evidence. One candidate closure campaign evaluates an optical film detector, requiring a miss rate of at most 0.1 percent demonstrated across 2,995 zero-failure trials on seeded fluid films, the trial count required by the zero-failure sizing of section 7.7.1. Until the sensor passes this test, the lower speed limit stays in force. Smaller test campaigns do not provide enough statistical confidence. Zero misses across 1,000 independent trials bounds the miss probability only at 0.002991 at 95 percent confidence. In addition, the detector must see far enough ahead that sensing latency, permission processing, and braking finish before the wheels reach the fluid. Forward range, inference latency, false-alarm rate, and post-detection friction assumptions must all be declared in advance. Reactive wheel-slip reflexes can limit further acceleration once the wheels spin, but they cannot guarantee stopping distance before the tires hit the film.

While the target miss rate of 0.1 percent is chosen illustratively here, a production deployment must derive it from the site's hazard budget. The detector works inside the conditional shield relation of equation 18.2, with fluid film encounters in place of hazardous action proposals. If films appear along transit routes at an arrival rate λ_{film} and facility engineering allocates a hazard budget λ_{alloc} to this failure mode, the detector must satisfy $\lambda_{\text{film}}\, p_{\text{miss}} \leq \lambda_{\text{alloc}}$. Choosing the risk allocation λ_{alloc} is an accountable engineering judgment, whereas estimating the encounter rate λ_{film} comes from maintenance and spill logs.

Aisle navigation adds a second register entry: moving people at blind corners. Stopping-distance budgets are sized against stationary obstacles, so a person who keeps walking toward the mobile base during the stop consumes clearance distance that the budget never set aside. As shown in section 12.3.1, accounting for a person walking toward the robot throughout the stop caps the permissible base speed at the rack corner far below normal transit speeds. The safety premise behind normal aisle speed assumes that no person walks out of the occluded cross aisle during an emergency stop, leaving a person's presence in the hidden cross aisle as an unobserved state. Restricted service therefore requires physical barriers or access controls that block human cross-traffic during automated runs; painted floor lines do not satisfy this condition. Facility operations owns this restriction. A proposed blind-corner presence sensor cannot earn credit in the safety case until its field of view, latency, and miss rate pass qualification under the same zero-failure statistical standard applied to the film detector.

↩ Clearance eroded by a person approaching from an occluded cross aisle at walking speed is established in section 9.7.

The automated picking station adds a third entry, covering what the arm grasps. Its premise is that the object the gripper picks up, and then hands to a coworker through the `accept_item` interface, is the object the task names. As shown in section 10.7, semantic grounding can fail silently. When a thin-walled red glass jar sits alone where the red ceramic mug was expected, the grounding model mistakes the jar for the mug and still satisfies every geometric check in the planner and permission layers. The missing observables are object identity and crush strength, which neither wrist cameras nor visual foundation models can verify reliably before contact.

↩ The `accept_item` handover entry, which grants no motion authority and caps the arm's approach to the coworker's hand, is established in section 14.2.1.

Containing this hazard takes a two-part operating restriction. First, facility operations restricts conveyor loading to verified items from a declared stock-keeping unit (SKU) list that excludes fragile look-alikes. Second, the pick station admits a grasp only when optical singulation confirms a single object in the pick window; multiple objects abort the automated intent and route the tote to manual picking. Singulation removes geometric confusion among permitted items, but it does not measure what an object is made of; an off-list glass jar arriving alone is kept out only by upstream loading controls. Lowering the grip-force limit enough to protect fragile items would require measured crush limits for every item in inventory, which is itself an unverified physical assumption. Facility operations and the application engineering team co-own the item catalog and singulation rules. The closure test requires qualifying an automated check at the station, such as a radio-frequency identification (RFID) reader or a combined scale-and-barcode check, with a false-accept rate of at most 0.1 percent at 95 percent confidence across 2,995 failure-free trials with seeded look-alikes. Table 18.2 compares these three entries side by side, listing the four required components for each open premise.

Table 18.2: Residual-claims register for the aisle and the pick station: Proposed responses to three open premises behind the mobile manipulator's aisle speed and its pick; operating credit requires the supporting evidence stipulated in the restricted-service branch. For each, the register names the missing physical observable, the hazard it permits, the operating restriction and its accountable owner, and the predeclared closure test that would retire the restriction.

Claim and missing state	Hazard mechanism	Active containment and owner	Predeclared closure test
Braking traction: every aisle floor supplies $\mu \geq 0.204$; friction beneath a clear film is unobserved.	At $\mu = 0.05$ the available deceleration falls to 0.49 m/s^2, and the known-component budget at 1.3 m/s already grows to 2.13 m against a 1.10 m clear distance.	Candidate in the actual records: 1 m/s on qualified, controlled floors ($\mu \geq 0.12$); full timing and reserve must support it. Uncontrolled routes excluded. *Owner*: site operations, through the spill procedure for pallet-jack routes.	A floor-film detector with a miss rate of at most 0.1% at 95% confidence, from 2,995 failure-free seeded-film trials, plus timing and clearance tests; the restriction holds until it passes.
Walking person: no person approaches the rack end during a stop; presence in the hidden cross aisle is unobserved.	A person walking at 1.6 m/s through the whole stop would cap the base far below its aisle speed at the rack end (section 12.3.1).	Controlled separation excluding continuing human approach during a stop; no credit for an unqualified presence sensor. *Owner*: site operations.	Qualify coverage, detection timing, and the complete response; 2,995 failure-free trials support a 0.1% miss bound at 95% confidence for the declared trial population.
Object identity: the object grasped is the object the task names; identity and fragility before contact are unobserved.	A confident grounding to a thin-walled glass jar in place of the absent mug passes every geometric check, and a grip the ceramic mug needs can crush the glass.	Feed control admits to the conveyor only items on the station's declared list, none of them a fragile look-alike; singulation admits a grasp only with one object in the pick window. An off-list item arriving alone is contained only by the feed procedure. *Owner*: site operations, jointly with the task profile.	A qualified identity check at the station (tag read or scale-and-code) with a false-accept rate of at most 0.1% at 95% confidence, from 2,995 failure-free seeded look-alike trials; the restriction holds until it passes.

The register also holds a fourth entry, a timing premise, which the table leaves out because its hazard is the same overrun as the first row's and only its missing evidence differs. Measured capture-to-dispatch latency excludes the downstream dispatch-to-admission interval. The placement allocation budgets that interval at 63.3 ms out of the 100.8 ms timing allowance at the aisle speed, leaving 37.5 ms of reserve. Stated in the register's four elements, the missing observable is the loaded worst-case dispatch-to-admission interval, which steady-state inference benchmarks do not bound.

DRAFT

Because that interval remains unverified, the runtime systems team owns an active restriction that holds the aisle speed as an uncertified candidate rather than an authorized mode. The closure test is supported timing and response analysis under declared workload and resource bounds, challenged by loaded and adversarial measurements of both latency intervals. Until that test shows that the interval fits its allocation with positive reserve and meets the lease duration and renewal requirements of the execution contracts, the restriction stays in force. The stipulated service branch assumes that timing evidence for its derated mode; in the baseline records the entry remains open.

18.3.3.1 Maintaining the restrictions

Writing an open assumption into a machine-readable register file does not turn it into a measured physical state. If the signed speed limits and site procedures are not wired into the release gate and daily floor work, the restriction exists only on paper. Operating restrictions in the register must therefore attach directly to the runtime enforcers and site workflows that govern daily operation. Cryptographically signed speed envelopes constrain the onboard permission path, while scheduled maintenance intervals bind facility operations. Release pipelines check that both controls are active in the authorized configuration, while runtime monitors enforce only the physical bounds that onboard sensors can read.

Model retraining or software updates must inherit every open restriction whose closure test has not yet passed. Release gates must check the signed operating limits and the status of their supporting evidence before authorizing a deployment. Dropping to a restricted mode requires its own validated safety case; an open register entry does not automatically clear a slower mode for service. At runtime, low-level controllers enforce speed ceilings and actuator limits, while facility crews maintain floor traction and conveyor loading rules at the scheduled intervals.

A restriction can also lapse in the middle of a motion, when a signed envelope expires, an inspection interval runs out while the base is in a route, or a deployment gate withdraws a mode. The lapse must hand over to the fallback ladder rather than to a generic stop. A trajectory chunk already executing inside the old restriction may finish only if its lease, state estimate, envelope, and supporting physical premises remain valid through completion. Withdrawing permission for new proposals can preserve an already admitted chunk under those conditions; loss of a premise that supports its execution cannot. Losing active permission altogether demands a physically feasible stop within the remaining budget. The rung must match the state, because controlled deceleration, holding brakes at zero velocity, torque removal, and full power isolation produce different transients. No register entry can replace those physical distinctions with a single emergency-stop primitive.

↩ The ladder of state-matched fallback responses, from minimal projection to complete torque removal, is established in section 12.9.

New sensors can justify wider operating envelopes only after they pass empirical qualification. Where real-time detection is impractical, the register must rely on a conservative action, passive containment, periodic proof testing, or a restricted operating domain (the responses to a hidden state that section 18.3.4.2 develops). Choosing among those responses requires comparing the distance at which a detector could spot the hazard against the deadline for committed motion.

18.3.4 Failures without detectors

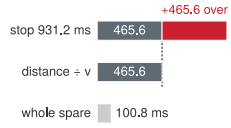
An automated floor-film detector can retire the surface-friction restriction only if its coverage, false-alarm rate, and detection latency fit inside the route's stopping budget rather than a standalone model benchmark. In the known-component budget, running at the candidate aisle speed leaves 131.0 mm of physical margin, which corresponds to an allowable delay of 100.8 ms. Setting aside 63.3 ms for dispatch-to-admission processing leaves 37.5 ms of timing reserve. That reserve is an upper bound on unallocated latency, not a certified budget for new perception pipelines, and it offers no protection against a pedestrian who keeps walking toward the robot during the stop.

A forward-looking fluid detector faces an even tighter spatial deadline. The required detection range, minus the distance the robot travels during sensor integration and neural inference, must cover the full dry-floor stopping distance before the tires reach the leading edge of the film:

$$d_{\text{detect}} \geq v\, t_{\text{detect}} + d_{\text{budget}}(v), \tag{18.3}$$

where $d_{\text{budget}}(v)$ denotes the known-component dry-floor budget of notebook 18.2, the seven rows of table 12.1. The detection interval t_{detect} covers only the film detector's own work, from the moment the film enters its range to the moment it reports. That report is the observation that starts the

pre-brake chain, so the observation age and admission already inside d_{budget} follow it rather than overlap it. Where the two do overlap in a real pipeline, adding them is conservative. With a chosen sensing and inference latency of 100 ms at the 1.3 m/s aisle speed, the detector must see the film at least 1.10 m ahead. That range is almost exactly the 1.10 m clear distance, and not by coincidence. The dry budget and the spare together make up the clear distance, and the detector's 100 ms of travel nearly equals the 100.8 ms that the spare buys. A detector that sees only as far as the clear distance therefore spends the whole timing allowance by itself, leaving nothing for the 63.3 ms dispatch-to-admission allocation. To fit beside that allocation, its latency must stay under the 37.5 ms reserve, or its range must grow. If classification occurs only after the drive wheels enter the fluid, the stopping distance expands to 2.13 m, far beyond the 1.10 m clear distance. A classification received after the wheels cross onto the film can serve incident analysis, but it arrives too late to avert the collision.



18.3.4.1 Observational indistinguishability and the action deadline

When an oil film and dry concrete produce identical camera and lidar readings until the robot is already inside its dry-floor stopping distance, no classifier running on those sensors can trigger a stop in time. That limit is observational indistinguishability. Consider two physical world states, s_A and s_B. In state s_A, a commanded actuator trajectory $\mathbf{u}(t)$ runs safely. In state s_B, that same command $\mathbf{u}(t)$ causes structural damage or human injury, requiring the permission path to trigger an emergency stop. The constraint governing this stop is distance rather than elapsed time: because braking changes the robot's speed along its path, the point of harm is a place in the room. Let d_{rem} denote the remaining distance to that boundary when the distinguishing observation arrives. An emergency stop finishes short of the hazard only if:

$$d_{\text{rem}} \geq v\,(T_{\text{comp}} + T_{\text{act}}) + d_{\text{brake}}(v), \tag{18.4}$$

matching the physical stopping relation used throughout this book. The enforcer's compute time and the actuator's response time together act as the pre-brake delay τ_{delay}, counted from the arrival of the distinguishing observation rather than from a fixed capture event, and $d_{\text{brake}}(v)$ is the braking distance of the chosen stop. Dividing this distance constraint by the approach speed gives an equivalent observation deadline: $t_{\text{deadline}} = t_{\text{harm}} - T_{\text{comp}} - T_{\text{act}} - d_{\text{brake}}(v)/v$, where t_{harm} is the instant the unbraked trajectory would reach impact. Because t_{harm} marks when the robot would reach the hazard at constant cruising speed v, the quantity $t_{\text{harm}} - t_{\text{deadline}}$ expresses the required spatial clearance d_{rem} in units of cruising-speed travel time. Once braking begins, the decelerating robot takes longer than $d_{\text{brake}}(v)/v$ to cover the remaining distance, so it safely comes to rest just short of the spatial boundary at a clock instant later than t_{harm}. A common mistake subtracts the full stopping duration T_{stop} instead of the speed-normalized distance d_{brake}/v, treating the robot as if it kept moving at full cruising speed until the instant it came to rest. For the jerk-limited profile from 1.3 m/s, braking lasts 931.2 ms but covers a distance equal to only 465.6 ms of constant-speed travel. Writing the deadline purely in time over-reserves 465.6 ms, or 605.3 mm of clearance, an error larger than the entire 131.0 mm spare. The time form errs on the safe side, but it refuses operating modes that the distance form rightly admits. Manipulator contact follows the same logic: once an end-effector touches a stiff surface, contact force rather than position sets the observation deadline (section 12.7.2).

The paired worlds in figure 18.3 separate physical state from observable history. Their common brake command has different consequences, although the depicted channel supplies the same inputs through the action deadline.

Charging the full stop time over-reserves several times the entire spare.

A timely separating observation changes this argument only if the machine can obtain it within the same physical budget. When no such observation is available, the permission path must choose an action qualified for both candidate states or withhold the operating mode.

If the sensor stream $\mathbf{y}(t)$ produced under state s_A matches that under s_B up to t_{deadline} for every admissible control input, no algorithm acting on those measurements can tell the safe state apart from the hazardous state in time to prevent harm:

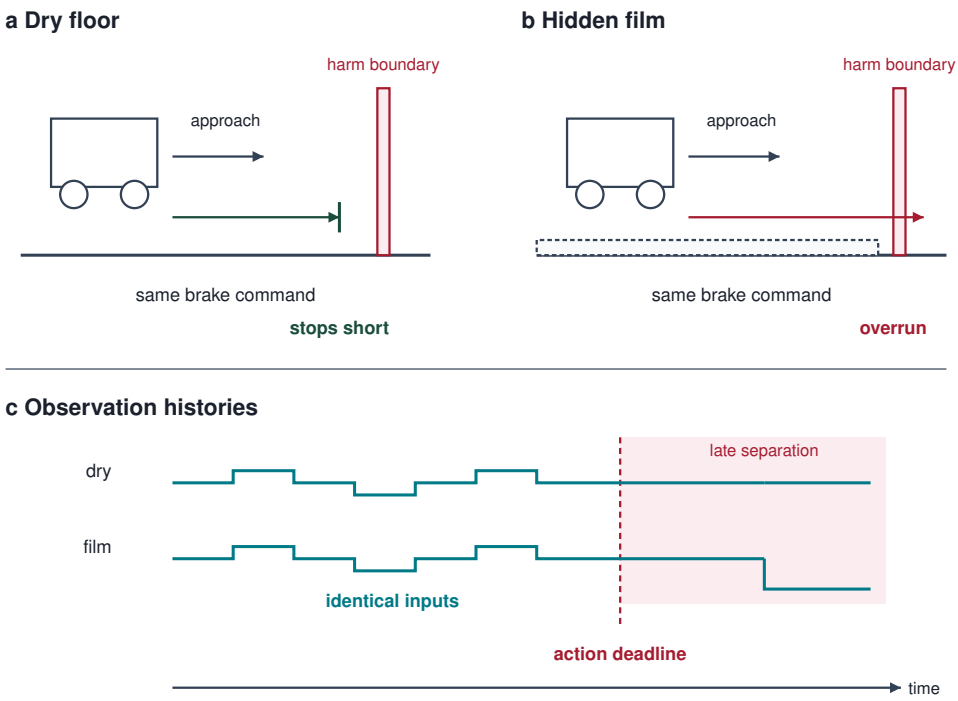


Figure 18.3: Different Worlds, Identical Timely Evidence: The dry-floor and hidden-film cases share an approach and brake command but reach different stopping positions. Their schematic observation traces remain identical until after the deadline set by equation 18.4. A later distinction cannot justify a state-specific response that had to begin earlier. The traces illustrate the stated observation policy; they do not prove that every admissible probe or additional sensor would also fail.

Definition 18.1: Observational indistinguishability

Observational indistinguishability is the condition in which two physical states that require different responses produce the same observation history, under every input the machine may admissibly apply, until the deadline by which a state-specific response must begin.

1. **Significance**: It turns an observation limit into a stopping-budget violation. The deadline is set by equation 18.4, so if the film and the dry floor look identical until the remaining distance falls below $v(T_{\text{comp}} + T_{\text{act}}) + d_{\text{brake}}(v)$, that evidence cannot justify continuing the dry-floor mode. The machine must instead use a response already qualified for both states or withhold that mode.
2. **Distinction**: Noise and weak detectors obscure information that more data or a better model can recover; indistinguishability means the information is absent from the channel. Unlike unobservability (definition 9.3), which asks whether a state can ever be reconstructed from the output history, it is tied to a deadline and to the inputs the machine may apply.
3. **Common pitfall**: A frequent misconception is that a more capable classifier on the same channel will eventually separate the states. Identical histories give every classifier identical inputs. A designed probe can separate states hidden under the current observation policy only when an admissible excitation reveals a difference before the deadline. If every admissible input leaves the histories identical, the response requires a new channel or an action valid in both states.

↩ The observation contract, which bounds the age and error of what a channel reports but cannot certify a state the channel never carries, is established in section 8.8.

The qualification *under every input the machine may admissibly apply* matters because whether two states look different often depends on how the machine excites the plant, as shown in nonlinear observability theory (Hermann and Krener 1977). In some settings, an engineer can inject a small, safe control test input that makes the two states produce different sensor readings before the deadline. This technique is **active probing**: applying a bounded test excitation to expose hidden state differences in the sensor stream before the action deadline, the same excitation that section 9.8 uses to expose a drifting force-sensor bias. Active probing draws on auxiliary signal design[5] from fault detection (Campbell and Nikoukhah 2004). For example, a controlled tug at a qualified proof load can check whether a door latch holds at that load before the arm commits to its full pull, though it does not measure the latch's remaining yield margin. On the floor, a brief torque pulse at low speed, applied before the base enters a route, makes the wheels slip measurably on a film and not on dry concrete, turning the friction under the tires into telemetry. Such a slip check measures only the patch of floor the wheels already stand on; it cannot see a film ahead, which is why the forward detector above has its own range condition. Active probing costs time and disturbs the motion, and both costs must fit inside the safety budgets. Where no admissible probe can separate the states within the timing budget, the design must fall back on conservative actions or passive mechanical containment.

5 **Auxiliary Signal Design**: The multimodel method computes a small test input that guarantees the normal model and each declared failure model produce different outputs within a fixed test horizon, despite bounded disturbances (Campbell and Nikoukhah 2004). A probe can therefore rule out only the failures someone wrote down as models, which is why the hidden premise must first be named in the register. The input bound and the horizon map onto this chapter's budgets, since the probe must fit the force envelope and the separation must arrive before t_{deadline}.

18.3.4.2 Responses when the state remains hidden

Active probing is the first of five design responses when passive runtime observations leave candidate physical states indistinguishable. When an admissible excitation can separate the states before the deadline, *active probing* supplies the missing observation online; if every admissible input leaves them indistinguishable, the remaining four responses must carry the claim without online separation. *Proof testing* measures the state from outside the runtime channel at scheduled intervals, such as an unloaded tare of a sensor or a load test of a latch, and covers the time between tests by argument. A *conservative action* chooses a command safe in both candidate states, such as a speed low enough for the film. When control commands alone cannot bound the interaction, *passive containment* limits the physical consequence mechanically, such as a compliant element that caps contact force whatever the software believes. A *restricted operational domain* withholds authority altogether from states that cannot be told apart, such as routes without a spill procedure. The register entries above already used the conservative action and the restricted domain, and active probing was shown at the latch and the floor. The wrist sensor and the latch below show proof testing and passive containment at work on the running machine.

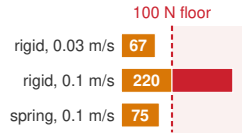
Sensor drift is the slow form of the same barrier. The wrist strain gauge of section 9.8, whose bias wanders as thermal cycles and mechanical stress relaxation alter its bridge resistance, reports only the sum of contact force and bias. A drifting bias and a real change in force therefore produce the same reading and a zero innovation. What this chapter adds is the choice of response. Every contact threshold that depends on that signal inherits the drift, and no response chosen at runtime can see it. The response must therefore be proof testing, meaning an unloaded tare or a proof-test fixture at an interval short enough that the drift accumulated between tests stays inside the threshold's margin.

↩ Mechanical degradation and thermal calibration drift as continuing obligations of a release verdict are established in section 16.5.1.

A weakened door latch poses the same observability barrier on a millisecond timescale. Before the metal yields, joint torque sensors read the same reaction force against a fatigued latch as against a sound one, so the torque channel carries no information about how much yield margin remains. Because plastic yield is permanent, no software command sent after the latch bends can undo the damage, and running a faster classifier on joint torque signals adds zero protection. A credible safety strategy must bring in information from outside the runtime torque channel. Scheduled proof tests[6] check that the latch survives a specified proof load at fixed intervals, without measuring its ultimate yield strength. Even so, proof testing holds only if maintenance records show that fatigue, wear, and corrosion cannot push the latch's yield strength below the arm's contact ceiling between tests.

6 **Proof Test**: Functional safety defines a proof test as a periodic test that reveals dangerous failures no online diagnostic can detect, so that the function can be restored to its as-new condition (International Electrotechnical Commission 2010a). A hidden failure that arrives at a constant rate λ is present, on average over a test interval T, for a fraction of about $\lambda T/2$ of the time when λT is small. The interval is therefore itself a safety parameter, because it bounds how long a weakened latch can go unseen.

Adding a passive compliant element to the structure can mechanically cap interaction forces across a qualified deflection stroke, the principle behind series elastic actuators (Pratt and Williamson 1995) and mechanical torque limiters. Two physical conditions govern compliant load paths, both set by the stroke the arm *actively drives* after contact detection rather than the total uncompressed spring length. When a contact tripwire F_{trip} triggers, the arm keeps moving during its controller response latency t_{resp} before decelerating at rate a_{arm}, driving the mechanism through a post-contact stroke of



$\Delta x_{\text{driven}} = v\,t_{\text{resp}} + v^2/(2a_{\text{arm}})$. To keep the contact force below the declared strength floor F_{floor} (a lower bound on the latch's strength, unrelated to the floor friction), the equivalent stiffness k_{eq} of the combined series load path (compliant element and strike plate) must satisfy equation 18.5:

$$F_{\text{trip}} + k_{\text{eq}}\,\Delta x_{\text{driven}} \le F_{\text{floor}} \quad\Longleftrightarrow\quad k_{\text{eq}} \le \frac{F_{\text{floor}} - F_{\text{trip}}}{v\,t_{\text{resp}} + v^2/(2a_{\text{arm}})}. \tag{18.5}$$

In addition, the compliant element's allowable stroke must exceed its deflection under the peak allowable force, $(F_{\text{floor}} - F_{\text{preload}})/k_{\text{spring}}$, so the spring never bottoms out against a hard stop. The threshold F_{floor} is not the latch's actual yield strength, which remains unobserved between proof tests; it is a chosen lower strength bound recorded as an assumption in the register until physical evidence supports it. Accountable judgment chooses the design bound; it cannot create material strength.

The warehouse door latch shows what passive compliance buys. During a guarded approach at 0.03 m/s, meeting a stiff strike plate of stiffness 4.0×10^5 N/m satisfies equation 18.5 with a required arm deceleration of 2.95 m/s², matching the guarded latch stop derived in section 12.7.2. At a faster approach speed of 0.10 m/s, however, the same stiff contact would require an impossible arm deceleration of 400 m/s², forcing the permission path to refuse the trajectory. Holding arm deceleration to the guarded stopping bound instead drives the arm through 1.89 mm after it crosses the 15 N tripwire, capping the allowable series stiffness at 44.9 kN/m. Because series compliance combines inversely ($1/k_{\text{eq}} = 1/k_{\text{spring}} + 1/k_{\text{latch}}$), pairing the compliant element with the strike plate requires a spring stiffness of at most 50.5 kN/m and an available stroke of at least 2.0 mm to stay within the 100 N design force.

This kinematic calculation assumes a stiff position-tracking drive that enforces the commanded a_{arm} deceleration profile throughout the post-tripwire stroke regardless of contact reaction. Once spring compression exceeds $m_{\text{eff}}\,a_{\text{arm}}$, the passive spring alone would decelerate the m_{eff} effective mass faster than a_{arm}, so a controller that tracks the gentler kinematic ramp keeps pushing forward into the spring until the stroke completes. If the safety response instead cuts motor torque completely, the arm's effective mass 12 kg coasts into the spring, and energy conservation sets the peak force. A spring compressed to force F stores potential energy $F^2/(2k_{\text{eq}})$; at the tripwire, the spring already holds $F_{\text{trip}}^2/(2k_{\text{eq}})$, and the coasting mass adds its kinetic energy $m_{\text{eff}}v^2/2$. The resulting peak impact force is $\sqrt{F_{\text{trip}}^2 + k_{\text{eq}}\,m_{\text{eff}}\,v^2}$, the dynamic impact regime that governs high-speed robot collisions (Haddadin et al. 2009). With the series spring installed, this coasting peak is 74.9 N, below the 100 N that the braked case reaches. That result is not a paradox. The stiffness bound was sized for a drive that holds the arm to the gentle 2.95 m/s² stop and so keeps pushing through the whole 1.89 mm stroke, bringing the force right to the floor. With torque removed, nothing pushes; the spring alone slows the 12 kg effective mass, harder than that commanded stop, and halts it in a shorter stroke at a lower force. Striking the stiff plate without compliance, by contrast, produces peak forces of 219.6 N at the faster approach speed and 67.4 N under the guarded approach. Within the qualified approach-speed and stroke envelope, the compliant element keeps both modeled responses at or below the latch's declared design strength; driving beyond that stroke would bottom out the spring and break the bound. Even so, passive compliance does not verify latch strength: qualification must still test damping, material fatigue, and structural load paths rather than spring stiffness alone.

A series spring keeps the coasting peak under the declared 100 N floor.

The door latch, the oil film, and the packaging tab pose the same problem. When a safety premise cannot be evaluated before an execution deadline, the first question is whether an admissible probe can separate the states in time. If it can, active probing supplies the missing observation; otherwise proof testing, a conservative action, passive containment, or a restricted operational domain must support the claim. The choice among them depends on the claim each response can support and the evidence needed to maintain it, and every such mitigation must also state the evidence that would retire it.

DRAFT

Checkpoint 18.2: Premises no sensor reports

The warehouse machine's hardest limits are premises its own telemetry cannot check, and each one needs an entry, a restriction, and a response chosen before the deadline.

- ☐ **Friction estimate**: A friction survey measures an aisle at $\mu = 0.15$. Given the 2 m/s^2 braking bound, compute the available deceleration from equation 18.1 and determine whether the brake or the floor binds.
- ☐ **Register entry**: For the weakened door latch, state the four components of its register entry: the missing observable, the restriction, the owner, and the closure test.
- ☐ **Shield credit**: Explain why equation 18.2 gives no credit against the oil film, and identify which term the film would enter.
- ☐ **Hidden-state responses**: For a state hidden under the current observation policy, identify the five possible engineering responses, determine when active probing is available, and classify the series spring at the latch.

18.4 Choosing the Next Capability

Pouring engineering effort into a faster proposer when an unmeasured floor or an unseated tab actually limits the cell leaves the operating restriction in place. In a deployed packaging cell, restricted transit speeds and human-supervised sign-offs call for different investments. Speeding up proposal generation improves throughput inside the current safety envelope, whereas qualifying a new contact or engagement sensor can retire the need for human sign-off altogether. Each advance requires two deliverables: a predeclared task metric and a physical test of the operating premise it changes. Tuning execution inside an existing envelope and gathering the evidence to widen that envelope are distinct engineering programs, and the register's open entries decide which one the next capability needs.

18.4.1 Match the experiment to the missing evidence

Treating every open entry in the residual-claims register by training another neural detector fails whenever the missing evidence is a field evaluation, a mathematical bound, or a fallback that the body cannot execute. The open entries do not all call for the same kind of work; each falls into one of four gap classes, and the class, not the entry's urgency, decides which experiment can close it:

- *Unmeasured observables* require dedicated sensors that can tell the relevant physical states apart before the action deadline passes.
- *Evaluation deficits* require randomized field trials or statistical estimators that represent the actual operating population while accounting for correlated samples and rare tail events.
- *Theoretical deficits* require bounded analytical arguments whose physical premises can be proved mathematically or tested on the actual hardware plant.
- *Scope mismatches* require changing the system architecture or narrowing the operational design domain.

Naming the exact gap class directs the next experiment to the evidence a register entry actually lacks, turning the open premises in the claims register into distinct work programs. Undetected floor films, hidden cross-aisle pedestrians, ambiguous object identities, and unseated packaging tabs are unmeasured observables. Each calls for either a qualified sensor channel with a tested miss bound or an operating restriction that avoids the hazard, such as the downstream manual inspection that stands in for the tab sensor. Loaded dispatch-to-admission timing requires a supported timing bound under declared workload and resource limits, challenged by loaded and adversarial latency measurements. By contrast, the coverage factor c_h for a safety shield requires statistical qualification on the declared population of hazardous proposals, whereas finite stress tests alone cannot establish a worst-case timing bound. Gaps between formal plant models and physical hardware are theoretical deficits, requiring robust control bounds. A scope mismatch differs from all three because no measurement, trial, or proof inside the current architecture can fix it. Claiming a de-energized safe

stop for a balancing biped is the clearest example: cutting torque is itself the hazard, so the remedy is a different fallback architecture or a narrower claim, as section 18.4.3 discusses.

Statistical extreme value theory bounds rare tail exceedances only when its asymptotic and independence assumptions hold; fitting a parametric curve to test data cannot validate unmodeled contact physics or reveal unobserved floor friction. Similarly, Hamilton-Jacobi reachability analysis yields invariant sets only for an explicitly declared plant and disturbance bound. Moving an unverified friction assumption from field testing into a rigid-body simulator or an analytical proof leaves it just as unverified as before.

↪ Extreme value theory and its asymptotic and independence assumptions are developed in section A.10.

↪ Hamilton-Jacobi reachability and its declared disturbance model are developed in section B.6.3.

18.4.2 What a restriction costs

Knowing which experiment would close an entry does not say whether running it is worth the cost. An entry in the residual-claims register can buy protection at a throughput cost. On the warehouse machine, the oil-film restriction lowers cruising speed along the aisle from 1.3 m/s to 1 m/s, imposing a 23.1 percent speed penalty. At steady cruise, this derating stretches transit time across each 30 m aisle segment from 23.1 s to 30 s. That single constraint adds 30 percent more transit time per leg before accounting for acceleration profiles and docking maneuvers. Because transit time scales as $1/v$, the percentage increase in leg time exceeds the percentage cut in speed.

An operational restriction remains in force until its closure test passes. That test carries a tangible empirical cost: the 2,995 seeded-film physical trials specified in the register, for example. The separate claim about safety shield coverage requires 29,956 seeded hazardous proposals; that campaign does not close the film entry. The claims register therefore confronts systems engineers with an economic optimization problem alongside the technical one. On throughput savings alone, a formal closure campaign pays back when the cumulative value recovered exceeds the combined cost of the test campaign and the sensing instrument it qualifies. A full investment decision must also account for changes in exposure, maintenance, and the value of newly supported tasks. An operational restriction can remain the economical choice when its physical premise can be maintained reliably at low cost, such as through qualified cleaning and spill-control procedures along a few pallet-jack routes. Evaluating this trade-off requires site-specific parameters: the economic value of a completed task, the machine's active duty hours on restricted routes, and the marginal expense of executing controlled test trials. In the absence of proprietary site economics, time provides the universal benchmark that transfers directly across facilities.

The same operational accounting governs fleet deployments. When commercial logistics facilities contract bipedal humanoids under robots-as-a-service agreements (GXO Logistics 2024), commercial performance is measured by volume moved, 100,000 totes at an initial customer facility by late 2025 (Agility Robotics 2025). In these operational environments, physical interventions, speed restrictions, and withheld autonomy modes can reduce completed-task throughput; their billing effect depends on the service contract. The gating criteria established during release validation translate directly into ongoing operating expenses.

Intervention rates incur a double cost. Frequent human takeovers consume costly labor hours and tether fleet operations to local technician availability. Conversely, rare interventions introduce the classic ironies of automation: an operator who seldom intervenes struggles to maintain the situational awareness and manual dexterity needed when an emergency takeover occurs (Bainbridge 1983). A defensible business case therefore reports proposer autonomy, whole-machine task success, and protective responses separately, as the first fallacy in section 18.5 insists, because each carries a different price.

↩ The labor a deployment moves onto technicians, sweep crews, and remote assistants, and the uses of their data it bars, are established in section 17.8.

18.4.3 Research that changes an engineering result

The oil-film campaign can be priced because the closure test itself is already known: run 2,995 paired braking trials on a representative spill or qualify an online probe. Other open entries in a register cannot be closed by scheduling a standard test campaign because no engineering method yet supplies the missing evidence. In physical AI, research warrants industry and academic investment when its resolution improves useful task performance within justified limits or supplies support for a broader operating claim. Six central challenges define this research frontier as of 2026 (table 18.3); each stresses one of the four laws, falls into one gap class of section 18.4.1, and names the form of evidence that would count as progress.

Generalist and cross-embodiment policies stress the fourth law, permission must be earned, because evidence gathered on one body and one model version must now earn permission for another. A single pretrained vision-language-action (VLA) foundation model can now control diverse kinematics. For example, flow-matching architectures have been trained across single-arm, dual-arm, and mobile manipulation platforms from a unified model (Black et al. 2024), using datasets from different embodiments. Modern pipelines continuously fine-tune from production deployments via reinforcement learning with human interventions (Physical Intelligence et al. 2025) or remap learned trajectories across distinct kinematic morphologies (Gemini Robotics Team 2025a).

↩ Why demonstrations logged on one embodiment carry its dynamics and do not transfer unchanged to another is established in section 5.9.

However, empirical safety evidence compiled on a dual-arm cobot cannot be assumed to hold when that same policy executes on a mobile manipulator. Furthermore, policies that continually adapt in production require reopening the release claims whose supporting evidence depends on the changed behavior (section 16.9). The enduring challenge is establishing formal transfer guarantees across both physical embodiments and continuous model updates. Concrete progress requires rigorous transfer arguments with explicit kinematic and dynamic equivalence conditions, verifiable by predicting a new morphology's closed-loop failure distributions before physical deployment. The cross-embodiment approach also reinforces the necessity of an independent permission pipeline: physical protection limits are calibrated to each specific mechanical chassis and remain invariant regardless of how frequently upstream generalist weights are updated.

Data scaling is the empirical frontier of the second law, endogenous data. Large-scale empirical studies encompassing more than 40,000 real-robot teleoperated demonstrations indicate that out-of-distribution generalization across novel environments and visual scenes follows an approximate power law governed by environmental diversity, whereas collecting redundant demonstrations within identical scenes shows sharp diminishing returns (Lin et al. 2025). In physical systems, structural diversity rather than raw sample count dictates data utility.

The open challenge is determining whether these empirical scaling laws generalize to contact-rich manipulation, long-horizon multi-step planning, and safety-critical edge states. In embodied settings, an agent's closed-loop control actions actively determine its subsequent perceptual distributions, concentrating risk in rare, unmodeled corner cases. Meaningful progress requires publishing verified scaling curves that measure tail-risk closed-loop failure rates within declared operational design domains (ODDs), replacing benchmark evaluations that measure only average-case task completion rates.

↩ Why the diversity of pooled demonstrations, not their raw count, governs their value to a target task is established in section 5.9.3.

Generative world models also stress the fourth law, because they offer a way around the physical exposure wall only if their rollouts count as evidence. Latent dynamics formulations and high-fidelity video generation models increasingly act as general-purpose physics simulators (NVIDIA, Agarwal, et al. 2025; Assran et al. 2025). Researchers have begun deploying these generative models directly as policy evaluators, demonstrating strong correlation with real-robot task execution on benchmark tasks (Jeon et al. 2026). Synthetic rollouts execute at large parallel scale for a fraction of the cost of physical hardware hours.

Nevertheless, strict evidentiary limits constrain synthetic evaluation. A learned world model may estimate latent physical variables, but its training fit does not validate those estimates in unobserved regimes or justify extrapolating friction discontinuities or structural compliance omitted from its training distribution. The central research question is establishing when synthetic evaluation in a learned world model constitutes valid evidentiary support for real-world release claims. Genuine progress requires formalizing proxy-transfer bounds (section 7.4.2) validated against the empirical tail of real-world physical failures rather than aggregate nominal success, accompanied by end-to-end dataset and architecture provenance tracking.

↩ Provenance records for learned world models, binding architecture, checkpoint, and dataset lineage, are established in section 6.4.3.

Dynamically stable machines, such as bipedal humanoids and high-speed quadrupeds, are the most stringent test of the first law, irreversibility. As highlighted in perspective 4.2, perspective 7.2, perspective 13.1, and perspective 16.1, the entire architectural chain of proposal, permission, and admission applies directly to balancing robots, with one catastrophic exception: fallback safe states. For the wheeled platform or stationary manipulator considered here, the fallback first reaches a qualified, mechanically restrained standstill before removing drive torque. On a balancing biped in mid-stride, cutting motor power induces an unrecoverable ballistic fall, transforming the safety mechanism into the primary hazard. Instead of bringing the system to an immediate stop, a balancing machine must execute dynamic recovery maneuvers: taking a stabilizing step,

initiating a controlled crouch, or executing an active powered descent to a mechanically supported resting posture. Traditional functional safety standards, however, were built around fail-passive de-energization (the torque-removal rungs of the fallback ladder, which section 12.9.1 treats as fail-safe only for a plant already at a mechanically restrained standstill). This created what safety researchers term the *fail-passive gap*[7] (Ding et al. 2026). Bridging this divide requires certifying active closed-loop balance stabilization as a safety-rated critical function. Demonstrating meaningful progress requires designing certifiable dynamic reaction chains, analogous to automotive emergency braking profiles. These chains must reliably steer the robot from each qualified gait phase, under the declared fault conditions, into a stable, supported configuration within bounded peak power and kinetic energy budgets. The most capable learned machines are thus the ones for which a safe stop is hardest to define.

Contact-rich, dexterous manipulation centers on physical AI's canonical unobserved state: high-frequency contact interaction. Determining whether a snap-fit latch yields, a packaging tab seats, or a fragile container begins to crush cannot be reliably deduced from joint motor currents or external RGB-D cameras alone. High-resolution tactile sensing provides a direct channel for several of these contact dynamics; each claimed observation still needs qualification for its materials, geometry, and deadline. Modern vision-based elastomeric tactile sensors directly capture surface deformation fields, contact geometry, and distributed shear stresses at the end-effector (Yuan et al. 2017).

Closing the loop on contact, however, challenges the third law, proposal is not permission. Contact forces escalate within milliseconds of initial impact, far outstripping the round-trip latency of high-level neural planners and placing strict burdens on low-level passive or series elastic compliance (section 18.3.4.2). The open engineering challenge is integrating tactile feedback into the formal permission path. Concrete progress requires qualifying tactile perception channels with rigorous statistical miss rates for incipient slip and shear yield, coupled with low-latency impedance controllers whose force limits can be deterministically verified and bounded by safety hardware (Tedrake 2023).

Certifying learned models that directly implement safety functions is the central challenge of the fourth law. Although such components are assigned the notified-body route of section 16.3.4, the robotics industry lacks standardized methodologies to certify deep neural networks at automotive or industrial safety integrity levels (SIL) or PL, because current verification techniques face stark limitations. Exact satisfiability modulo theories (SMT)-based and mixed-integer linear programming verification tools can establish formal input-output properties over declared neural network weights (Katz et al. 2017), yet these proofs remain vulnerable to open-world modeling gaps outside the declared plant and observations. Purely statistical validation collides with the exposure wall, requiring billions of physical test cycles to establish low target failure probabilities. Runtime safety filters and shield wrappers transfer the verification burden onto the shield's own coverage and latency envelope (Hsu et al. 2024). The unresolved systems challenge is constructing hybrid safety arguments: composing analytical proofs where deterministic physics models are tractable with statistical bounds where perceptual models operate, and allocating risk budgets across both tiers. Until such composite certification arguments mature, the architecture developed here keeps learned proposers outside the safety-critical permission path. Verifiable progress requires publishing complete, audited conformity dossiers for learned safety components alongside their formal assurance cases.

7 | **Fail-Passive and Fail-Operational**: Avionics separates a fail-passive function, whose failure causes no significant deviation of path or attitude and hands the task back to the crew, from a fail-operational one, which keeps performing through a failure. Removing torque from a wheeled base is fail-passive in this sense only after it reaches a qualified, mechanically restrained rest. A balancing biped in mid-stride has no such resting state, so its posture control must remain operational until the machine reaches a supported rest, and the certifiable reaction must be a controlled one.

↩ Optical elastomer tactile sensing and its timing and calibration obligations are established in section 8.2.6.

DRAFT

Table 18.3: A research agenda keyed to the four laws, as of 2026: Each row names an open problem, the law it stresses, the gap class of section 18.4.1 it belongs to, and the evidence that would count as progress. The last column dates the state of practice and should be refreshed in later editions; the durable content is in the first four columns.

Open problem	Law stressed	Gap class	Progress would be	State of practice, as of 2026
Generalist, cross-embodiment policies	Permission must be earned	Evaluation deficit	Evidence that transfers across bodies and updates under a stated equivalence condition	One policy across several robot types (Black et al. 2024); learning from deployment with corrections (Physical Intelligence et al. 2025); motion transfer between embodiments (Gemini Robotics Team 2025a)
Data scaling	Endogenous data	Evaluation deficit	Scaling curves on closed-loop failure rates inside a declared ODD	Roughly power-law gains in environment and object diversity, saturating in demonstrations per environment (Lin et al. 2025)
World models as evaluators	Permission must be earned	Evaluation deficit	A proxy-transfer condition validated on the failure tail	General world foundation models (NVIDIA, Agarwal, et al. 2025; Assran et al. 2025); a world model built for policy evaluation (Jeon et al. 2026)
Fall-safe dynamically stable machines	Irreversibility	Scope mismatch	A certified, actively controlled reaction chain to a supported rest state	The fail-passive gap located in a humanoid pick-and-place cell (Ding et al. 2026)
Contact-rich, dexterous manipulation	Proposal is not permission	Unmeasured observable	A qualified tactile channel and a checkable contact-force bound	High-resolution vision-based tactile sensing (Yuan et al. 2017)
Certifying learned safety functions	Permission must be earned	Theoretical deficit	A published conformity assessment of a learned safety component	Third-party assessment required in the EU from 20 January 2027 (European Parliament and Council of the European Union 2023); network verification of declared models (Katz et al. 2017)

Two systems challenges cut across all six problems. The first is continual online adaptation, which turns the model into a moving target. Whether a proposer retrains asynchronously on aggregated fleet telemetry or adapts its latent state online to accommodate component wear and shifting terrain (Kumar et al. 2021), background model updates must never starve the permission pipeline of compute or bus bandwidth. The second is multi-robot fleet coordination, which couples otherwise independent permission boundaries. Transmitting shared task intents across lossy wireless links cannot substitute for the local, hard-real-time sensor streams required by an individual robot's admission gate. Physically cooperative manipulation of a shared payload likewise couples actuator contact dynamics directly across platforms. Across all of these problems, advancing physical AI does not require abandoning established systems rigor; it requires extending it. Unlocking the next capability begins by isolating a concrete physical task that the current system cannot safely execute, identifying the missing empirical premise or unmeasured observable, and engineering the precise evidential argument required to justify expanding the machine's operational envelope.

18.5 Fallacies and Pitfalls

When engineers move physical AI systems such as the warehouse mobile manipulator or the packaging cell from isolated benchmarks to production floors, the traps that remain are conceptual. Every local calculation can succeed numerically while the system-level reasoning fails, because the team has misread how physical dynamics, learned proposers, and runtime enforcement relate. The traps below recur on both machines.

Fallacy: *A protective intervention means the whole machine failed its task.*

When a runtime safety governor or control barrier filter modifies an actuator command, engineers often mistakenly log the episode as a system-level failure. In practice, a least-change speed correction

or torque clamp often allows an autonomous mobile robot or packaging arm to complete its physical mission smoothly within safe boundaries. If the warehouse machine enters a route whose floor is inspected only to $\mu \geq 0.12$ and the governor trims its speed from the 1.3 m/s aisle speed to the register's 1 m/s restricted mode for that floor, the delivery still completes. The leg takes 30 percent longer.

Treating every safety intervention as a mission failure corrupts operational telemetry. Conflating proposer interventions with unrecoverable task aborts conceals where engineering effort should be directed. Development teams must track three metrics independently: raw proposer autonomy (the fraction of time the learned model operates without override), whole-machine task success (whether the physical objective was achieved within operational deadlines), and protective intervention frequency. Decoupling these signals reveals whether system bottlenecks stem from policy distribution shift, sensor latency in the perception pipeline, or overly conservative governor tuning.

↩ Proposer autonomy, task success, and protective intervention as separately recorded outcome channels are established in section 7.2.

Pitfall: *Treating a restriction as evidence that its physical premise holds.*

Deriving a tighter operational limit does not guarantee that the physical environment satisfies the assumptions behind that limit. The register's restricted mode for the warehouse machine, 1 m/s instead of 1.3 m/s, provides a stopping margin only on floors that hold $\mu \geq 0.12$. Under the clear film, where μ falls to 0.05 and the available deceleration to 0.49 m/s^2, the lower speed setpoint carries no stopping guarantee at all; the restriction rests on the same unmeasured premise as the mode it replaced.

Digital artifacts cannot substitute for physical friction. Neither a signed configuration parameter in software, nor a clear path reported by an RGB camera, proves that the ground provides adequate traction. Vision pipelines readily mistake transparent oil or thin ice for dry concrete. A restricted envelope therefore needs its own premise kept true, through the inspection and spill procedure the register assigns to facility operations or through a qualified forward film detector. Monitoring wheel slip and inertial deceleration can reveal, after the fact, that a premise failed, and should trigger the restriction for later motion, but it cannot rescue the stop already under way. A safety envelope is only as credible as the physical premise beneath it.

Fallacy: *More model capacity or simulated exposure settles every residual claim.*

Scaling up neural network parameter counts or running billions of simulated training steps improves policy interpolation across modeled conditions, but neither technique can overcome an unmodeled physical reality. A deep learning policy cannot infer an unobserved physical state, such as internal material stress, micro-slip at a fingertip, or variable ground compliance, if the sensor suite lacks the transducers to measure it. Similarly, physics simulators rely on simplified approximations of rigid-body contact, Coulomb friction, and non-deformable geometry. Generating large synthetic datasets within a simulator that omits real contact mechanics merely produces policies optimized for fictitious physical dynamics.

When an embodied system displays persistent edge-case failures, the solution rarely lies in adding more transformer layers or randomizing synthetic textures. Engineers must diagnose the specific physical claim that lacks empirical grounding. Resolving the defect requires choosing the appropriate engineering intervention: integrating a dedicated physical sensor to observe the missing state, introducing passive mechanical compliance to absorb unmodeled impact energy, constraining the operational design domain, or calibrating friction models against instrumented hardware trials.

DRAFT

Pitfall: *Charging the full stop time against an action deadline.*

An engineer who sizes the latest useful observation by subtracting the whole braking duration treats the machine as if it held its speed until it stopped instantly. For the jerk-limited stop from the 1.3 m/s aisle speed, braking lasts 931.2 ms but covers only the distance of 465.6 ms of travel at constant speed. The time form therefore over-reserves 465.6 ms, or 605.3 mm, more than the entire 131.0 mm spare.

The error is safe in the narrow sense that it never admits an unsafe stop, which is why it survives review. Its cost appears elsewhere. A deadline computed this way refuses operating modes the distance form correctly admits, and it hides how much timing allowance a new detector or a slower admission stage can still spend. The deadline belongs to the remaining distance, equation 18.4, with the braking term divided by speed, never to the stop's duration.

Fallacy: *A safety shield makes the proposer's error rate irrelevant.*

A shield attenuates hazardous proposals; it does not erase them. In notebook 18.3, a full release cycle of adjudicated proposals with no hazardous event still bounds the proposal rate only at $1.387 \times 10^{5}\ \mathrm{h}^{-1}$. A shield with interception coverage 0.9999 then leaves a modeled residual of $1.387 \times 10^{9}\ \mathrm{h}^{-1}$, above the $1 \times 10^{9}\ \mathrm{h}^{-1}$ target even with the common-cause term set to zero. Meeting the target at that proposal bound would need coverage of 0.9999279, and showing the assumed coverage alone takes 29,956 seeded hazardous proposals with no miss.

The residual of equation 18.2 is a product, so both factors need evidence, and a common-cause failure that blinds the shield in the same states where the proposer errs lowers coverage exactly where it matters. The shield is the reason the proposer need not be perfect, not a reason to stop measuring how often it errs.

Pitfall: *Qualifying a forward detector by its miss rate alone.*

A floor-film detector that passes 2,995 failure-free seeded trials has a miss bound of 0.1 percent, and a team may treat that result as closing the register entry. Detection that arrives too late is a miss in every sense that matters to the stop. At the 1.3 m/s aisle speed with a 100 ms sensing and inference latency, equation 18.3 requires the detector to see the film 1.10 m ahead, about the whole 1.10 m clear distance. At that range the latency leaves nothing for the 63.3 ms dispatch-to-admission allocation. To fit beside it, the detector's latency must stay under the 37.5 ms reserve.

A detector that reports only once the wheels are on the film faces a 2.13 m stop, turning a statistically accurate classification into an unrecoverable overrun. The closure test must therefore predeclare range, latency, false-alarm rate, and the friction assumed after detection, alongside the miss rate, and qualify them together on the routes the restriction covers.

18.6 Summary

The warehouse mobile manipulator now carries one connected design argument, and the packaging cell shows that the same argument transfers to a machine with different mechanics, rates, and hazards. The book opened by asking why a better prediction can still produce a worse physical action, and the chapter's answer is concrete. A neural network optimizes expected statistical loss over its training distribution, but the physical plant operates under continuous Newtonian mechanics, electromagnetism, and thermodynamics. A better proposer cannot supply the friction premise that an unobserved oil film removes, because no input it receives measures the tire-ground contact interface. It cannot make a derated operating mode evaluated, because the operational restriction that shortens the stop also displaces the proposer into physical configurations its training and evaluation never sampled. It cannot close a detectorless claim such as the glare-hidden packaging tab, because the physical sensor required to resolve that state does not exist on the machine. Nor can a faster forward pass recover the stopping distance already consumed while the vehicle cruised under unguided momentum ($d_{\mathrm{blind}} = v\tau_{\mathrm{delay}}$). In each case, the physical outcome is judged by dynamics, timing, and environmental evidence that the learned prediction does not contain.

The learned model must therefore be engineered as an unprivileged component of a machine, with the rest of the machine supplying what the model lacks, one law at a time. The first law, irreversibility, turns the body's kinetic, actuator, and thermal limits into budgets that bound any proposal, and the friction floor showed that a single unmeasured term can void those budgets. The

second law, endogenous data, confines competence to the states the closed loop actually visits, which is why the packaging cell's restricted mode opened a regime its evaluation never sampled. The third law, proposal is not permission, places an independent permission path between proposal and actuator, and the shield-dilution bound showed that this path improves a hazard-rate claim only for the hazards it can detect and intercept in time. The fourth law, permission must be earned, grants the machine only what its evidence supports, and the residual-claims register gives each unobserved premise a restriction, an owner, and a predeclared closure test. Table 18.4 collects the relations the chapter applied to both machines, what each bounds or decides, and where the book derives it.

Table 18.4: Key equations of the chapter: Each equation the chapter applies to the warehouse machine or the packaging cell, what it bounds or decides, and where the book derives it. The first two and the zero-failure count are derived in earlier chapters and reused here; the others are stated in this chapter.

Equation	What it bounds or decides	Where derived
$d_{\text{stop}} = v\tau_{\text{delay}} + v^2/2a_{\text{brake}}$	Whether a mode's stop fits its clearance, and whether delay or braking dominates	equation 2.2
$v_{\max} = -a_{\text{brake}}\tau_{\text{delay}} + \sqrt{(a_{\text{brake}}\tau_{\text{delay}})^2 + 2a_{\text{brake}}D_{\text{avail}}}$	The speed ceiling a stopping budget admits	equation 2.3; jerk ramps in equation 12.2
$a = \min(a_{\text{brake}}, \mu g)$	Whether the brake or the floor binds, and the friction floor a_{brake}/g	equation 18.1
$\lambda_{\text{system},h} \le \lambda_{\text{proposal},h}(1-c_h) + \lambda_{\text{other}}$	What a shield adds to a hazard-rate claim, and the coverage the claim needs	equation 18.2
$n = \lceil \ln\alpha_{\text{sig}} / \ln(1-p_{\text{fail}}) \rceil$	Failure-free trials that bound a miss or false-accept probability p_{fail}	equation 7.5
$d_{\text{detect}} \ge v\,t_{\text{detect}} + d_{\text{budget}}(v)$	The range at which a detector must report a hazard ahead of the machine	equation 18.3
$d_{\text{rem}} \ge v\,(T_{\text{comp}} + T_{\text{act}}) + d_{\text{brake}}(v)$	The latest point at which a distinguishing observation can still help	equation 18.4
$F_{\text{trip}} + k_{\text{eq}}\,\Delta x_{\text{driven}} \le F_{\text{floor}}$	The stiffness of a passive element that bounds contact force	equation 18.5

RAFT

Key Takeaways: Engineering a machine that senses and acts

- **Useful service joins the four laws:** Body limits, learned competence, independent permission, and maintained evidence must support the same task; a better prediction strengthens only one link of that argument.
- **Competence can grow:** New qualified experience, retraining, and regression evaluation can extend what the next candidate can justify.
- **Admission can preserve success:** A minimally corrected proposal can complete useful work; proposer autonomy, task success, and protection require separate measures.
- **Restrictions need evidence:** A lower speed still needs traction, clearance, and a feasible response. A stipulated supported branch teaches the release decision without turning illustrative records into measurements.
- **Residual limits select the next experiment:** Missing observations, evaluation support, proof premises, and task scope call for different engineering responses.

The chain from body limits to a release decision can be carried through for any machine, but the chapter's last lesson lies where that chain runs out. The running machine's hardest limits were not its slowest computation or its weakest model; they were premises no sensor reports, a floor's friction and a latch's strength. Engineering judgment at that edge means naming such a premise, restricting the machine until evidence arrives, and choosing the next measurement, learning experiment, architectural change, or narrower domain by which open premise it retires. Chapter 1 promised the ability to design, teach, integrate, evaluate, and maintain such a machine within justified operating

limits, and to name, when the evidence is incomplete, what would support the next capability. That ability to build, verify, and justify a machine that senses and acts is the enduring discipline this book develops.

What's Next: From physical AI to the systems discipline

The next unfamiliar machine will bring a different body, task, and environment. Its engineering begins by tracing how observations become proposals and how admitted commands become force, motion, and heat. The methods developed here provide a way to teach useful behavior, integrate it with timely physical control, and determine which operating claims the resulting evidence supports. This work is dedicated to the students, researchers, and systems engineers who take up the challenge of giving machines safe and capable hands in an open physical world.

A

Machine Learning Background

This appendix supplies the machine learning and statistical tools needed to interpret learned action proposals, size their computation, and evaluate the evidence for their use. It develops uncertainty measures, spatial representations, policy-learning objectives, and rare-event bounds as consultable references for the main text. Each tool separates what a model or test establishes from the physical clearance and timing conditions that the permission path must enforce.

A.1 How to Use This Appendix

Use the table to enter at the relevant problem. The probability section explains expectations, densities, and uncertainty; spatial representations then connect image arrays to metric geometry. Policy sections distinguish the training objective from runtime execution, and the final sections distinguish statistical evidence from a physical guarantee. The derivations use matrix multiplication, derivatives, and integrals; the prose following each result states the engineering consequence so that a reader can consult the result before working through its proof.

A.2 Probability, Information Theory, and Calibration

Commanding an uncalibrated motor torque stresses gearboxes, violates physical clearance envelopes, and risks destructive contact collisions across an irreversible causal boundary, unlike a software prediction error that merely degrades a recommendation or text token. Autonomous machines must therefore reason quantitatively about uncertainty across perception, intent estimation, and world modeling. In closed-loop physical AI, uncertainty quantification determines whether a candidate action proposal is dispatched to motor controllers or intercepted by a safety governor.

A.2.1 Conditional probability and Bayes' rule

When a sensor returns observed evidence x, the conditional distribution $p(y \mid x)$ characterizes the updated belief over y. For continuous parameters, p in the following expressions denotes a density; probabilities over regions require integration. By Bayes' rule:

$$p(\theta \mid \mathcal{D}) = \frac{p(\mathcal{D} \mid \theta)p(\theta)}{p(\mathcal{D})} = \frac{p(\mathcal{D} \mid \theta)p(\theta)}{\int_\Theta p(\mathcal{D} \mid \theta')p(\theta')\,d\theta'}$$

where $p(\theta)$ represents prior belief over model parameters or latent states $\theta \in \Theta$, $p(\mathcal{D} \mid \theta)$ represents the likelihood of physical dataset or sensor observation sequence $\mathcal{D} = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$, and $p(\theta \mid \mathcal{D})$ represents the updated posterior belief.

In high-dimensional learning systems, integrating over the parameter manifold Θ to compute the marginal likelihood (evidence) $p(\mathcal{D}) = \int_\Theta p(\mathcal{D} \mid \theta)p(\theta)\,d\theta$ is analytically and computationally intractable. Real-time autonomy resolves this intractability through two complementary paradigms:

1. **Maximum a posteriori (MAP) estimation:** Replacing posterior integration with point optimization:
$$\theta_{\text{MAP}} = \arg\max_\theta \left[\sum_{i=1}^{N} \ln p(\mathbf{x}_i \mid \theta) + \ln p(\theta)\right]$$
With conditionally independent observations and a summed log-likelihood, a zero-mean isotropic Gaussian prior $p(\theta) = \mathcal{N}(\mathbf{0}, \sigma_0^2\mathbf{I})$ gives the log-prior $\ln p(\theta) = -\frac{\|\theta\|_2^2}{2\sigma_0^2} - \frac{d}{2}\ln(2\pi\sigma_0^2)$. Maximizing the posterior objective is mathematically identical to minimizing negative log-likelihood with an explicit ℓ_2 penalty $\frac{\lambda_{\text{reg}}}{2}\|\theta\|_2^2$, where $\lambda_{\text{reg}} = 1/\sigma_0^2$. However, MAP estimation yields only a single deterministic point estimate θ_{MAP}. The point estimate does not report posterior variance; it does not establish that the underlying uncertainty is zero. In continuous control, epistemic uncertainty (ignorance arising from lack of training data in unfamiliar operational domains) must be sharply distinguished from aleatoric uncertainty (stochasticity inherent to sensor noise, turbulent airflow, or non-deterministic contact friction). A point-estimated model can still predict observation noise, but that output alone does not quantify uncertainty about its fitted parameters.
2. **Variational inference:** Approximating the true posterior $p(\theta \mid \mathcal{D})$ with a tractable variational distribution family $q_\phi(\theta)$ by maximizing the Evidence Lower Bound (ELBO):
$$\ln p(\mathcal{D}) = \mathbb{E}_{\theta\sim q_\phi(\theta)}\left[\ln \frac{p(\mathcal{D},\theta)}{q_\phi(\theta)}\right] + \mathcal{D}_{\text{KL}}\left(q_\phi(\theta) \parallel p(\theta \mid \mathcal{D})\right) \geq \mathbb{E}_{\theta\sim q_\phi(\theta)}[\ln p(\mathcal{D} \mid \theta)] - \mathcal{D}_{\text{KL}}\left(q_\phi(\theta) \parallel p(\theta)\right)$$

Because the Kullback-Leibler divergence is non-negative ($\mathcal{D}_{\mathrm{KL}} \geq 0$), the lower bound holds, with equality when the variational distribution equals the posterior almost everywhere. Variational inference converts intractable high-dimensional integration into continuous gradient-based optimization over variational parameters ϕ. This formulation provides the analytical foundation for the latent-variable action chunking and generative decoders derived in section A.5.1, where latent variables capture human demonstrator intent and style without collapsing multimodal physical actions into destructive spatial averages.

A.2.2 Shannon entropy and ambiguity thresholds

When a perception or intent model spreads probability across several candidate targets, entropy quantifies the average uncertainty or information content contained in that distribution. For a discrete random variable X taking values in alphabet $\mathcal{X}$:[1]

$$H(X) = -\sum_{x \in \mathcal{X}} p(x) \log_2 p(x) = \mathbb{E}_{x \sim p}\left[\log_2 \frac{1}{p(x)}\right]$$

[1] **Shannon Information Entropy**: Entropy quantifies average uncertainty within a specified discrete distribution. Its physical meaning depends on whether that distribution is calibrated to the relevant referents and observations.

For continuous random variables governing physical state $\mathbf{x} \in \mathbb{R}^d$ with probability density $p(\mathbf{x})$, the **differential entropy** evaluates to:

$$h(\mathbf{X}) = -\int_{\mathbb{R}^d} p(\mathbf{x}) \ln p(\mathbf{x})\, d\mathbf{x}$$

Under a multivariate Gaussian distribution $\mathbf{x} \sim \mathcal{N}(\mu, \Sigma)$ with positive-definite covariance $\Sigma \in \mathbb{R}^{d \times d}$, substituting the Gaussian density $p(\mathbf{x}) = (2\pi)^{-d/2}(\det\Sigma)^{-1/2}\exp(-\frac{1}{2}(\mathbf{x}-\mu)^\top\Sigma^{-1}(\mathbf{x}-\mu))$ yields:

$$\begin{aligned} h(\mathbf{X}) &= -\mathbb{E}\left[-\frac{d}{2}\ln(2\pi) - \frac{1}{2}\ln(\det\Sigma) - \frac{1}{2}(\mathbf{x}-\mu)^\top\Sigma^{-1}(\mathbf{x}-\mu)\right] \\ &= \frac{d}{2}\ln(2\pi) + \frac{1}{2}\ln(\det\Sigma) + \frac{1}{2}\operatorname{Tr}\left(\Sigma^{-1}\mathbb{E}[(\mathbf{x}-\mu)(\mathbf{x}-\mu)^\top]\right) \\ &= \frac{1}{2}\ln\left((2\pi e)^d \det\Sigma\right) \end{aligned}$$

Unlike discrete entropy, differential entropy depends on coordinate units and can be negative. Comparisons require the same coordinates and units. For a Gaussian it scales with the logarithmic volume of the physical uncertainty ellipsoid $\det\Sigma$. In state estimation, sensor fusion, and Kalman filtering, an informative measurement update shrinks $\det\Sigma$, producing an exact physical information gain $\Delta h = h_{\text{prior}} - h_{\text{post}} = \frac{1}{2}\ln(\det\Sigma_{\text{prior}}/\det\Sigma_{\text{post}})$. Under an isotropic Gaussian distribution $\mathcal{N}(\mu, \sigma^2\mathbf{I})$, this reduces to $h(\mathbf{X}) = \frac{d}{2}\ln(2\pi e\sigma^2)$. In continuous reinforcement learning, such as Soft Actor-Critic (SAC), the unsquashed diagonal Gaussian policy has entropy $\mathcal{H}(\pi(\cdot \mid s)) = \frac{d_a}{2}(1+\ln(2\pi)) + \sum_{i=1}^{d_a}\ln\sigma_i^\pi(s)$ with d_a action dimensions and conditional standard deviations σ_i^π. Entropy regularization encourages exploration; after bounding actions with a nonlinear transformation, its Jacobian changes this entropy, as the SAC derivation below shows.

To quantify information divergence between an empirical demonstrator distribution p and a learned policy distribution q, information theory defines the **Kullback-Leibler (KL) divergence** (relative entropy):

$$\mathcal{D}_{\mathrm{KL}}(p \parallel q) = \int_{\mathbb{R}^d} p(\mathbf{x}) \ln\left(\frac{p(\mathbf{x})}{q(\mathbf{x})}\right) d\mathbf{x}$$

where $\mathcal{D}_{\mathrm{KL}}(p \parallel q) \geq 0$ by Gibbs' inequality, with equality if and only if $p = q$ almost everywhere.

In closed-loop decision making, Shannon entropy provides an instantaneous monitor of policy ambiguity. When a vision-language planner encounters an underspecified scene with two equally probable referents (such as two identical cups), the discrete action entropy approaches its maximum $H(X) \to \log_2 2 = 1.0$ bit. A calibrated threshold gates actuation, issuing an ambiguity fault (`ERR_GROUNDING_AMBIGUITY`) that commands a stationary hold while active perception collects disambiguating viewpoints. However, because an overfitted neural network can be confidently wrong, entropy alone cannot guarantee semantic correctness; it must operate in tandem with physical clearance monitors.

DRAFT

A.2.3 Softmax overconfidence and calibration error

A perception classifier that reports a 0.99 softmax score on a wet-floor reflection or an unfamiliar obstacle is measuring logit separation rather than empirical accuracy. Standard neural classification heads normalize raw logit vectors $\mathbf{z} = [z_1, \ldots, z_K]^\top \in \mathbb{R}^K$ into categorical distributions using the softmax function:

$$\sigma(\mathbf{z})_i = \frac{e^{z_i/T_{\text{cal}}}}{\sum_{j=1}^{K} e^{z_j/T_{\text{cal}}}}$$

where $T_{\text{cal}} > 0$ is a temperature hyperparameter (defaulting to $T_{\text{cal}} = 1$). The softmax operator maps logits onto the open probability simplex $\Delta^{K-1} = \{\mathbf{p} \in \mathbb{R}^K : \sum_i p_i = 1, p_i > 0\}$ strictly through algebraic exponentiation.

A cross-entropy training objective does not by itself establish calibration. At $T_{\text{cal}} = 1$, for target class $y \in \{1, \ldots, K\}$, the cross-entropy loss evaluates to $\mathcal{L}_{\text{CE}}(\mathbf{z}, y) = -z_c + \ln \sum_{j=1}^{K} e^{z_j}$. Differentiating with respect to any logit z_i:

$$\frac{\partial \mathcal{L}_{\text{CE}}}{\partial z_i} = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}} - \mathbf{1}(i = y) = \sigma(\mathbf{z})_i - \mathbf{1}(i = y)$$

For the ground-truth class y, the derivative is negative until its predicted probability approaches unity. For an individually fitted example, cross-entropy decreases as the correct class separates from the other logits; separable, unregularized training can therefore keep increasing those margins. This is not a proof that every trained network is overconfident or that noisy examples can all be fitted simultaneously. A large softmax output measures relative logit separation, while calibration asks whether predictions with that confidence are correct at the corresponding frequency.

To quantify whether predicted probabilities match empirical physical frequencies, reliability engineering computes the **Expected Calibration Error (ECE)** and **Maximum Calibration Error (MCE)**:[2]

$$\text{ECE} = \sum_{m=1}^{N_{\text{bins}}} \frac{|B_m|}{N} \left|\text{acc}(B_m) - \text{conf}(B_m)\right|, \qquad \text{MCE} = \max_{m \in \{1, \ldots, N_{\text{bins}}\}} \left|\text{acc}(B_m) - \text{conf}(B_m)\right|$$

Empty bins contribute zero to ECE and are omitted from MCE; accuracy and confidence averages are defined only for nonempty bins. Here B_m is the set of validation examples whose predicted confidence falls in $((m-1)/N_{\text{bins}}, m/N_{\text{bins}}]$. The size $|B_m|$ is the sample count in bin m, and N is the total validation sample count. The mean predicted confidence is $\text{conf}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \hat{p}_i$, and the empirical accuracy is $\text{acc}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \mathbf{1}(\hat{y}_i = y_i)$.

To recalibrate an overconfident model post-hoc without altering its classification accuracy, **temperature scaling** optimizes a single scalar parameter $T_{\text{cal}} > 0$ on a held-out calibration dataset $\mathcal{D}_{\text{cal}}$:

$$T^*_{\text{cal}} = \arg\min_{T_{\text{cal}} > 0} \left[-\sum_{(\mathbf{x}, y) \in \mathcal{D}_{\text{cal}}} \ln \left(\frac{e^{z_c(\mathbf{x})/T_{\text{cal}}}}{\sum_{j=1}^{K} e^{z_j(\mathbf{x})/T_{\text{cal}}}} \right) \right]$$

Because T^*_{cal} scales all logits uniformly, the ranking $\arg\max_i (z_i/T_{\text{cal}}) = \arg\max_i z_i$ remains unchanged for all $T_{\text{cal}} > 0$, preserving top-1 accuracy. Temperatures above one soften probabilities, while temperatures below one sharpen them; optimizing calibration loss does not guarantee exact calibration. However, temperature scaling rests on the classical assumption that deployment data is identically distributed to calibration data ($p_{\text{deploy}} = p_{\text{cal}}$). In physical AI, an embodied agent continually encounters non-stationary environmental shifts: lens flare, wet floor reflectance, novel obstacle textures, or altered motor dynamics. Temperature scaling cannot repair or detect out-of-distribution inputs: scaling an out-of-distribution logit vector by scalar T^*_{cal} still yields near-unity confidence if the raw relative logit separation remains large. In safety-critical autonomy, post-hoc calibration requires separately validated uncertainty and clearance checks. Conformal coverage also depends on its sampling assumptions, commonly exchangeability; it does not automatically survive deployment shift.

[2] **Expected Calibration Error**: Binned calibration metrics quantify the divergence between neural prediction confidence and realized empirical accuracy across confidence intervals. Separable, unregularized cross-entropy training can keep increasing logit margins; whether a fitted network is overconfident must be assessed on representative held-out data. Relying on uncalibrated confidence scores to gate safety fallbacks permits undetected distribution shifts to corrupt closed-loop actuation.

DRAFT

A.3 Spatial Representations and Scene Parameterization

Detecting a door handle at pixel $(142, 88)$ in a wrist-camera image cannot tell a joint controller where to move until that pixel ray is combined with metric depth and transformed through the camera, wrist, arm, and mobile-base coordinate frames. Unlike language models that operate on discrete semantic tokens, an embodied policy must bind high-dimensional sensor arrays (RGB-D cameras, time-of-flight rangefinders, and lidars) to rigid physical links and Euclidean 3D reference frames.

A.3.1 Special Euclidean group $SE(3)$ transforms

Rigid body transformations in 3D Euclidean space belong to the Special Euclidean Lie group $SE(3)$, combining a 3×3 orthonormal rotation matrix $\mathbf{R} \in SO(3)$ ($\mathbf{R}^\top \mathbf{R} = \mathbf{I}$, $\det(\mathbf{R}) = +1$) with a translation vector $\mathbf{t} \in \mathbb{R}^3$:

$$\mathbf{T} = \begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}^\top & 1 \end{bmatrix} \in SE(3) \subset \mathbb{R}^{4\times 4}$$

A homogeneous coordinate vector $\tilde{\mathbf{p}} = [\mathbf{p}^\top, 1]^\top \in \mathbb{R}^4$ transforms across coordinate frames via matrix-vector multiplication:

$$\tilde{\mathbf{p}}' = \mathbf{T}\tilde{\mathbf{p}} \iff \mathbf{p}' = \mathbf{R}\mathbf{p} + \mathbf{t}$$

Let $\mathbf{T}_{AB}$ denote the transform mapping coordinates from frame B into frame A. For a kinematic chain comprising world frame W, mobile base B, end effector E, and wrist camera C, the forward composite transformation evaluates via associative matrix multiplication:

$$\mathbf{T}_{WC} = \mathbf{T}_{WB}\mathbf{T}_{BE}\mathbf{T}_{EC}$$

The inverse transform admits an exact closed-form evaluation avoiding general 4×4 matrix inversion:

$$\mathbf{T}^{-1} = \begin{bmatrix} \mathbf{R}^\top & -\mathbf{R}^\top \mathbf{t} \\ \mathbf{0}^\top & 1 \end{bmatrix}$$

A.3.1.1 Lie algebra $\mathfrak{se}(3)$ and manifold perturbation

Because $SE(3)$ forms a smooth, non-Euclidean Riemannian manifold rather than a linear vector space, unconstrained optimization (such as gradient descent during camera pose estimation or neural trajectory generation) cannot directly add matrices ($\mathbf{T}_1 + \mathbf{T}_2 \notin SE(3)$). Regressing 3D rotations directly using Euler angles induces topological singularities (gimbal lock at pitch $\pm 90^\circ$) where degrees of freedom collapse. Unconstrained unit quaternions $\mathbf{q}_{\text{quat}} \in S^3$ suffer from the antipodal double-cover ambiguity ($\mathbf{q}_{\text{quat}}$ and $-\mathbf{q}_{\text{quat}}$ represent the identical physical rotation). In continuous neural policy training, minimizing ℓ_2 regression loss over quaternions produces severe gradient cancellation when the network predicts opposite hemispheres for nearby states. To ensure topological continuity across continuous rotations, modern spatial policies either output continuous 6D rotation representations (the first two columns of $\mathbf{R}$ orthonormalized via Gram-Schmidt) or parameterize local variations in the tangent space at the identity: the Lie algebra $\mathfrak{se}(3)$.

For the finite pose increment below, a twist coordinate vector $\xi = [\mathbf{v}^\top, \omega^\top]^\top \in \mathbb{R}^6$ combines integrated translation coordinates $\mathbf{v}$ and rotation coordinates ω. If these symbols instead denote velocities, multiply the matrix twist by elapsed time before exponentiating. The wedge operator $(\cdot)^\wedge$ maps ξ to its matrix Lie algebra representation:

$$\hat{\xi} = \xi^\wedge = \begin{bmatrix} [\omega]_\times & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{bmatrix} \in \mathfrak{se}(3), \quad \text{where } [\omega]_\times = \begin{bmatrix} 0 & -\omega_z & \omega_y \\ \omega_z & 0 & -\omega_x \\ -\omega_y & \omega_x & 0 \end{bmatrix}$$

The exponential map $\exp : \mathfrak{se}(3) \to SE(3)$ computes finite rigid transformations in closed form via Rodrigues' formula:

$$\exp(\hat{\xi}) = \begin{bmatrix} \exp([\omega]_\times) & \mathbf{V}\mathbf{v} \\ \mathbf{0}^\top & 1 \end{bmatrix}$$

DRAFT

where $\theta_{\text{rot}} = \|\omega\|$, $\exp([\omega]_\times) = \mathbf{I} + \frac{\sin\theta_{\text{rot}}}{\theta_{\text{rot}}}[\omega]_\times + \frac{1-\cos\theta_{\text{rot}}}{\theta_{\text{rot}}^2}[\omega]_\times^2$, and $\mathbf{V} = \mathbf{I} + \frac{1-\cos\theta_{\text{rot}}}{\theta_{\text{rot}}^2}[\omega]_\times + \frac{\theta_{\text{rot}}-\sin\theta_{\text{rot}}}{\theta_{\text{rot}}^3}[\omega]_\times^2$.

In spatial tracking and state estimation, small pose uncertainties are modeled by perturbing the mean transform with a zero-mean Gaussian twist vector in the local frame: $\mathbf{T}' = \mathbf{T}\exp(\widehat{\epsilon})$, with $\epsilon \sim \mathcal{N}(\mathbf{0}, \Sigma_\xi)$ and covariance $\Sigma_\xi \in \mathbb{R}^{6\times 6}$. The exponential keeps the updated pose on $SE(3)$. The covariance describes local tangent coordinates, not a Gaussian distribution over matrix entries; its approximation is reliable only while the local perturbation model is adequate. At zero rotation, evaluate the coefficients above by their continuous limits to avoid division by zero.

A.3.2 Visual patch tokenization, attention, and 3D metric lifting

A vision transformer that slices three 224×224 camera frames into 14×14-pixel patches produces 768 visual tokens per control step. Yet none of those tokens carries metric 3D distance until camera intrinsics and depth measurements lift the 2D image plane into Euclidean space. Embodied vision-language-action (VLA) models and spatial transformers convert continuous sensory streams into discrete tokens for neural attention, then lift candidate spatial predictions into 3D coordinates for physical reasoning. Section 3.3 and section 3.4 use the token counts derived here to size the application processor's memory traffic.

A.3.2.1 Convolutional encoders versus vision transformer tokenization

Physical AI architectures employ two primary paradigms for encoding raw camera observations into visual features:

1. **Convolutional Encoders (ConvNets):** Classical visuomotor backbones (such as ResNet-18/34/50 or modern ConvNeXt variants) process images through hierarchical sliding-window convolutions. Convolutions possess an intrinsic inductive bias: **translational equivariance** ($\text{Conv}(\text{Shift}(\mathbf{I})) = \text{Shift}(\text{Conv}(\mathbf{I}))$) and local spatial compactness. Because small 3×3 filter weights are repeatedly applied across thousands of image pixel locations, convolutional feature extraction achieves high arithmetic intensity (FLOPs per byte transferred from DRAM) in early layers. Intermediate feature activations stream through on-chip SRAM line buffers, minimizing off-chip memory bandwidth consumption and reducing traffic when the accelerator mapping and buffer capacity permit reuse. Deterministic latency still requires a timing analysis under contention. However, local receptive fields require deep network stacks to capture global scene context, limiting their ability to resolve long-range semantic relationships (such as attending from a robot gripper to a distant receptacle).
2. **Vision Transformers (ViTs):** Vision transformers discard local sliding windows in favor of non-overlapping patch tokenization and global multi-head self-attention. While ViTs lack hardwired translational equivariance, they establish global receptive fields across the entire image at layer 1. The operational trade-off is computational complexity and memory bandwidth: self-attention scales quadratically ($\mathcal{O}(N^2)$) in token count N. On embedded edge accelerators operating at single-frame batch sizes, materializing full $N \times N$ attention matrices generates substantial activation memory traffic that stresses shared system memory buses.

A.3.2.2 2D vision transformer patch tokenization

Consider an RGB image $\mathbf{I} \in \mathbb{R}^{H\times W\times C}$ captured by an onboard camera with spatial resolution $H \times W$ and C color channels. Feeding raw pixels to a multilayer perceptron would discard spatial locality and inflate the parameter count. A vision transformer frontend therefore partitions the image into a non-overlapping sequence of N patches of $p_{\text{patch}} \times p_{\text{patch}}$ pixels, with H and W divisible by p_{patch} after any chosen crop or padding:

$$N = \frac{H \cdot W}{p_{\text{patch}}^2}$$

Each patch, indexed by its row and column (h, w) in the camera plane, is flattened into a vector $\mathbf{x}_p^{(h,w)} \in \mathbb{R}^{p_{\text{patch}}^2 C}$. A trainable linear projection $\mathbf{W}_{\text{patch}} \in \mathbb{R}^{(p_{\text{patch}}^2 C)\times d}$ maps each flattened patch into the transformer's hidden dimension d. Without positional information or position-dependent masks, self-attention is permutation-equivariant: permuting the input rows permutes the output rows. Therefore the model knows nothing of spatial proximity unless position is added explicitly:

$$\mathbf{z}_0^{(h,w)} = \mathbf{x}_p^{(h,w)}\mathbf{W}_{\text{patch}} + \mathbf{E}_{\text{pos}}^{2D}(h,w) + \mathbf{e}_{\text{cam}}$$

The 2D position embedding $\mathbf{E}^{2D}_{\text{pos}}(h, w)$ decomposes along the vertical axis h and the horizontal axis w, using sinusoidal frequency bands or learned coordinate embeddings. It encodes position in the image plane and carries no metric 3D distance. When several cameras feed one model, such as an overhead camera for scene context and a wrist camera for millimeter-scale alignment, a learned camera identifier $\mathbf{e}_{\text{cam}} \in \{\mathbf{e}_{\text{overhead}}, \mathbf{e}_{\text{wrist}}\}$ distinguishes their reference frames. Some architectures also prepend a summary token $\mathbf{x}_{\text{class}} \in \mathbb{R}^d$ to the sequence.

To make the dimensions concrete, take a square RGB frame 224 pixels on a side (illustrative; see the Reader Guide) with patch size $p_{\text{patch}} = 14$. The frame divides into 16 patches on a side, 256 in all. Each patch holds 196 pixels across 3 color channels, a flattened vector of 588 values, and $\mathbf{W}_{\text{patch}}$ maps each such vector into a 4096-dimensional model space. One frame therefore becomes 256 tokens of width 4096. A robot with 3 cameras (two wrist cameras and one overhead) supplies $3 \times 256 = 768$ visual tokens per step before any text or proprioceptive token is added.

The visual tokens then join the rest of the input. A natural-language directive such as "grasp the red mug by its handle" is tokenized by byte-pair encoding into text embeddings $\mathbf{z}_{\text{text}} \in \mathbb{R}^{S_{\text{text}} \times d}$. The robot's configuration (joint angles, joint velocities, and gripper state) passes through a linear layer into proprioceptive tokens $\mathbf{z}_{\text{proprio}} \in \mathbb{R}^{K_s \times d}$. The three streams concatenate into one multimodal input sequence:

$$\mathbf{Z} = [\mathbf{z}_{\text{vision}} \,|\, \mathbf{z}_{\text{text}} \,|\, \mathbf{z}_{\text{proprio}}] \in \mathbb{R}^{N_{\text{total}} \times d}$$

A.3.2.3 Self-attention over the combined sequence

The combined sequence $\mathbf{Z}$ passes through a stack of transformer layers, each consisting of multi-head self-attention and a feed-forward network. Self-attention projects each token through learned matrices $\mathbf{W}_Q$, $\mathbf{W}_K$, and $\mathbf{W}_V$ into a query $\mathbf{q}_i$, a key $\mathbf{k}_j$, and a value, and computes pairwise attention weights over the whole sequence:

$$A_{ij} = \frac{\exp\left(\mathbf{q}_i^\top \mathbf{k}_j / \sqrt{d_{\text{head}}}\right)}{\sum_m \exp\left(\mathbf{q}_i^\top \mathbf{k}_m / \sqrt{d_{\text{head}}}\right)}$$

A text token such as "handle" can attend to visual patch tokens, but a high attention weight is not a verified grasp location or metric pose. A trained spatial decoder may produce a 2D affordance heatmap, and placing the gripper in 3D still takes depth evidence, camera calibration, and the metric lifting below. A rolling key-value (KV) cache stores prior token states for attention. It neither tracks object permanence nor maintains a 3D position and velocity; an explicit state estimator must associate observations across frames and widen its uncertainty while the mug is occluded.

A.3.2.4 Pinhole back-projection and 3D metric lifting

Standard 2D patch tokens lack metric scale due to projective ambiguity: along any optical ray $\lambda[u, v, 1]^\top$, infinitely many 3D points project to identical pixel coordinates. To interface with physical control barrier filters, kinetic stopping calculators, and obstacle clearance envelopes, 2D visual predictions must be lifted into metric 3D coordinates $\mathbf{p}_{\text{world}} \in \mathbb{R}^3$.

Let $[u, v]^\top$ denote pixel coordinates on the image sensor, and let the calibrated pinhole camera intrinsic matrix be:

$$\mathbf{K} = \begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix}$$

where (f_x, f_y) are focal lengths in pixels and (c_x, c_y) is the principal point. Given an aligned optical-axis depth measurement $Z_{\text{meas}} = Z_c > 0$ (obtained from stereo disparity, time-of-flight lidar, or calibrated depth sensors), the 3D position in the camera coordinate frame $\mathbf{p}_c \in \mathbb{R}^3$ is recovered via inverse intrinsic projection:

$$\mathbf{p}_c = Z_{\text{meas}} \cdot \mathbf{K}^{-1} \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} (u - c_x)\frac{Z_{\text{meas}}}{f_x} \\ (v - c_y)\frac{Z_{\text{meas}}}{f_y} \\ Z_{\text{meas}} \end{bmatrix}$$

DRAFT

Transforming $\mathbf{p}_c$ into the robot base or world frame W uses the rigid extrinsic transform $\mathbf{T}_{WC} \in SE(3)$ defined in this section:

$$\tilde{\mathbf{p}}_W = \mathbf{T}_{WC}\tilde{\mathbf{p}}_C \implies \mathbf{p}_{\text{world}} = \mathbf{R}_{WC}\mathbf{p}_c + \mathbf{t}_{WC}$$

A sensor reporting range along a ray must first convert it to optical-axis depth; substituting raw range for Z_{meas} distorts off-axis geometry. The permission path and kinematic reachability evaluators require this metric 3D reconstruction; ungrounded 2D tokens cannot establish whether a proposed trajectory satisfies physical clearance boundaries d_{stop}.

A.3.3 Camera-to-bird's-eye-view lifting

Checking whether a mobile base can pass a warehouse pillar requires obstacle footprints in meters on the floor plane, whereas each onboard camera observes the aisle in perspective pixels along rays of unknown depth. A bird's-eye-view (BEV) representation places the features of every camera in one metric grid on the ground plane, the frame in which planners and clearance checks work. Figure A.1 stages this transformation across four sequential processing blocks. Monocular 2D feature extraction works on the raw camera images. Categorical depth distribution estimation lifts each feature ray into a 3D frustum of discrete hypothesis bins. Extrinsic coordinate transformation splats the frustum points into a metric ground-plane grid of vertical pillars. A final permission gate bounds spatial clearance residuals before dispatching commands.

1. **Feature extraction.** A vision backbone, such as DINOv2 (Oquab et al. 2023) or a lightweight convolutional network, maps image $\mathbf{I} \in \mathbb{R}^{H\times W\times 3}$ to a grid of feature vectors:

   $$\mathbf{f}_{u,v} = \text{Backbone}(\mathbf{I})[u,v] \in \mathbb{R}^C$$

   Forward projection (equation 8.2) collapses each 3D ray onto one pixel. Consequently, a feature $\mathbf{f}_{u,v}$ stands for a whole ray in space while its metric depth remains unknown.

2. **Lift.** LSS represents that ambiguity rather than resolving it. Along the bearing ray $\mathbf{K}^{-1}[u,v,1]^\top$ of equation 8.3, the network scores D discrete depth bins spanning $[d_{\text{min}}, d_{\text{max}}]$, for example 64 bins from 0.5 m to 20 m, spaced linearly or logarithmically:

   $$\alpha_{u,v} = \text{softmax}(\mathbf{d}_{u,v}) \in \Delta^{D-1}$$

   An outer product lifts each 2D feature into a frustum of 3D points, one per depth hypothesis:

   $$\mathbf{c}_{u,v,k} = \alpha_{u,v}(k)\cdot\mathbf{f}_{u,v} \in \mathbb{R}^C \quad \text{at } \mathbf{p}_c(u,v,d_k) = d_k\mathbf{K}^{-1}\begin{bmatrix} u \\ v \\ 1 \end{bmatrix}$$

   For a feature map 128 cells on a side, with 64 depth bins and 64 feature channels, the frustum tensor holds about 67.1 million values, 134.2 MB per frame at FP16. This is a materialized tensor footprint for one camera. Actual DRAM traffic depends on whether the runtime materializes, tiles, or fuses lifting with pooling; zero-copy handoff avoids an extra copy but does not eliminate tensor reads and writes.

3. **Splat.** The calibrated extrinsic transform $\mathbf{T}^{\text{cam}}_{\text{base}} \in SE(3)$, with rotation $\mathbf{R}^{\text{cam}}_{\text{base}}$ and translation $\mathbf{t}^{\text{cam}}_{\text{base}}$, maps every frustum point from the camera's optical frame into the robot base frame:

   $$\mathbf{p}_{\text{body}} = \mathbf{R}^{\text{cam}}_{\text{base}}\mathbf{p}_c + \mathbf{t}^{\text{cam}}_{\text{base}}$$

   The workspace is discretized into a grid of vertical pillars, for example 200 cells on a side covering a 20 m square at 0.1 m resolution. The splat sums every frustum feature that falls within pillar (X,Y), using accelerated cumulative sums or point-pillar pooling (Philion and Fidler 2020; Z. Liu et al. 2023):

   $$\mathbf{V}_{\text{BEV}}(X,Y) = \sum_{(u,v,k)\in\text{Pillar}(X,Y)} \mathbf{c}_{u,v,k}$$

DRAFT

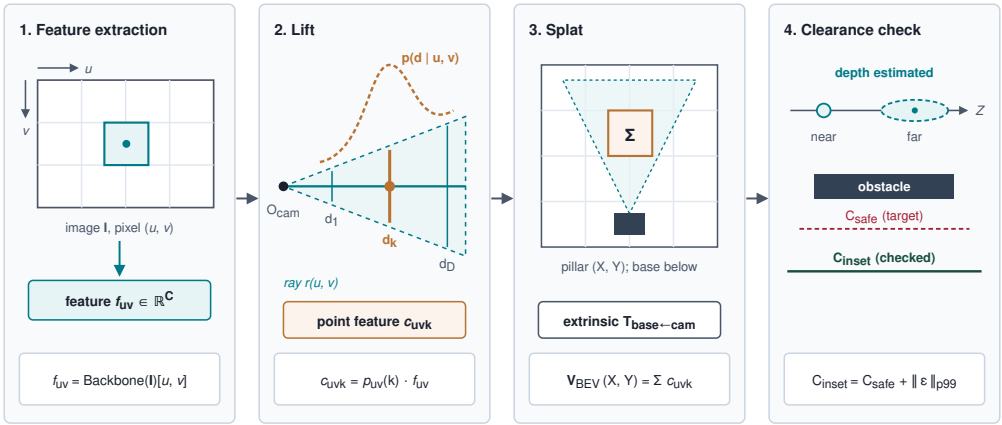

Figure A.1: Camera ray frustum lifting and BEV splatting: LSS (Philion and Fidler 2020) places learned depth hypotheses from each camera in a shared metric BEV frame; that coordinate transform does not resolve monocular depth ambiguity. The final clearance inset requires separately validated metric residuals, bias, and a chosen tail quantile or deterministic error bound before permission. (Architecture adapted from Philion and Fidler (2020).)

On parallel GPU accelerators, naive scatter-add operations create severe write-port contention and non-coalesced DRAM transactions when hundreds of frustum points map to the identical BEV pillar. Optimized runtimes eliminate this bottleneck by sorting frustum points by pillar index and executing parallel cumulative-sum prefix scans or precomputed index-table indirection (Z. Liu et al. 2023). The splat aligns the cameras' hypotheses in one metric frame. It cannot fill a region no camera saw or remove depth-scale error, so the footprint it assigns to a pedestrian still depends on the depth hypotheses and the calibration. That dependence is why the clearance panel closing figure A.1 marks depth as estimated and only the inset as checked.

The softmax over depth bins expresses weights the model assigns, and its entropy is not a calibrated metric covariance. The clearance inset of section 8.6 therefore rests on separately validated spatial residuals, not on the lifted weights.

A.3.4 Inverse-depth parameterization

In visual-inertial odometry and SLAM, representing distant 3D landmarks in standard Cartesian coordinates (x, y, z) induces extreme non-linearity: small pixel tracking errors produce quadratic depth errors ($\delta z \propto z^2$). Under **inverse-depth parameterization**, a 3D feature is parameterized by the 6D vector $\mathbf{y} = [x_0, y_0, z_0, \theta_{az}, \phi, \rho]^\top$. Here (x_0, y_0, z_0) is the optical center when first observed, (θ_{az}, ϕ) are azimuth and elevation angles, and $\rho = 1/d$ is inverse depth:[3]

$$\mathbf{p}(d) = \begin{bmatrix} x_0 \\ y_0 \\ z_0 \end{bmatrix} + \frac{1}{\rho} \begin{bmatrix} \cos\phi \sin\theta_{az} \\ -\sin\phi \\ \cos\phi \cos\theta_{az} \end{bmatrix}$$

At optical infinity ($d \to \infty$), inverse depth approaches zero ($\rho \to 0$). This parameterization can improve estimator conditioning for distant features; covariance shape and numerical stability still depend on the measurement model, noise assumptions, and estimator implementation.

3 **Inverse-Depth Parameterization**: Civera and colleagues used inverse depth to represent distant visual landmarks in monocular estimation.

A.3.5 3D Gaussian splatting parameters

A neural scene reconstructed from camera images can render a photorealistic view of a workcell while filling unobserved regions with semi-transparent floaters or hollow shells that offer no conservative collision surface. Continuous neural scene representations parameterize physical environments through collections of 3D Gaussians (Kerbl et al. 2023), where each Gaussian $G_i(\mathbf{p})$ is defined by four core physical and radiometric attributes:

1. **Spatial mean ($\mu_i \in \mathbb{R}^3$):** The 3D centroid in world coordinates.
2. **Covariance matrix ($\Sigma_i \in \mathbb{R}^{3\times3}$):** Defining ellipsoidal shape and orientation. To guarantee that Σ_i remains symmetric and positive semi-definite throughout gradient descent, it is factorized into an orthonormal rotation matrix $\mathbf{R}_i \in SO(3)$ (parameterized by a unit quaternion $\mathbf{q}_{\text{quat}_i}$) and a positive scaling diagonal matrix $\mathbf{S}_i = \text{diag}(s_{x_i}, s_{y_i}, s_{z_i})$:
$$\Sigma_i = \mathbf{R}_i \mathbf{S}_i \mathbf{S}_i^\top \mathbf{R}_i^\top$$
3. **Radiance appearance (c_i):** Parameterized via Spherical Harmonics (SH) coefficients up to degree 3 (16 coefficients per color channel) to capture view-dependent specular reflections.
4. **Opacity ($\alpha_i \in [0,1]$):** Modeled via a sigmoid activation $\alpha_i = \sigma(o_i) = \frac{1}{1+e^{-o_i}}$ over unbounded logit $o_i \in \mathbb{R}$ to bound opacity. Sigmoid gradients can still vanish near saturation.

A.3.5.1 Camera projection and screen-space covariance

During real-time novel-view synthesis, 3D Gaussians are transformed into the camera optical frame via rigid extrinsic transform $\mathbf{T}_{CW} \in SE(3)$, where $\mathbf{R}_{CW} \in SO(3)$ is the rotational component:
$$\mathbf{p}_c = [x, y, z]^\top = \mathbf{R}_{CW}\mu_i + \mathbf{t}_{CW}$$
The pinhole camera model projects 3D point $\mathbf{p}_c$ to image pixel coordinates $[u, v]^\top$:
$$\pi(x, y, z) = \begin{bmatrix} f_x \frac{x}{z} + c_x \\ f_y \frac{y}{z} + c_y \end{bmatrix}$$
Because perspective projection is non-linear in depth z, 3D Gaussian Splatting applies an affine first-order Taylor approximation evaluated at the Gaussian center $\mathbf{p}_c$. The projection Jacobian $\mathbf{J} \in \mathbb{R}^{2\times3}$ evaluates to:
$$\mathbf{J} = \frac{\partial \pi}{\partial \mathbf{p}_c} = \begin{bmatrix} \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} & \frac{\partial u}{\partial z} \\ \frac{\partial v}{\partial x} & \frac{\partial v}{\partial y} & \frac{\partial v}{\partial z} \end{bmatrix} = \begin{bmatrix} \frac{f_x}{z} & 0 & -\frac{f_x x}{z^2} \\ 0 & \frac{f_y}{z} & -\frac{f_y y}{z^2} \end{bmatrix}$$
The projected 2D screen-space covariance $\Sigma_{2D} \in \mathbb{R}^{2\times2}$ is then:
$$\Sigma_{2D} = \mathbf{J}\mathbf{R}_{CW}\Sigma_i\mathbf{R}_{CW}^\top\mathbf{J}^\top$$
where a low-pass filter ($\Sigma'_{2D} = \Sigma_{2D} + s\mathbf{I}_2$ with $s \approx 0.3$ pixel^2) is added to prevent aliasing when a Gaussian projects to sub-pixel footprints.

A.3.5.2 Differentiable alpha-blending and clearance limits

To render pixel color $C(u, v)$, tile-based rasterization bins Gaussians into 16×16 pixel screen tiles, sorts overlapping Gaussians along the camera optical axis by depth z, and computes front-to-back alpha-blended volume rendering:
$$C = \sum_{i\in\mathcal{N}} c_i \alpha'_i T_i, \quad \text{where } T_i = \prod_{j=1}^{i-1}(1-\alpha'_j)$$
Here T_i represents cumulative optical transmittance along the viewing ray, initialized to $T_1 = 1$. In this rendering equation, α'_i is the pixel-dependent opacity contribution, including the projected Gaussian footprint, rather than the stored opacity α_i. An implementation may terminate when the remaining transmittance is sufficiently small; the error tolerance, scene density, and hardware determine the resulting speed.

However, a physical AI systems engineer must recognize the boundary between visual rendering and physical clearance. The 3D Gaussian parameters are optimized strictly against 2D photometric rendering loss (such as ℓ_1 color difference and SSIM). Gaussians frequently fit unobserved scene regions with semi-transparent "floaters," hollow shells, or blurred volumetric density. Neither the stored opacity α_i nor the spatial gradient $\nabla_{\mathbf{p}} G_i(\mathbf{p})$ of its density constitutes a conservative collision

DRAFT

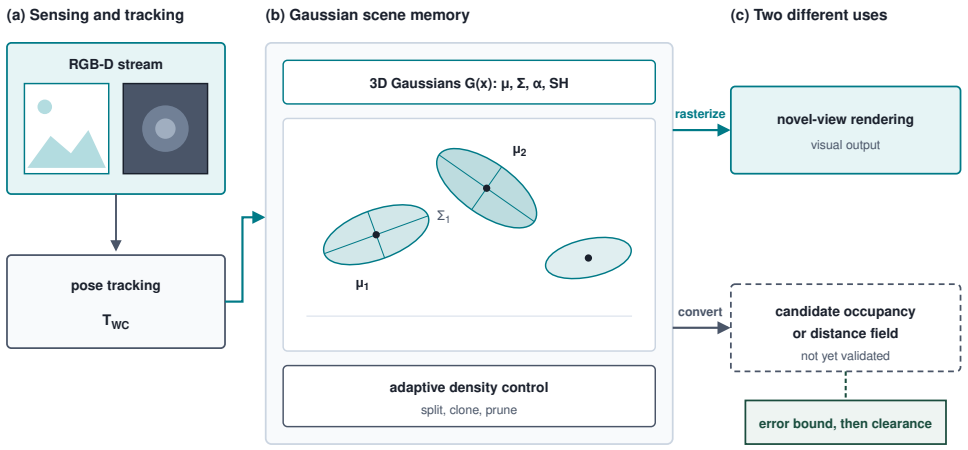

Figure A.2: Gaussian memory and clearance handoff: Camera observations update a Gaussian scene for novel-view rendering. Its visual output does not directly supply conservative collision distance; a separately validated geometry or occupancy conversion and permission check are required (Kerbl et al. 2023; Matsuki et al. 2024).

surface. Figure A.2 partitions this architectural handoff across three functional panels. Panel (a) tracks camera poses from an incoming RGB-D stream. Panel (b) maintains the 3D Gaussian memory primitives (mean, covariance ellipsoid, opacity, and spherical-harmonic color) under adaptive splitting, cloning, and pruning. Panel (c) decouples photometric rasterization from physical safety, routing Gaussian primitives through an unvalidated candidate occupancy or signed distance field before an explicit error-bounding step admits the clearance envelope.

Storage per primitive depends on its packing and spherical-harmonic degree, so a map's footprint is its primitive count times that packing. A dense cubic grid instead stores $\mathcal{O}(N^3)$ cells, and a sparse occupancy map stores only allocated structure, whose size depends on the observed geometry and the accuracy target. Figure A.3 plots these three storage scaling regimes on logarithmic axes as grid resolution spans from 10 to 10^4 cells per dimension. The cubic grid grows steeply as $\mathcal{O}(N^3)$ and passes gigabytes at modest resolutions. The surface-allocated octree scales along an $\mathcal{O}(N^2)$ trajectory. The stylized Gaussian scene maintains a flat baseline under an assumed fixed primitive count of 500,000 elements.

For the Gaussian packing in the plot, 500,000 primitives at 56 bytes each require 28 MB. A deployment chooses its representation after measuring map completeness, update time, query time, and the conversion needed for conservative clearance.

A.3.6 Log-odds occupancy and signed-distance fusion

When a pallet jack moves out of a warehouse aisle, an occupancy map that records only range hits leaves a phantom obstacle blocking the path unless subsequent sensor rays actively clear the empty sightlines. Discrete volumetric grids model 3D occupancy uncertainty through recursive Bayesian estimation. Let $m_i \in \{0, 1\}$ denote the binary occupancy state of voxel i ($m_i = 1$ occupied, $m_i = 0$ free). Given a temporal sequence of range observations $z_{1:t} = (z_1, \ldots, z_t)$, Bayes' rule expresses the posterior occupancy:

$$p(m_i \mid z_{1:t}) = \frac{p(z_t \mid m_i, z_{1:t-1}) p(m_i \mid z_{1:t-1})}{p(z_t \mid z_{1:t-1})}$$

Assuming that observation z_t is conditionally independent of past observations given the true static occupancy m_i ($p(z_t \mid m_i, z_{1:t-1}) = p(z_t \mid m_i)$), and writing the identical relation for the unoccupied state $\neg m_i$ ($m_i = 0$):

$$p(\neg m_i \mid z_{1:t}) = \frac{p(z_t \mid \neg m_i) p(\neg m_i \mid z_{1:t-1})}{p(z_t \mid z_{1:t-1})}$$

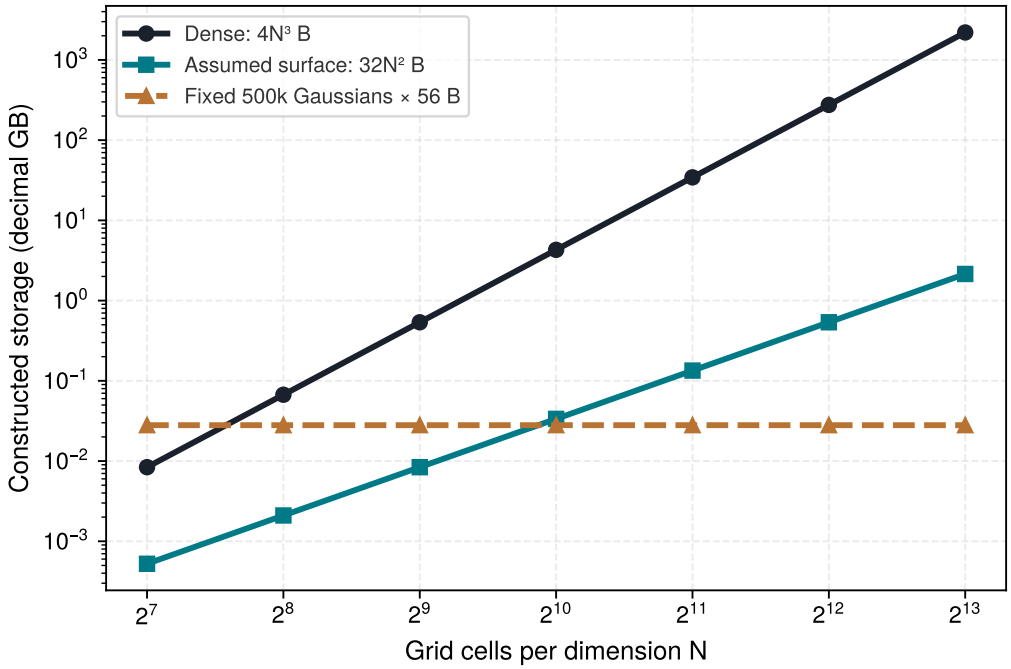

Figure A.3: Constructed spatial-memory storage scenarios: A dense cube uses four bytes per voxel, the octree allocates one 32-byte surface cell per squared grid dimension, and the Gaussian scene holds a fixed count and packing while grid resolution varies. These are storage models, not equal-fidelity or measured runtime benchmarks; Gaussian count must rise if a stricter geometry target requires it.

Dividing the two equations cancels the common evidence normalizer $p(z_t \mid z_{1:t-1})$:

$$\frac{p(m_i \mid z_{1:t})}{p(\neg m_i \mid z_{1:t})} = \frac{p(z_t \mid m_i)}{p(z_t \mid \neg m_i)} \frac{p(m_i \mid z_{1:t-1})}{p(\neg m_i \mid z_{1:t-1})}$$

Applying Bayes' rule to the measurement likelihood $p(z_t \mid m_i) = \frac{p(m_i|z_t)p(z_t)}{p(m_i)}$ gives the measurement odds ratio:

$$\frac{p(z_t \mid m_i)}{p(z_t \mid \neg m_i)} = \frac{p(m_i \mid z_t)}{1-p(m_i \mid z_t)} \frac{1-p(m_i)}{p(m_i)}$$

Taking the natural logarithm of the odds ratio defines the log-odds quantity $L(x) = \ln \frac{p(x)}{1-p(x)}$. Substituting yields the canonical **additive log-odds update**:[4]

$$L_t(m_i) = L_{t-1}(m_i) + \underbrace{\ln \frac{p(m_i \mid z_t)}{1-p(m_i \mid z_t)}}_{\text{inverse sensor model } L_{\text{sensor}}} - \underbrace{\ln \frac{p(m_i)}{1-p(m_i)}}_{\text{prior belief } L_0}$$

where $p(m_i \mid z_t)$ is the calibrated inverse sensor model. When prior belief is uninformative ($p(m_i) = 0.5 \implies L_0 = 0$), the update reduces to simple addition: $L_t(m_i) = L_{t-1}(m_i) + L_{\text{sensor}}$.

Along a range sensor ray, voxels traversed before the hit receive negative log-odds evidence ($L_{\text{free}} < 0$), while the voxel containing the return receives positive evidence ($L_{\text{occ}} > 0$). Voxels beyond the return receive no update. With the uninformative prior used here, zero evidence corresponds to $L_{\text{sensor}} = 0$. To prevent numerical saturation lockup where an obstacle that was observed occupied hundreds of times requires hundreds of empty observations before clearing, updates are clamped within finite bounds $[L_{\min}, L_{\max}]$ (e.g., $[-2.0, +3.5]$).

[4] **Recursive Log-Odds Occupancy**: The log-odds formulation maps probability values from the bounded unit interval to the unbounded real line, turning nonlinear Bayesian product updates into fast additions. Dynamic ranges are clamped by upper and lower saturation bounds to prevent saturation lockup. Failure to clamp log-odds values delays the clearing of dynamic obstacles when physical objects vacate the workspace.

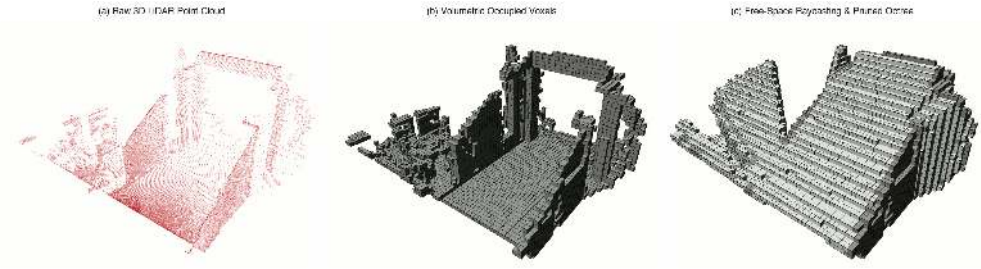

Figure A.4: Probabilistic octree volumetric mapping: A corridor traversal reconstructed from raw point cloud into a probabilistic octree and then into explicit free, occupied, and unknown space (Hornung et al. 2013). The third panel is what distinguishes spatial memory from an accumulated point cloud, because raycasting records evidence of emptiness along sightlines, letting the map actively retire a phantom obstacle track instead of waiting for a timeout to expire it. (Credit: Autonomous Intelligent Systems Lab, University of Freiburg (Hornung et al. 2013).)

A.3.6.1 Octree occupancy and free-space raycasting

Occupancy grid mapping (Elfes 1989) tessellates space into cells and applies this update to every cell a ray touches. A volumetric raycast walks each return's sightline with the three-dimensional digital differential analyzer (3D-DDA) traversal (Amanatides and Woo 1987). Hierarchical stores such as OctoMap (Hornung et al. 2013) and OpenVDB (Museth 2013) allocate cells only where rays have passed, so storage follows the observed volume rather than the bounding cube. Figure A.4 traces this spatial-memory pipeline across three successive representations during an indoor mobile robot traversal. Panel (a) shows the unorganized, noisy 3D point cloud acquired by a tilting range scanner. Panel (b) shows the hierarchical 8-ary octree that adaptively clusters occupied volumes. Panel (c) shows the explicit ternary classification that differentiates confirmed free-space voxels (white) and occupied obstacle cells (dark) from unobserved unknown volumes. Free-space evidence recorded along ray sightlines lets the map retire a phantom obstacle once the same region is seen empty, while a never-observed cell stays unknown however long the map runs. Section 9.6 applies this rule to the aisle, where only fresh free-space evidence can vouch that a path is clear.

A.3.6.2 Truncated signed distance fusion

A truncated signed distance field (TSDF), fused volumetrically at camera rate by KinectFusion (Newcombe et al. 2011) and incrementally on robots by Voxblox (Oleynikova et al. 2017), stores in each voxel $\mathbf{p}_{\text{vox}}$ a *metric projective distance* $D(\mathbf{p}_{\text{vox}}) \in [-\mu_{\text{tsdf}}, +\mu_{\text{tsdf}}]$. This distance is positive in front of an observed return along its sensing ray. Each voxel also stores a dimensionless fusion weight $W(\mathbf{p}_{\text{vox}})$. For a calibrated depth image, transform the voxel center into camera coordinates $\mathbf{p}_c = [X_c, Y_c, Z_c]^\top$ and project it to pixel (u, v). Its projective sample is $s = Z_{\text{meas}}(u, v) - Z_c$. For a range ray, the equivalent along-ray sample is $s = r_{\text{hit}} - r_{\text{voxel}}$; both are positive before the hit. Near the return, the sample is clamped in meters and fused into the running weighted average:

$$d_\mu(\mathbf{p}_{\text{vox}}) = \max(-\mu_{\text{tsdf}}, \min(\mu_{\text{tsdf}}, s)), \qquad D_t(\mathbf{p}_{\text{vox}}) = \frac{W_{t-1}(\mathbf{p}_{\text{vox}}) D_{t-1}(\mathbf{p}_{\text{vox}}) + w_t d_\mu(\mathbf{p}_{\text{vox}})}{W_{t-1}(\mathbf{p}_{\text{vox}}) + w_t}$$

where w_t is the dimensionless observation weight and the stored weight $W_t = W_{t-1} + w_t$ is capped at $W_{\max}$. Fusion uses a valid capture-time pose and refuses a sample older than the voxel's last evidence epoch. A negative sample just behind the measured return contributes to the local zero crossing under the surface model; it does not certify an unseen obstacle interior.

Interpolating observed samples gives an approximate gradient near a zero crossing, limited by unknown voxels, projective bias, discretization, and moving objects. A projective TSDF is therefore not the nearest-surface Euclidean distance a clearance decision needs. A clearance query therefore reads a validated occupancy or Euclidean signed distance field (ESDF) with an unknown-space policy, the conversion section 9.6 requires of every scene representation before the permission path relies on it.

A.3.6.3 One frame's update and its memory traffic

Each incoming depth frame must pass a freshness gate before updating occupancy along its rays and fusing TSDF samples inside the truncation band (algorithm A.1), and the notebook after the pseudocode prices the resulting update traffic that section 9.6 charges against the memory bus. The update procedure rejects the frame before touching the map when its capture epoch is too old or older than the last evidence of any cell it would update. It then clears and marks occupancy along each ray and fuses TSDF samples only inside the truncation band. Every updated cell takes the capture epoch, not the update time, so a later consumer can judge each cell's freshness.

Algorithm A.1 Occupancy Raycast and Metric TSDF Fusion

Require: returns $\mathcal{P}$ captured at t_0 in one capture clock; valid pose; occupancy $\mathcal{O}$; metric TSDF $\mathcal{V}$; truncation μ; evidence half-life $t_{1/2}$; serialized frame updates
Ensure: observed free/occupied cells and near-surface TSDF samples updated without refreshing unseen cells

$(t_{0,c}, \epsilon_{\text{sync}}) \leftarrow$ ConvertCaptureToControllerClock(t_0)
if clock conversion invalid or $t_{\text{now},c} - t_{0,c} + \epsilon_{\text{sync}} > t_{\text{age,max}}$ **then**

DRAFT

Napkin Math A.1: DRAM bandwidth of 3D TSDF voxel grids

Practical Engineering Question: What are the distance-and-weight payload and modeled DRAM bandwidth of sparse vs. dense TSDF representations?

1. Dense allocation. A manipulation workcell of 10 m × 10 m × 3 m (300 m^3) at 1 cm pitch holds 300,000,000 voxels. At 4 bytes per voxel (16-bit distance plus 16-bit fusion weight), excluding occupancy, per-cell evidence epochs, and allocator overhead, the distance-and-weight payload is 1.20 GB. Refining the pitch to 5 mm for tool contact raises the count to 2,400,000,000 voxels and the partial payload to 9.60 GB, which alone exceeds an illustrative 8 GB memory budget.

2. Sparse allocation. Surfaces occupy a thin manifold within the volume. Grouping voxels into 512-voxel leaf blocks and allocating only within the truncation band, assumed to be 3 percent

of the volume, gives 17,579 blocks. With a 32-byte leaf header, the payload is 36.6 MB at 1 cm and 292.5 MB at 5 mm. A full map must also budget the separate occupancy layer, per-cell epochs, block lookup and allocator metadata, and capacity for the unknown-space policy.

3. Traversal and DRAM traffic. A 640 × 480 depth stream at 60 Hz supplies 18.432 million rays per second. Along a 3 m ray at 1 cm pitch the traversal visits 300 cells. The 294 cells before the hit receive occupancy free-ray updates, and the 6 cells near the return receive TSDF fusion. Sparse TSDF allocation saves map capacity; it removes neither the traversal nor the occupancy updates. At 8 bytes of assumed read/write traffic per update, sending every update to DRAM costs 44.2 GB/s. At an assumed 95 percent cache hit fraction for both occupancy and TSDF updates, the modeled DRAM demand falls to 2.21 GB/s, a 20× reduction. The hit rate depends on ray overlap, atomics, evictions, and writeback on the chosen hardware; it is an input to measure, not a property of the map structure.

Systems insight: Sparse allocation yields 33× less modeled TSDF payload in this surface-fraction scenario, while bus demand depends on measured locality and on all traversed-cell work. Whether that demand fits beside policy inference on a shared bus is the contention question of section 13.3.

A.4 Function Approximation and Sensitivity Bounds

A sensor perturbation can change a neural action proposal even when the physical scene has barely moved. A sensitivity bound limits that change relative to the input error and supplies a quantity to compare with available actuator headroom. The bound concerns the proposal; the permission path must still check the plant state and enforce current limits.

A.4.1 Multilayer perceptrons in continuous control

For high-rate proprioceptive feedback loops (such as 500–1000 Hz quadruped balance, bipedal locomotion, and arm impedance control), physical policies frequently employ **Multilayer Perceptrons (MLPs)** rather than deep spatial transformers. A canonical continuous MLP policy takes a low-dimensional proprioceptive vector $\mathbf{x} \in \mathbb{R}^d$ (joint positions $\mathbf{q}$, velocities $\dot{\mathbf{q}}$, IMU angular rates, projected gravity, and previous action history). It then evaluates a sequence of N_L affine transformations interleaved with element-wise non-linear activations:

$$\mathbf{h}_0 = \mathbf{x}, \quad \mathbf{h}_\ell = f_\ell(\mathbf{W}_\ell \mathbf{h}_{\ell-1} + \mathbf{b}_\ell) \quad \text{for } \ell = 1, \dots, N_L, \quad \pi(\mathbf{x}) = \mathbf{W}_{\text{out}} \mathbf{h}_{N_L} + \mathbf{b}_{\text{out}}$$

where $\mathbf{W}_\ell \in \mathbb{R}^{n_\ell \times n_{\ell-1}}$ are weight matrices and $\mathbf{b}_\ell \in \mathbb{R}^{n_\ell}$ are bias vectors.

A.4.1.1 Systems profile and roofline limits of MLP policies

A compact MLP can keep its weights and activations in on-chip memory, reducing interference from camera direct memory access and other DRAM clients. Capacity alone does not establish residency: cache replacement, shared clients, scheduling, and accelerator transfers determine the memory level that supplies each layer.

For a dense layer with $d_{\text{in}} d_{\text{out}}$ weights, a single input vector requires approximately $2 d_{\text{in}} d_{\text{out}}$ floating-point operations. If each weight occupies $s_{\text{elem,W}}$ bytes and is read once from the memory level being analyzed, the weight-only arithmetic intensity is

$$I_{\text{MLP}} \approx \frac{2}{s_{\text{elem,W}}} \text{ FLOP/byte.}$$

Activation traffic lowers this ratio; weight reuse across inputs raises it. The relevant roofline compares this intensity with compute throughput divided by bandwidth at that same memory level. Cache-resident weights therefore change the applicable bandwidth, not the amount of arithmetic.

A deployment budgets weights, scratch buffers, and hidden activations together, preallocates runtime storage, and measures or bounds worst-case execution under interference. A short average forward pass does not by itself justify placing inference in an interrupt handler or guarantee a control deadline.

A.4.2 Lipschitz continuity and spectral normalization

Bounding how strongly a network amplifies input perturbations requires a global sensitivity constant. A neural policy $\pi : \mathcal{X} \to \mathcal{U}$ is L_{lip}-Lipschitz continuous if there exists a non-negative scalar constant L_{lip} such that for all $\mathbf{x}_1, \mathbf{x}_2 \in \mathcal{X}$:

$$\|\pi(\mathbf{x}_1) - \pi(\mathbf{x}_2)\|_{\mathcal{U}} \leq L_{\text{lip}} \|\mathbf{x}_1 - \mathbf{x}_2\|_{\mathcal{X}}$$

For a feedforward network with N_L layers $\pi(\mathbf{x}) = f_{N_L}(\mathbf{W}_{N_L} \dots f_1(\mathbf{W}_1 \mathbf{x}))$, let L_{ϕ_k} bound each activation's slope over the input domain. The composed Lipschitz bound is:

$$L_{\text{lip}} \leq \prod_{k=1}^{N_L} L_{\phi_k} \|\mathbf{W}_k\|_2$$

where $\|\mathbf{W}_k\|_2 = \sigma_{\max}(\mathbf{W}_k)$ is the spectral norm (the largest singular value of weight matrix $\mathbf{W}_k$). Standard activations such as ReLU and Tanh are 1-Lipschitz in their scalar forms; exact GeLU has maximum derivative about 1.1289, so assigning it a factor of one would understate the bound.

The product is an upper bound, not necessarily the smallest Lipschitz constant. Its physical interpretation depends on normalization. A network receiving position and velocity in different units needs declared input scales; converting its normalized output to torque introduces another scale factor. Without those conversions, multiplying a position error by a dimensionless network bound cannot yield a torque error.

To bound policy sensitivity directly during training, **spectral normalization** reparameterizes each weight matrix by its spectral norm:

$$\overline{\mathbf{W}}_k = \frac{\mathbf{W}_k}{\sigma_{\max}(\mathbf{W}_k)}$$

where $\sigma_{\max}(\mathbf{W}_k)$ is estimated efficiently via power iteration during forward passes. Division by the exact nonzero spectral norm gives $\|\overline{\mathbf{W}}_k\|_2 = 1$. Finite power iteration generally gives an estimate, not a certified upper bound; a safety argument must account for its error. Even an exact network sensitivity bound does not prove closed-loop plant stability.

A.4.3 Perturbation amplification and supervisory clamping

In physical systems, input state $\mathbf{x}$ is corrupted by sensor measurement noise $\delta\mathbf{x}$ bounded by $\|\delta\mathbf{x}\| \leq \epsilon$. The resulting deviation in commanded control action is bounded by:

$$\|\delta\mathbf{u}_{\text{nom}}\| = \|\pi(\mathbf{x} + \delta\mathbf{x}) - \pi(\mathbf{x})\| \leq L_{\text{lip}}\epsilon$$

The constant has output-units per input-unit once normalization is included. Compare $L_{\text{lip}}\epsilon$ with the actuator headroom at the current operating state. Spectral normalization bounds the network, while stability, safe torque, and sensor validity require a plant model and a state-dependent permission check.

A.5 Imitation Learning and Compounding Covariate Shift

Behavioral cloning fits a policy to demonstrator state-action pairs. Two different failures need different remedies: ambiguous demonstrations can make a point predictor average incompatible actions, while feedback can carry even an accurate predictor into states missing from its training data. The decoder derivations address the first problem; the coupling bound and DAgger address the second.

A.5.1 Mode averaging and the decoders that avoid it

When human demonstrators steer left around a central pillar half the time ($\mathbf{a} = +1.0$) and right the other half ($\mathbf{a} = -1.0$), a policy trained with mean squared error averages the two commands to $\mathbf{a} = 0.0$ and drives dead center into the pillar. To see why squared-error regression produces that collision, consider an imitation learning objective minimizing mean squared error (ℓ_2 loss) over demonstration distribution $\mathcal{D}_{\text{demo}}$:

$$\min_{\pi} \mathbb{E}_{(\mathbf{o},\mathbf{a})\sim\mathcal{D}_{\text{demo}}} \left[\|\mathbf{a} - \pi(\mathbf{o})\|_2^2\right]$$

DRAFT

By the law of total expectation, decomposing the error around the conditional mean $\mathbb{E}[\mathbf{a} \mid \mathbf{o}]$ yields an orthogonal variance decomposition:

$$\begin{aligned}\mathbb{E}_{\mathbf{a}|\mathbf{o}}\left[\|\mathbf{a}-\pi(\mathbf{o})\|_2^2 \mid \mathbf{o}\right] &= \mathbb{E}_{\mathbf{a}|\mathbf{o}}\left[\|(\mathbf{a}-\mathbb{E}[\mathbf{a} \mid \mathbf{o}])+(\mathbb{E}[\mathbf{a} \mid \mathbf{o}]-\pi(\mathbf{o}))\|_2^2 \mid \mathbf{o}\right] \\ &= \mathbb{E}_{\mathbf{a}|\mathbf{o}}\left[\|\mathbf{a}-\mathbb{E}[\mathbf{a} \mid \mathbf{o}]\|_2^2 \mid \mathbf{o}\right]+\|\mathbb{E}[\mathbf{a} \mid \mathbf{o}]-\pi(\mathbf{o})\|_2^2 \\ &\quad +2\left\langle \mathbb{E}_{\mathbf{a}|\mathbf{o}}[\mathbf{a}-\mathbb{E}[\mathbf{a} \mid \mathbf{o}] \mid \mathbf{o}],\, \mathbb{E}[\mathbf{a} \mid \mathbf{o}]-\pi(\mathbf{o})\right\rangle\end{aligned}$$

Because $\mathbb{E}_{\mathbf{a}|\mathbf{o}}[\mathbf{a}-\mathbb{E}[\mathbf{a} \mid \mathbf{o}] \mid \mathbf{o}]=\mathbf{0}$, the cross-term vanishes identically, leaving:

$$\mathbb{E}_{(\mathbf{o},\mathbf{a})\sim\mathcal{D}_{\text{demo}}}\left[\|\mathbf{a}-\pi(\mathbf{o})\|_2^2\right]=\mathbb{E}_{\mathbf{o}}\left[\operatorname{Tr}(\operatorname{Cov}(\mathbf{a} \mid \mathbf{o}))\right]+\mathbb{E}_{\mathbf{o}}\left[\|\mathbb{E}[\mathbf{a} \mid \mathbf{o}]-\pi(\mathbf{o})\|_2^2\right]$$

The first term is the irreducible conditional variance of demonstrator behavior. The second term is non-negative and strictly minimized if and only if the policy evaluates to the **conditional expectation**:

$$\pi^*(\mathbf{o})=\mathbb{E}[\mathbf{a} \mid \mathbf{o}]=\int_{\mathcal{A}} \mathbf{a}\, p(\mathbf{a} \mid \mathbf{o})\, d\mathbf{a}$$

In digital machine learning tasks (such as computer vision regression), predicting the conditional expectation over ambiguous targets produces a blurry reconstruction, a soft pixel average that remains safely confined to software memory. In physical AI systems, commanded actions cross the causal boundary into continuous Euclidean space governed by non-convex obstacles, joint limits, and irreversible contact dynamics.

Demonstrator behavior in physical manipulation and navigation is inherently multimodal:

- Dodging an obstacle: an expert steers left ($\mathbf{a}=+1.0$) or right ($\mathbf{a}=-1.0$) around a central pillar with equal probability $\Pr(\mathbf{a}=+1 \mid \mathbf{o})=\Pr(\mathbf{a}=-1 \mid \mathbf{o})=0.5$.
- Symmetrical manipulation: an end effector approaches a cylindrical object from azimuth $\theta_{\text{az}}=0^\circ$ or $\theta_{\text{az}}=180^\circ$.
- Assembly routing: threading a flexible cable clockwise or counter-clockwise around a structural fastener.

Because demonstration density $p(\mathbf{a} \mid \mathbf{o})$ is supported on disjoint, disconnected modes separated by an obstacle, the conditional expectation computes the arithmetic mean:

$$\pi^*(\mathbf{o})=0.5(+1.0)+0.5(-1.0)=0.0$$

This mean action lies in a region of zero demonstration probability ($\Pr(\mathbf{a}=0.0 \mid \mathbf{o})=0$). In the physical workspace, the coordinate $\mathbf{a}=0.0$ corresponds precisely to the geometric position of the central obstacle. Commanding $\pi^*(\mathbf{o})=0.0$ instructs the steering actuator to hold dead center at full cruising speed, driving the physical robot directly into the pillar. In physical autonomy, regression mode averaging does not produce a cosmetic blur; it can propose a collision unless the permission path rejects it.

A.5.1.1 Decoder families

A probabilistic decoder can avoid mode averaging by parameterizing the conditional action distribution $p(\mathbf{a} \mid \mathbf{o})$ rather than its expectation. The families below trade inference cost against distributional expressiveness; none of them supplies recovery states that the demonstrations lack. Section 6.2 compares them by the network evaluations each chunk costs, which is where the choice reaches the control deadline.

1. **Deterministic direct regression (MLP).** A feedforward network trained with squared error predicts one action per observation and, with sufficient capacity and ideal optimization, fits the conditional mean. The restriction comes from the point-output objective, not from MLPs as a network family; an MLP can also parameterize a mixture or stochastic policy. One evaluation avoids iterative sampling cost but does not resolve ambiguous demonstrations.

DRAFT

2. **Mixture density networks.** A Gaussian mixture head predicts nonnegative weights summing to one, means, and positive-definite covariances:

$$\pi(\mathbf{a} \mid \mathbf{o}) = \sum_{m=1}^{M} w_m(\mathbf{o})\, \mathcal{N}(\mathbf{a}; \mu_m(\mathbf{o}), \Sigma_m(\mathbf{o})).$$

   Sampling a component or selecting a mode preserves alternatives in one network evaluation. Computing the mixture mean would restore the original averaging problem. Covariance regularization and component coverage matter because likelihood optimization can collapse a component onto a few observations.

3. **Implicit behavioral cloning.** Implicit behavioral cloning (IBC) (Florence et al. 2022) learns an energy-based model $E_\theta(\mathbf{o}, \mathbf{a}) \in \mathbb{R}$, trained with contrastive or InfoNCE objectives to assign low energy to demonstrated state-action pairs and high energy to counterfactual actions. Inference solves

$$\mathbf{a}^* = \arg\min_{\mathbf{a}} E_\theta(\mathbf{o}, \mathbf{a})$$

   An energy function can have several separated minima, and selecting its minimizing action can change discontinuously even when the energy network is continuous. Inference requires iterative derivative-free or gradient-based optimization whose latency and convergence depend on sample counts and accelerator parallelism, with risks of settling into suboptimal local energy minima.

4. **Conditional diffusion and flow matching.** Diffusion Policy (Chi et al. 2025) and flow-matching decoders generate entire action trajectory chunks via iterative denoising or ordinary differential equation (ODE) integration. Their training targets injected noise vectors or continuous velocity fields conditioned on corrupted states, observations, and timesteps rather than clean actions, allowing multimodal sampling instead of directly regressing a clean action mean. Approximation error and the sampling procedure still affect whether distinct modes survive. Section A.5.2 derives both objectives and prices their sampling steps.

5. **Latent-variable chunking.** Action Chunking with Transformers (ACT) (Zhao et al. 2023) predicts an action trajectory chunk $\mathbf{A}_t = (\mathbf{a}_t, \mathbf{a}_{t+1}, \ldots, \mathbf{a}_{t+H-1}) \in \mathbb{R}^{H \times d_a}$ from observation $\mathbf{o}_t$ using a Conditional Variational Autoencoder (CVAE). The true objective is to maximize the conditional log-marginal likelihood of demonstrated chunks across dataset $\mathcal{D}_{\text{demo}}$:

$$\ln p_\theta(\mathbf{A}_t \mid \mathbf{o}_t) = \ln \int_{\mathcal{Z}} p_\theta(\mathbf{A}_t, \mathbf{z} \mid \mathbf{o}_t)\, d\mathbf{z}$$

   Because this marginalization is intractable, ACT introduces a variational posterior $q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)$ parameterized by a transformer encoder. Expanding the identity with $p_\theta(\mathbf{A}_t, \mathbf{z} \mid \mathbf{o}_t) = p_\theta(\mathbf{A}_t \mid \mathbf{o}_t, \mathbf{z}) p_\theta(\mathbf{z})$:

$$\begin{aligned}
\ln p_\theta(\mathbf{A}_t \mid \mathbf{o}_t) &= \int_{\mathcal{Z}} q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \ln p_\theta(\mathbf{A}_t \mid \mathbf{o}_t)\, d\mathbf{z} \\
&= \int_{\mathcal{Z}} q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \ln \left(\frac{p_\theta(\mathbf{A}_t, \mathbf{z} \mid \mathbf{o}_t)}{q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)} \cdot \frac{q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)}{p_\theta(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)} \right) d\mathbf{z} \\
&= \int_{\mathcal{Z}} q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \ln \frac{p_\theta(\mathbf{A}_t, \mathbf{z} \mid \mathbf{o}_t)}{q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)}\, d\mathbf{z} + \int_{\mathcal{Z}} q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \ln \frac{q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)}{p_\theta(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)}\, d\mathbf{z} \\
&= \mathbb{E}_{\mathbf{z} \sim q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)} \left[\ln \frac{p_\theta(\mathbf{A}_t \mid \mathbf{o}_t, \mathbf{z}) p_\theta(\mathbf{z})}{q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)} \right] + \mathcal{D}_{\text{KL}} \left(q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \parallel p_\theta(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \right) \\
&\geq \mathbb{E}_{\mathbf{z} \sim q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t)} [\ln p_\theta(\mathbf{A}_t \mid \mathbf{o}_t, \mathbf{z})] - \mathcal{D}_{\text{KL}} \left(q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \parallel p_\theta(\mathbf{z}) \right) \equiv \mathcal{L}_{\text{ELBO}}(\theta, \phi)
\end{aligned}$$

   Assuming standard isotropic Gaussian prior $p_\theta(\mathbf{z}) = \mathcal{N}(\mathbf{0}, \mathbf{I})$ and diagonal Gaussian variational posterior $q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) = \mathcal{N}(\mu_\phi, \text{diag}(\sigma_\phi^2))$, the Kullback-Leibler divergence evaluates in closed form:

$$\mathcal{D}_{\text{KL}} \left(q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \parallel \mathcal{N}(\mathbf{0}, \mathbf{I}) \right) = \frac{1}{2} \sum_{j=1}^{d_z} \left(\sigma_{\phi,j}^2 + \mu_{\phi,j}^2 - 1 - \ln(\sigma_{\phi,j}^2) \right)$$

DRAFT

Sampling directly as $\mathbf{z} \sim q_\phi$ is a stochastic operation that prevents backpropagation because the node has no analytical derivatives with respect to encoder parameters ϕ. ACT resolves this via the **reparameterization trick**: isolating stochasticity into parameter-free standard normal noise $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$:

$$\mathbf{z} = \mu_\phi(\mathbf{o}_t, \mathbf{A}_t) + \sigma_\phi(\mathbf{o}_t, \mathbf{A}_t) \odot \epsilon, \quad \text{yielding } \frac{\partial \mathbf{z}}{\partial \mu_\phi} = \mathbf{I}, \quad \frac{\partial \mathbf{z}}{\partial \sigma_\phi} = \operatorname{diag}(\epsilon)$$

To parameterize the reconstruction likelihood, ACT models $p_\theta(\mathbf{A}_t \mid \mathbf{o}_t, \mathbf{z})$ as an isotropic Laplace distribution:

$$p_\theta(\mathbf{A}_t \mid \mathbf{o}_t, \mathbf{z}) = \frac{1}{(2b)^{Hd_a}} \exp\left(-\frac{\|\mathbf{A}_t - \pi_\theta(\mathbf{o}_t, \mathbf{z})\|_1}{b}\right)$$

Maximizing the log-likelihood is equivalent to minimizing the ℓ_1 norm $\|\mathbf{A}_t - \pi_\theta(\mathbf{o}_t, \mathbf{z})\|_1$. Away from zero residual, ℓ_1 loss gives constant-magnitude gradients with respect to each predicted action component, whereas ℓ_2 loss gives greater influence to large residuals. Neither loss alone filters demonstrator tremor or guarantees freedom from overfitting; those outcomes depend on the data, regularization, and temporal model. Weighting the KL regularizer by hyperparameter $\beta > 0$ yields the full training loss:

$$\mathcal{L}_{\text{ACT}}(\theta, \phi) = \mathbb{E}_{(\mathbf{o}_t, \mathbf{A}_t) \sim \mathcal{D}_{\text{demo}}, \epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})} \left[\|\mathbf{A}_t - \pi_\theta(\mathbf{o}_t, \mu_\phi + \sigma_\phi \odot \epsilon)\|_1 + \beta \mathcal{D}_{\text{KL}}\left(q_\phi(\mathbf{z} \mid \mathbf{o}_t, \mathbf{A}_t) \parallel \mathcal{N}(\mathbf{0}, \mathbf{I})\right) \right]$$

The latent variable $\mathbf{z} \in \mathbb{R}^{d_z}$ can encode variation among demonstrations, while the decoder predicts all H actions together. Neither separated latent clusters nor kinematic smoothness follows from the architecture alone. Executing H_{exec} actions before replanning reduces policy interventions, but increases the time before new observations can alter the proposal. Substituting S/H into the single-step compounding bound is not justified without new chunk-level error and cost assumptions.

At test time the variational encoder, which requires the future demonstration chunk, is discarded. Setting $\mathbf{z} = \mathbf{0}$ evaluates the decoder at the prior mean in one forward pass. That latent point is not guaranteed to select the most probable demonstrated mode. Sampling the prior can expose additional modes but also poorly trained latent regions. ACT combines overlapping chunk predictions through **temporal ensembling**; for example, an exponentially recency-weighted convention is:

$$\mathbf{a}_t = \frac{\sum_{i=0}^{\min(t, H-1)} w_i \, \mathbf{A}_{t-i}[i]}{\sum_{i=0}^{\min(t, H-1)} w_i},$$

Each weight w_i decays exponentially with the offset i, so this convention favors recent predictions. Averaging incompatible chunks can still create an invalid action; the admitted command must satisfy current limits.

6. **Discrete action tokens.** Vision-language-action models such as RT-1, RT-2, and OpenVLA (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024) discretize continuous action dimensions into B uniform bins (commonly 256) and emit categorical tokens:

$$\text{bin}(a_k) = \min\left(B - 1, \left\lfloor B \frac{a_k - a_{\min}}{a_{\max} - a_{\min}} \right\rfloor\right)$$

For an action clipped to the declared range, this assigns one of B equal-width bins, including the upper endpoint. Decoding to bin centers gives maximum scalar quantization error $(a_{\max} - a_{\min})/(2B)$. Categorical sampling or mode selection preserves alternatives; taking their mean reintroduces averaging. A decoder that emits one token per action dimension autoregressively needs d_a sequential predictions, although other tokenizations and parallel heads have different costs.

DRAFT

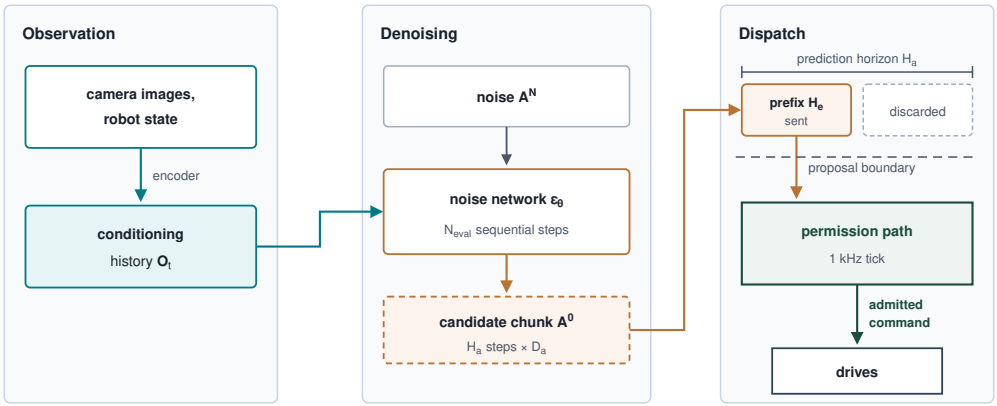

Figure A.5: Diffusion policy architecture: A continuous trajectory diffusion policy for visuomotor control, denoising a candidate action chunk from Gaussian noise across N_{eval} iterations and dispatching only a prefix of it before re-planning. Asynchronous buffering and an independent high-rate permission path can separate slower chunk generation from actuation. Conditional denoising can represent alternative demonstrated paths without taking their direct-regression mean. (Adapted from Chi et al. (2025)).

A.5.2 Continuous trajectory diffusion and flow matching

Sampling one distinct trajectory around an obstacle avoids the collision caused by averaging two paths, but running 16 sequential denoising passes through a 48-million-parameter U-Net takes 40.4 ms and overruns a 25 ms synchronous setpoint deadline. Continuous trajectory diffusion treats policy synthesis as generative denoising over continuous multi-step action trajectory chunks $\mathbf{A} \in \mathbb{R}^{H \times d_a}$ conditioned on visual and proprioceptive observation histories $\mathbf{O}$ (Chi et al. 2025). Here H counts physical action steps, d_a counts action dimensions, and the later N_{eval} counts inference evaluations; diffusion time is not physical execution time. Rather than predicting an unconstrained point estimate via mean squared error, diffusion models represent complex multimodal action distributions without collapsing into mode averaging.

The closed-loop visuomotor diffusion pipeline has three coordinated architectural columns (figure A.5). The left observation column encodes visual camera streams and proprioceptive joint history into a conditioning vector. The center denoising column applies a noise network across N_{eval} sequential reverse-diffusion steps to refine Gaussian noise into a candidate action chunk. The right dispatch column extracts an execution prefix from the prediction horizon and routes those candidate actions across the proposal boundary into the 1 kHz permission path. It also discards the unexecuted tail before re-planning. The noise-prediction backbone ϵ_θ is typically implemented using either a 1D Temporal Convolutional (Conv1D) U-Net or a Diffusion Transformer (DiT):

- **1D temporal convolutional U-Net:** Convolutions across the action horizon reuse filters at many positions. Feature-wise linear modulation (FiLM) supplies observation and diffusion-step conditioning. Layer widths, intermediate tensors, and accelerator tiling determine whether activations stay on chip.
- **Diffusion transformer (DiT):** Attention connects action tokens and visual conditioning. The action horizon and conditioning length determine attention work, while kernel fusion determines how much intermediate storage reaches DRAM. Neither backbone implies a fixed parameter count or per-step latency; the worked budget below declares one illustrative configuration.

A.5.2.1 Forward diffusion and variance scheduling

The forward diffusion process progressively corrupts a ground-truth demonstrated action chunk $\mathbf{A}^0 \sim p_{\text{data}}(\mathbf{A})$ with Gaussian noise across N discrete timesteps (or continuous diffusion time $t_{\text{diff}} \in [0,1]$):

$$q(\mathbf{A}^k \mid \mathbf{A}^{k-1}) = \mathcal{N}\left(\mathbf{A}^k; \sqrt{1-\beta_k}\mathbf{A}^{k-1}, \beta_k \mathbf{I}\right)$$

where $\{\beta_k \in (0,1)\}_{k=1}^{N}$ denotes a predefined variance schedule. Defining $\alpha_k = 1-\beta_k$, the one-step transition evaluates to:

$$\mathbf{A}^k = \sqrt{\alpha_k}\mathbf{A}^{k-1} + \sqrt{1-\alpha_k}\epsilon_{k-1}, \quad \epsilon_{k-1} \sim \mathcal{N}(\mathbf{0},\mathbf{I})$$

Unrolling this recursion for $k=2$:

$$\begin{aligned}\mathbf{A}^2 &= \sqrt{\alpha_2}\left(\sqrt{\alpha_1}\mathbf{A}^0 + \sqrt{1-\alpha_1}\epsilon_0\right) + \sqrt{1-\alpha_2}\epsilon_1 \\ &= \sqrt{\alpha_2\alpha_1}\mathbf{A}^0 + \sqrt{\alpha_2(1-\alpha_1)}\epsilon_0 + \sqrt{1-\alpha_2}\epsilon_1\end{aligned}$$

Because the linear combination of two independent zero-mean Gaussian random variables $\mathcal{N}(\mathbf{0},\sigma_a^2\mathbf{I})$ and $\mathcal{N}(\mathbf{0},\sigma_b^2\mathbf{I})$ is itself a Gaussian with variance $(\sigma_a^2+\sigma_b^2)\mathbf{I}$, the combined variance of the noise terms simplifies algebraically:

$$\alpha_2(1-\alpha_1) + (1-\alpha_2) = \alpha_2 - \alpha_1\alpha_2 + 1 - \alpha_2 = 1 - \alpha_1\alpha_2$$

Defining the cumulative variance product $\bar{\alpha}_k = \prod_{s=1}^{k}\alpha_s$, mathematical induction establishes the closed-form marginal distribution at any arbitrary diffusion step k directly from clean action chunk $\mathbf{A}^0$:

$$q(\mathbf{A}^k \mid \mathbf{A}^0) = \mathcal{N}\left(\mathbf{A}^k; \sqrt{\bar{\alpha}_k}\mathbf{A}^0, (1-\bar{\alpha}_k)\mathbf{I}\right)$$

allowing immediate sampling of noisy trajectories during training without simulating intermediate Markov chain transitions:

$$\mathbf{A}^k = \sqrt{\bar{\alpha}_k}\mathbf{A}^0 + \sqrt{1-\bar{\alpha}_k}\epsilon, \quad \epsilon \sim \mathcal{N}(\mathbf{0},\mathbf{I})$$

A.5.2.2 Reverse denoising and score-matching objective

The generative reverse process synthesizes an action trajectory from pure Gaussian noise $\mathbf{A}^N \sim \mathcal{N}(\mathbf{0},\mathbf{I})$ by parameterizing the conditional reverse transition distribution $p_\theta(\mathbf{A}^{k-1} \mid \mathbf{A}^k, \mathbf{O})$:

$$p_\theta(\mathbf{A}^{k-1} \mid \mathbf{A}^k, \mathbf{O}) = \mathcal{N}\left(\mathbf{A}^{k-1}; \mu_\theta(\mathbf{A}^k, \mathbf{O}, k), \Sigma_k\right)$$

By Bayes' rule, the true reverse posterior conditioned on the clean trajectory $\mathbf{A}^0$ is tractable and Gaussian: $q(\mathbf{A}^{k-1} \mid \mathbf{A}^k, \mathbf{A}^0) = \mathcal{N}(\mathbf{A}^{k-1}; \tilde{\mu}_k(\mathbf{A}^k, \mathbf{A}^0), \tilde{\beta}_k\mathbf{I})$, where:

$$\tilde{\mu}_k(\mathbf{A}^k, \mathbf{A}^0) = \frac{\sqrt{\bar{\alpha}_{k-1}}\beta_k}{1-\bar{\alpha}_k}\mathbf{A}^0 + \frac{\sqrt{\alpha_k}(1-\bar{\alpha}_{k-1})}{1-\bar{\alpha}_k}\mathbf{A}^k$$

Because $\mathbf{A}^0$ is unobserved at test time, the reverse process substitutes an estimate of $\mathbf{A}^0$ derived from Tweedie's formula. For any Gaussian perturbation $\mathbf{x} \sim \mathcal{N}(\mathbf{x}_0, \sigma^2\mathbf{I})$ with prior density $p(\mathbf{x}_0)$, the conditional observation density is:

$$p(\mathbf{x} \mid \mathbf{x}_0) = \frac{1}{(2\pi\sigma^2)^{D/2}}\exp\left(-\frac{\|\mathbf{x}-\mathbf{x}_0\|^2}{2\sigma^2}\right)$$

Differentiating with respect to the noisy measurement $\mathbf{x}$:

$$\nabla_{\mathbf{x}} p(\mathbf{x} \mid \mathbf{x}_0) = -\frac{\mathbf{x}-\mathbf{x}_0}{\sigma^2}p(\mathbf{x} \mid \mathbf{x}_0)$$

The marginal density of noisy observations evaluates to $p(\mathbf{x}) = \int_{\mathbb{R}^D} p(\mathbf{x} \mid \mathbf{x}_0)p(\mathbf{x}_0)\,d\mathbf{x}_0$. Differentiating under the integral sign:

$$\nabla_{\mathbf{x}} p(\mathbf{x}) = \int_{\mathbb{R}^D} \nabla_{\mathbf{x}} p(\mathbf{x} \mid \mathbf{x}_0)p(\mathbf{x}_0)\,d\mathbf{x}_0 = -\frac{1}{\sigma^2}\int_{\mathbb{R}^D}(\mathbf{x}-\mathbf{x}_0)p(\mathbf{x} \mid \mathbf{x}_0)p(\mathbf{x}_0)\,d\mathbf{x}_0$$

Dividing both sides by the marginal density $p(\mathbf{x})$:

$$\frac{\nabla_{\mathbf{x}} p(\mathbf{x})}{p(\mathbf{x})} = \nabla_{\mathbf{x}} \ln p(\mathbf{x}) = -\frac{1}{\sigma^2}\left(\mathbf{x} - \int_{\mathbb{R}^D}\mathbf{x}_0\frac{p(\mathbf{x} \mid \mathbf{x}_0)p(\mathbf{x}_0)}{p(\mathbf{x})}\,d\mathbf{x}_0\right) = -\frac{\mathbf{x}-\mathbb{E}[\mathbf{x}_0 \mid \mathbf{x}]}{\sigma^2}$$

DRAFT

Multiplying by σ^2 and isolating $\mathbb{E}[\mathbf{x}_0 \mid \mathbf{x}]$ proves **Tweedie's formula**:

$$\mathbb{E}[\mathbf{x}_0 \mid \mathbf{x}] = \mathbf{x} + \sigma^2 \nabla_{\mathbf{x}} \ln p(\mathbf{x})$$

Tweedie's formula reveals that the Bayes-optimal reconstruction of clean state $\mathbf{x}_0$ equals the corrupted measurement $\mathbf{x}$ shifted along the marginal Stein score $\nabla_{\mathbf{x}} \ln p(\mathbf{x})$ scaled by noise variance σ^2. Rewriting the forward diffusion marginal $\mathbf{A}^k = \sqrt{\bar{\alpha}_k}\mathbf{A}^0 + \sqrt{1-\bar{\alpha}_k}\epsilon$ as $\frac{\mathbf{A}^k}{\sqrt{\bar{\alpha}_k}} = \mathbf{A}^0 + \frac{\sqrt{1-\bar{\alpha}_k}}{\sqrt{\bar{\alpha}_k}}\epsilon$, the effective noise variance is $\sigma^2 = \frac{1-\bar{\alpha}_k}{\bar{\alpha}_k}$. At the population optimum of the noise-prediction objective, Tweedie's formula equates the estimated clean trajectory $\hat{\mathbf{A}}^0$ and the Stein score $\nabla_{\mathbf{A}^k} \ln p(\mathbf{A}^k \mid \mathbf{O})$:

$$\nabla_{\mathbf{A}^k} \ln p(\mathbf{A}^k \mid \mathbf{O}) = -\frac{\epsilon_\theta(\mathbf{A}^k, \mathbf{O}, k)}{\sqrt{1-\bar{\alpha}_k}}$$

Substituting $\hat{\mathbf{A}}^0 = \frac{1}{\sqrt{\bar{\alpha}_k}}\left(\mathbf{A}^k - \sqrt{1-\bar{\alpha}_k}\epsilon_\theta(\mathbf{A}^k, \mathbf{O}, k)\right)$ into the posterior mean $\tilde{\mu}_k$ reparameterizes the reverse transition mean:

$$\mu_\theta(\mathbf{A}^k, \mathbf{O}, k) = \frac{1}{\sqrt{\alpha_k}}\left(\mathbf{A}^k - \frac{\beta_k}{\sqrt{1-\bar{\alpha}_k}}\epsilon_\theta(\mathbf{A}^k, \mathbf{O}, k)\right)$$

The noise-prediction network ϵ_θ is optimized via the simplified ℓ_2 denoising score-matching objective:

$$\mathcal{L}_{\text{diff}}(\theta) = \mathbb{E}_{k\sim\mathcal{U}\{1,N\},\epsilon\sim\mathcal{N}(\mathbf{0},\mathbf{I}),(\mathbf{O},\mathbf{A}^0)\sim\mathcal{D}_{\text{demo}}}\left[\left\|\epsilon - \epsilon_\theta\left(\sqrt{\bar{\alpha}_k}\mathbf{A}^0 + \sqrt{1-\bar{\alpha}_k}\epsilon, \mathbf{O}, k\right)\right\|^2\right]$$

By following the score function $\nabla_{\mathbf{A}^k} \ln p(\mathbf{A}^k \mid \mathbf{O})$, reverse diffusion steers stochastic sampling toward high-density demonstration modes rather than averaging incompatible modes into an obstacle collision. Each denoising step commits further to a single mode of the conditional action distribution.

A.5.2.3 Continuous flow matching and vector field regression

While standard diffusion models formulate generation as reverse stochastic differential equations (SDEs), **continuous flow matching** (Lipman et al. 2022) generates trajectories along deterministic probability flows defined by ordinary differential equations (ODEs):

$$\frac{d\mathbf{y}_t}{dt} = v_\theta(\mathbf{y}_t, t, \mathbf{O})$$

The continuous vector field v_θ drives a source noise distribution $\rho_0(\mathbf{y}) = \mathcal{N}(\mathbf{0}, \mathbf{I})$ to the empirical demonstration target distribution $\rho_1(\mathbf{y}) = p_{\text{data}}(\mathbf{y})$ across continuous time $t \in [0,1]$, governed by the **continuity equation**:

$$\frac{\partial \rho_t(\mathbf{y})}{\partial t} + \nabla \cdot (\rho_t(\mathbf{y}) u_t(\mathbf{y})) = 0$$

For a straight conditional interpolation path, the continuous trajectory interpolates linearly between source noise $\mathbf{y}_0 \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and demonstration chunk $\mathbf{y}_1 \sim \mathcal{D}_{\text{demo}}$:

$$\psi_t(\mathbf{y}_0) = (1-t)\mathbf{y}_0 + t\mathbf{y}_1, \quad t \in [0,1]$$

The conditional velocity along each paired-sample path is constant across time:

$$v_t(\mathbf{y} \mid \mathbf{y}_1) = \frac{d}{dt}\psi_t(\mathbf{y}_0) = \mathbf{y}_1 - \mathbf{y}_0$$

and the trajectory acceleration vanishes identically: $\frac{d^2}{dt^2}\psi_t(\mathbf{y}_0) = \mathbf{0}$. The **Conditional Flow Matching (CFM) theorem** (Lipman et al. 2022) proves a gradient identity. Regressing the neural vector field v_θ against this conditional vector field over paired samples $(\mathbf{y}_0, \mathbf{y}_1)$ gives the same gradients as regressing it against the intractable marginal velocity field $u_t(\mathbf{y})$:

$$\nabla_\theta \mathbb{E}_{t,\mathbf{y}_0,\mathbf{y}_1}\left[\|v_\theta(\psi_t(\mathbf{y}_0), t, \mathbf{O}) - (\mathbf{y}_1 - \mathbf{y}_0)\|^2\right] = \nabla_\theta \mathbb{E}_{t,\mathbf{y}\sim\rho_t}\left[\|v_\theta(\mathbf{y}, t, \mathbf{O}) - u_t(\mathbf{y})\|^2\right]$$

DRAFT

The network is therefore trained via direct mean squared regression:

$$\mathcal{L}_{\text{FM}}(\theta) = \mathbb{E}_{t\sim\mathcal{U}[0,1],\mathbf{y}_0\sim\mathcal{N}(\mathbf{0},\mathbf{I}),\mathbf{y}_1\sim\mathcal{D}_{\text{demo}}}\left[\left\|v_\theta\left((1-t)\mathbf{y}_0 + t\mathbf{y}_1, t, \mathbf{O}\right) - (\mathbf{y}_1 - \mathbf{y}_0)\right\|^2\right]$$

The conditional paths above are straight for each sampled pair, but the learned marginal velocity averages over pairs that reach the same intermediate point. Its integrated trajectories need not remain straight, and their numerical error need not vanish. Independent noise/data pairing also does not establish globally optimal transport. Flow matching can support fewer evaluations in a measured task, but the step count must satisfy an action-quality criterion; it is not a universal consequence of the interpolation formula.

A.5.2.4 Denoising steps against the control deadline

In continuous generative policies, the number of reverse evaluation steps N_{eval} is the governing systems lever trading off policy expressiveness at the physical plant against computational latency on accelerator hardware. The reverse trajectory discretizes a continuous probability flow ODE or reverse SDE. Discretizing this path across N_{eval} finite steps introduces numerical integration errors:

- **Sampling accuracy:** Reducing the number of evaluations increases numerical approximation error for a fixed solver and learned field. How that error changes multimodal coverage, collision rate, or setpoint smoothness depends on the learned distribution and solver. The architecture alone supplies no minimum acceptable step count.
- **Computational latency and roofline limits:** Reverse diffusion is an inherently sequential Markov chain: evaluation $k-1$ requires the tensor output of evaluation k. Denoising steps cannot be parallelized across the time dimension on GPU or NPU accelerators. Total chunk generation latency scales linearly with N_{eval}:[5]

  $$t_{\text{infer}} = t_{\text{vis}} + N_{\text{eval}} \cdot t_{\text{pass}}$$

  where t_{vis} is the one-time visual feature extraction latency per chunk and t_{pass} is the forward execution time of noise-prediction network ϵ_θ. A weight-transfer lower bound is $t_{\text{stream}} = M_{\text{weights}}/\text{BW}_{\text{mem}}$ when every evaluation reloads those weights. The roofline intensity must count all operations and traffic, including convolutional or token reuse and activation spills. Batch size alone does not make every decoder memory bound. The worked budget below evaluates this transfer bound separately from its assumed execution time.

A setpoint producer that must finish synchronously within Δt_{ctrl} misses its contract when $t_{\text{infer}} > \Delta t_{\text{ctrl}}$. The consequence depends on the controller's defined hold, interpolation, and fallback behavior; a deadline miss does not inherently imply a torque drop. Physical AI architectures resolve this latency-expressiveness trade-off through three coordinated mechanisms:

1. **Action chunking:** The policy predicts a multi-step trajectory chunk $\mathbf{A} \in \mathbb{R}^{H\times d_a}$ spanning prediction horizon H. Executing an execution horizon $H_{\text{exec}} \leq H$ amortizes the N_{eval}-step generation latency over $H_{\text{exec}}\Delta t_{\text{ctrl}}$ of physical robot motion.
2. **Fewer solver evaluations:** Flow matching, improved solvers, or distillation can reduce sequential evaluations when validation shows that the resulting action quality remains adequate. Reduced compute buys timing slack at the cost of a new approximation and validation obligation.
3. **Dual-rate asynchronous decoupling:** The application processor runs the generative denoising loop asynchronously at a relaxed rate (10–20 Hz), sending each action chunk across the proposal boundary over a black-channel link that carries a checksum and sequence number. A discrete safety microcontroller, which shares no memory with the application processor, receives the chunk into its own double buffer and executes synchronously at 1 kHz. It interpolates spline knots, enforces slew-rate limits, and gates commands through deterministic control barrier functions (section 1.7).

The numerical execution of this dual-rate pipeline spans both processors (algorithm A.2), and its geometry, denoising trajectory, and hardware split appear across the three panels of figure A.6. Panel (a) demonstrates multimodal action selection. It contrasts direct MSE regression, which averages divergent paths into an obstacle collision, against conditional diffusion, which samples distinct valid

[5] **Diffusion Denoising Latency Budget**: Sequential reverse diffusion cannot parallelize across sampling steps because each input requires the previous step's output. Total inference time $t_{\text{infer}} = t_{\text{vis}} + N_{\text{eval}}t_{\text{pass}}$ scales linearly with step count N_{eval}, making step reduction or asynchronous chunking essential for real-time actuation.

DRAFT

trajectory modes. Panel (b) traces the reverse-diffusion denoising sequence from isotropic Gaussian noise $\mathbf{A}^{N_{\text{eval}}}$ to a coherent action chunk $\mathbf{A}^0$. Panel (c) shows the asynchronous dual-rate hardware split, where the application processor streams candidate chunks over a black-channel serial link to a discrete 1 kHz safety microcontroller running double-buffering, freshness checks, and spline interpolation. Section 6.2 uses the timing budget below to evaluate which sampler fits the control deadline. The pseudocode assumes the microcontroller's receive path has already validated the proposal's capture epoch, clock conversion, configuration, validity interval, and handoff continuity. An absent, expired, or rejected chunk selects the defined fallback; spline interpolation and slew clamping alone do not implement that permission decision. The transmitted action must also pass the actuator interface that converts its declared units to drive commands.

Algorithm A.2 Diffusion Policy Trajectory Chunk Denoising and Dual-Rate Actuation

Require: observation history buffer $\mathbf{O}_t = (\mathbf{o}_{t-H_{\text{hist}}}, \ldots, \mathbf{o}_t)$ of length $H_{\text{hist}} + 1$, noise prediction network ϵ_θ, noise schedule $\{\alpha_k, \bar{\alpha}_k, \sigma_k\}_{k=1}^{N_{\text{diff}}}$, chunk horizon H, safety microcontroller loop period Δt_{mcu}
Ensure: line-rate joint torque setpoint / action vector $\mathbf{a}_t$

Application Processor: Asynchronous Trajectory Chunk Generation (10–20 Hz)
$\mathbf{E}_t \leftarrow \textsc{VisualEncoder}(\mathbf{O}_t)$
$\mathbf{A}^{N_{\text{diff}}} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_{Hd_a})$ ▷ *sample a flattened chunk, then reshape to $H \times d_a$*
for $k = N_{\text{diff}}$ **down to** 1 **do**
  $\hat{\epsilon} \leftarrow \epsilon_\theta(\mathbf{A}^k, \mathbf{E}_t, k)$
  $\mu_k \leftarrow \frac{1}{\sqrt{\alpha_k}} \left(\mathbf{A}^k - \frac{1-\alpha_k}{\sqrt{1-\bar{\alpha}_k}} \hat{\epsilon} \right)$
  $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ **if** $k > 1$ **else** $\mathbf{z} \leftarrow \mathbf{0}$
  $\mathbf{A}^{k-1} \leftarrow \mu_k + \sigma_k \mathbf{z}$
end for
$\mathbf{A}_{\text{chunk}} \leftarrow \mathbf{A}^0$
$\textsc{SendOverLink}(\mathbf{A}_{\text{chunk}})$ ▷ *checksum and sequence number; no shared memory*

Safety Microcontroller: Synchronous Deterministic Actuation (1 kHz)
if $\textsc{HasNewChunk}(\text{RxBuffer})$ **then** ▷ *receive interrupt fills the inactive buffer*
  $\textsc{UpdateSplineKnots}(\text{RxBuffer})$
end if
$\mathbf{a}_{\text{raw}} \leftarrow \textsc{CubicSplineInterpolate}(\mathbf{A}_{\text{chunk}}, t_{\text{current}})$
$\Delta\mathbf{a} \leftarrow \textsc{clamp}(\mathbf{a}_{\text{raw}} - \mathbf{a}_{\text{prev}}, -\dot{\mathbf{a}}_{\max} \Delta t_{\text{mcu}}, +\dot{\mathbf{a}}_{\max} \Delta t_{\text{mcu}})$ ▷ *kinematic slew-rate governor*
$\mathbf{a}_{\text{clamped}} \leftarrow \mathbf{a}_{\text{prev}} + \Delta\mathbf{a}$
$\mathbf{a}_t \leftarrow \textsc{SafetyGovernorClamp}(\mathbf{a}_{\text{clamped}})$ ▷ *deterministic envelope enforcement*
$\textsc{TransmitPwmRegisters}(\mathbf{a}_t)$
$\mathbf{a}_{\text{prev}} \leftarrow \mathbf{a}_t$
return $\mathbf{a}_t$

Consider a 7-DoF arm with a two-finger gripper ($d_a = 8$) whose policy generates chunks of 16 setpoints at a chosen 25 ms setpoint period (40 Hz), a 400 ms horizon. The noise-prediction network is a 1D temporal convolutional U-Net with 48 million parameters, 96 MB at FP16. Its timings below are illustrative inputs, not measurements of any device. The budget has three parts.

1. **Perception.** A visual encoder processes two synchronized RGB streams (wrist-mounted and over-the-shoulder) into the conditioning embedding $\mathbf{E}_t$ in $t_{\text{vis}} = 14$ ms per chunk. Because the features are extracted once per chunk before denoising begins, t_{vis} is a fixed cost whatever the sampling schedule.
2. **Denoising.** Each reverse step evaluates ϵ_θ at 14.2 GFLOP. At a peak bandwidth of 204.8 GB/s, streaming the weights once takes at least 0.469 ms, and the arithmetic intensity is about 147.9 FLOP/byte. With kernel launch overhead and activation spills, the time per evaluation is $t_{\text{pass}} = 1.65$ ms, and the sampler then sets the cost. A standard DDIM sampler with 16 steps

DRAFT

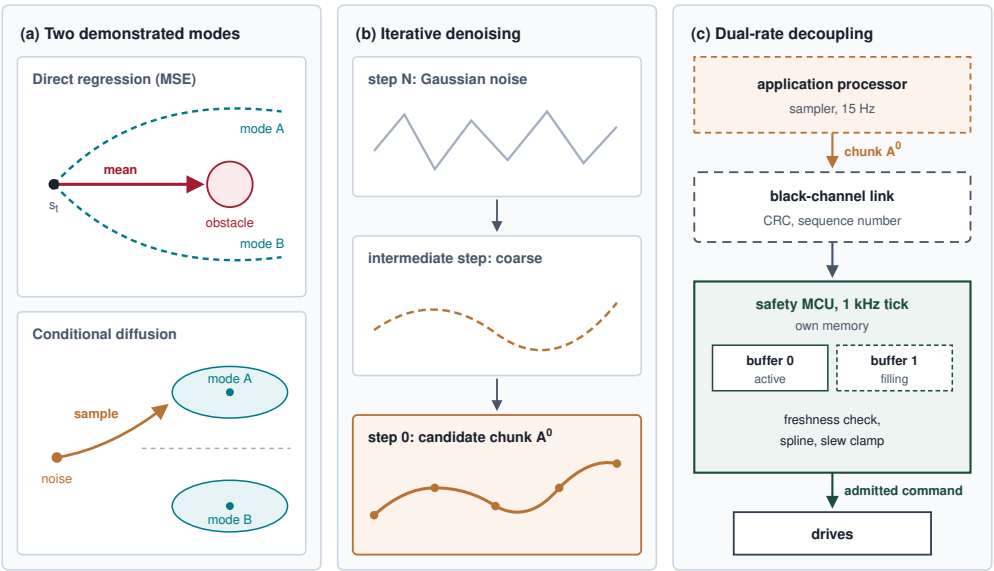

Figure A.6: Diffusion policy action chunk denoising and receding-horizon decoupling: (a) Multimodal resolution: direct regression with mean squared error averages divergent demonstrations into an invalid obstacle collision, whereas conditional diffusion can sample alternative demonstrated modes; generated paths still require clearance checks. (b) Iterative trajectory denoising: starting from Gaussian noise $\mathbf{A}^{N_{\text{eval}}} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$, reverse diffusion progressively resolves a coarse trajectory into a smooth action chunk $\mathbf{A}^0$. (c) Dual-rate decoupling: an asynchronous sampler on the application processor sends each chunk over a black-channel link to a discrete 1 kHz safety microcontroller, which holds it in its own double buffer and runs the freshness check, spline interpolation, and slew clamping. The two processors share no memory. (Adapted from Chi et al. (2025)).

denoises in 26.4 ms, for a total inference latency of 40.4 ms. A flow-matching decoder integrated with 2 Euler evaluations, assuming two steps meet the task's action-quality criterion, needs 3.3 ms, for a total of 17.3 ms.

3. **The deadline.** Run synchronously against the 25 ms period, the DDIM sampler overruns by 61.6 percent before any scheduling overhead. The two-evaluation flow decoder fits with 7.7 ms (30.8 percent) of compute-only slack, and it may run in lockstep only if its measured tail latency, bus transfer, and operating-system scheduling also fit. Run asynchronously at 15 Hz (a 66.7 ms period), the DDIM sampler refreshes the chunk buffer with 26.3 ms to spare. The permission path, at 1 kHz in the two-processor implementation, meanwhile interpolates the 400 ms chunk and checks its freshness, falling back when the chunk expires.

A.5.3 Compounding quadratic error in behavioral cloning

A 1 mm wrist-pose error on step 1 shifts the wrist camera viewpoint on step 2 into a slightly off-center state that the human demonstrator never visited. Whereas offline supervised evaluation samples from a fixed demonstration distribution, in closed-loop execution the current action $\mathbf{a}_t$ alters the subsequent physical state s_{t+1} and the next observation distribution, creating **compounding covariate shift**.

Let π^* denote the expert demonstrator policy and $\hat{\pi}$ denote the learned policy. Suppose the single-step error probability under the expert's state distribution is bounded by ϵ for all timesteps $t \in \{1, \dots, S\}$:

$$\forall t \leq S: \quad \mathbb{E}_{s \sim d^t_{\pi^*}}[\mathbf{1}(\hat{\pi}(s) \neq \pi^*(s))] \leq \epsilon$$

In digital supervised learning (such as fixed-image classification), evaluation inputs are held fixed, so the expected count of prediction errors scales as $\mathcal{O}(S\epsilon)$. In closed-loop physical AI, an action error alters the physical state of the robot, transporting it into states $s \notin \text{supp}(d_{\pi^*})$ that the demonstrator rarely or never visited. Offline training provides no valid statistical guarantee on action error in these learner-induced states.

To derive the compounding error bound, we construct a formal trajectory coupling argument (Ross et al. 2011). Let $\mathcal{E}_t$ denote the event that the policy makes its first mistake at time t ($\hat{\pi}(s_t) \neq \pi^*(s_t)$ and $\hat{\pi}(s_{t'}) = \pi^*(s_{t'})$ for all $t' < t$). Couple learner and expert trajectories with the same initial state and transition randomness. Until their first disagreement they coincide, so $\mathcal{E}_t$ is a subset of the disagreement event on the unconditioned expert trajectory and $\Pr(\mathcal{E}_t) \leq \epsilon$. Conditioning on earlier agreement need not preserve the expert state marginal.

The probability that at least one error has occurred at or before step t is bounded by a union bound:[6]

$$\Pr(\text{error by step } t) = \Pr\left(\bigcup_{t'=1}^{t} \mathcal{E}_{t'}\right) \leq \sum_{t'=1}^{t} \Pr(\mathcal{E}_{t'}) \leq t\epsilon$$

[6] **Compounding Error in Imitation Learning**: Ross and colleagues analyzed how learner actions shift the state distribution. Expert corrective labels on learner-visited states can reduce this exposure.

Once an error occurs, the robot diverges into unmodeled states where downstream incremental cost is bounded by at most $C_{\max}$ per step. Summing over the entire finite execution horizon S:

$$\begin{aligned} J(\hat{\pi}) - J(\pi^*) &\leq \sum_{t=1}^{S} C_{\max} \Pr(\text{error by step } t) \\ &\leq C_{\max} \sum_{t=1}^{S} t\epsilon \\ &= C_{\max}\epsilon \frac{S(S+1)}{2} = \mathcal{O}(S^2\epsilon) \end{aligned}$$

The quadratic expression is a worst-case upper bound on excess cumulative cost, not a prediction of geometric trajectory error or a probability. Since $\Pr(\text{error by step } t) \leq 1$, a tighter bound replaces $t\epsilon$ by $\min(1, t\epsilon)$. For continuous actions, the disagreement indicator needs a specified tolerance or a surrogate loss tied to a cost bound; exact equality is generally too restrictive.

A.5.4 Interactive dataset aggregation (DAgger) linear reduction

The **DAgger** (Dataset Aggregation) algorithm (Ross et al. 2011) addresses this distribution shift by collecting training data under the learner's induced state distribution $d_{\hat{\pi}_i}$. At each training iteration i, the loop proceeds in four steps:

1. Execute policy $\hat{\pi}_i$ under the applicable safety envelope to collect trajectories $\mathcal{T}_i = \{s_1, s_2, \ldots, s_S\}$.
2. Query the expert to label every visited state $s_t \in \mathcal{T}_i$ with the optimal recovery action $a^* = \pi^*(s_t)$.
3. Aggregate the recovery dataset $\mathcal{D} \leftarrow \mathcal{D} \cup \{(s_t, a^*)\}$.
4. Retrain policy $\hat{\pi}_{i+1}$ on the aggregated dataset.

For the DAgger bound, make a stronger assumption than the earlier per-step $C_{\max}$: one wrong action followed by the expert changes expected remaining cost by at most u, independent of horizon. With expert labels on learner-visited states, a no-regret online learner, sufficient hypothesis capacity, and a valid finite-sample bound δ_N, a selected policy can satisfy a bound of the form

$$J(\hat{\pi}) - J(\pi^*) \leq Su(\epsilon_N + \gamma_N + \delta_N),$$

where ϵ_N is best-in-class loss on the induced-state distribution, γ_N is average online-learning regret, and δ_N covers finite-sample generalization and policy selection. It scales linearly in S only when $u = \mathcal{O}(1)$ and those errors remain controlled. The drift states need expert corrective labels; appending recovery trajectories alone does not supply them.

A.5.5 Closed-loop trajectory distributions and evaluation estimands

Scoring a candidate policy on a static disk of recorded human demonstrations tests the policy on states the human visited, not on the states that the candidate's own motor commands and the permission path will drive the robot into. Let a physical rollout be parameterized by initial state s_0, environmental parameters e (lighting, surface friction, obstacle geometry), plant parameters m (payload mass, link inertias), and permission-path parameters κ (lease durations, barrier thresholds). Together these form a trial condition $c = (s_0, e, m, \kappa) \sim \mathcal{D}$ drawn from the operating domain. Under

DRAFT

candidate policy π_θ and physical plant transition dynamics $p_m(s_{t+1} \mid s_t, \mathbf{u}_t)$, the joint probability density of an executed trajectory $\tau = (s_0, \mathbf{u}_0, s_1, \mathbf{u}_1, \dots, s_T)$ over horizon T is:

$$p_{\text{cl}}(\tau \mid \pi_\theta, e, m, \kappa) = \rho_0(s_0 \mid e, m, \kappa) \prod_{t=0}^{T-1} \left[\int \pi_\theta(\mathbf{a}_t \mid \mathbf{o}_{0:t})\, G_\kappa(\mathbf{u}_t \mid s_t, \mathbf{a}_t)\, d\mathbf{a}_t \right] p_m(s_{t+1} \mid s_t, \mathbf{u}_t).$$

Here $\mathbf{o}_t = g(s_t, e)$ is the observation, $\mathbf{a}_t$ is a proposal, and G_κ maps proposals to admitted commands or fallback actions. The state includes the controller and permission-path memory needed to make the transition Markov. A deterministic permission map is represented by a point-mass kernel; marginalizing over operating conditions gives the deployment trajectory distribution.

The discounted state visitation distribution (state marginal) $d^{\pi_\theta}(s)$ induced by policy π_θ is:

$$d^{\pi_\theta}(s) = (1-\gamma) \sum_{t=0}^{\infty} \gamma^t \Pr(s_t = s \mid \pi_\theta)$$

or in the finite-horizon unweighted setting: $\bar{d}^{\pi_\theta}(s) = \frac{1}{T} \sum_{t=0}^{T-1} \Pr(s_t = s \mid \pi_\theta)$. Given a binary task success indicator $\phi(\tau) \in \{0, 1\}$ (e.g., reaching a target receptacle without exceeding torque or clearance limits), the true closed-loop task success probability across operating domain $\mathcal{D}$ is the formal expectation over trial conditions, including policy and transition randomness inside Traj:

$$p(\mathcal{D}) = \mathbb{E}_{c \sim \mathcal{D}}[\phi(\text{Traj}(c))]$$

Because the distribution of visited states d^{π_θ} depends directly on policy proposals and their admission, offline evaluations over fixed logged datasets $\mathcal{D}_{\text{demo}}$ evaluate predictions under d^{π^*}. Static validation scores therefore give no statistical bound over d^{π_θ} when candidate commands deviate from demonstrator actions.

A.6 Value Functions and Continuous Reinforcement Learning

When a latch policy learns by trial and error rather than from demonstrations, no expert label tells it which torque vector to apply at each millisecond. It must discover actions that maximize cumulative reward from interaction, making the reward definition, exploration conditions, and simulator fidelity central assumptions. The following derivations use a fully observed Markov state; a deployed actor with partial observations may require an estimator or history encoder. The transition model includes any fixed permission mechanism, while J here denotes reward to maximize rather than the imitation cost minimized above. Section 6.2.1 builds reward, return, value, and the Bellman relation from the machine's latch task; the derivations below assume that primer and extend it to continuous actions and off-policy learning.

A.6.1 Continuous Markov decision processes and policy gradients

Continuous physical control is formalized as a Markov Decision Process (MDP) defined by the tuple $\mathcal{M} = (\mathcal{S}, \mathcal{A}, p, r, \gamma, \rho_0)$, whose six components are:

- State space $\mathcal{S} \subseteq \mathbb{R}^{d_s}$ represents continuous physical states (joint angles, angular velocities, base pose, linear velocity);
- Action space $\mathcal{A} \subseteq \mathbb{R}^{d_a}$ represents continuous actuator commands (joint torques, motor phase currents, or impedance setpoints);
- Transition dynamics $p(s_{t+1} \mid s_t, \mathbf{a}_t)$ govern continuous plant kinematics and contact physics;
- Reward function $r(s_t, \mathbf{a}_t) \in \mathbb{R}$ quantifies task performance, energy efficiency, and actuator regularization;
- Discount factor $\gamma \in [0, 1)$ establishes the effective temporal planning horizon;
- Initial state distribution $\rho_0(s_0)$ characterizes starting configurations.

The goal is to learn a parameterized policy $\pi_\theta(\mathbf{a} \mid s)$ that maximizes the expected discounted cumulative return:

$$J(\pi_\theta) = \mathbb{E}_{\tau \sim \pi_\theta}[R(\tau)] = \int p_\theta(\tau) R(\tau)\, d\tau$$

DRAFT

where trajectory $\tau = (s_0, \mathbf{a}_0, s_1, \mathbf{a}_1, \dots)$ has cumulative return $R(\tau) = \sum_{t=0}^{\infty} \gamma^t r(s_t, \mathbf{a}_t)$ and probability density:

$$p_\theta(\tau) = \rho_0(s_0) \prod_{t=0}^{\infty} \pi_\theta(\mathbf{a}_t \mid s_t) p(s_{t+1} \mid s_t, \mathbf{a}_t)$$

Differentiating expected return $J(\pi_\theta)$ directly with respect to policy parameters θ yields:

$$\nabla_\theta J(\pi_\theta) = \int \nabla_\theta p_\theta(\tau) R(\tau)\, d\tau$$

Applying the score-function log-derivative identity $\nabla_\theta p_\theta(\tau) = p_\theta(\tau) \nabla_\theta \ln p_\theta(\tau)$:

$$\nabla_\theta J(\pi_\theta) = \int p_\theta(\tau) \nabla_\theta \ln p_\theta(\tau) R(\tau)\, d\tau = \mathbb{E}_{\tau \sim \pi_\theta} [\nabla_\theta \ln p_\theta(\tau) R(\tau)]$$

Taking the natural logarithm of the trajectory probability density decomposes it into initial, policy, and plant components:

$$\ln p_\theta(\tau) = \ln \rho_0(s_0) + \sum_{t=0}^{\infty} \ln \pi_\theta(\mathbf{a}_t \mid s_t) + \sum_{t=0}^{\infty} \ln p(s_{t+1} \mid s_t, \mathbf{a}_t)$$

Differentiating with respect to θ:

$$\nabla_\theta \ln p_\theta(\tau) = \sum_{t=0}^{\infty} \nabla_\theta \ln \pi_\theta(\mathbf{a}_t \mid s_t)$$

Neither the initial state distribution $\rho_0(s_0)$ nor the plant transition dynamics $p(s_{t+1} \mid s_t, \mathbf{a}_t)$ depend on policy weights θ, causing their gradients to vanish identically. In physical systems engineering, this property matters because continuous contact dynamics, dry friction stick-slip transitions, and impact collisions are non-differentiable or discontinuous, which makes analytic trajectory derivatives $\nabla_{\mathbf{a}} s_{t+1}$ ill-conditioned or undefined. The policy gradient formulation bypasses differentiating through plant physics.

By causality (future actions cannot alter past rewards) and subtracting a state-dependent baseline $V(s_t)$ to reduce variance without introducing bias, the **Policy Gradient Theorem** (Sutton and Barto 2018) evaluates the gradient over the state visitation distribution:

$$\nabla_\theta J(\pi_\theta) = \frac{1}{1-\gamma} \mathbb{E}_{s \sim d^{\pi_\theta}, \mathbf{a} \sim \pi_\theta(\cdot|s)} [\nabla_\theta \ln \pi_\theta(\mathbf{a} \mid s) Q^{\pi_\theta}(s, \mathbf{a})]$$

The factor $1/(1-\gamma)$ is required because the state visitation distribution is normalized. An action-independent baseline may replace Q by $Q - V$ without changing the expectation. Here $d^{\pi_\theta}(s) = (1-\gamma) \sum_{t=0}^{\infty} \gamma^t \Pr(s_t = s \mid \pi_\theta)$ is the discounted state visitation distribution, and $Q^{\pi_\theta}(s, \mathbf{a}) = \mathbb{E}_{\tau \sim \pi_\theta} \left[\sum_{k=0}^{\infty} \gamma^k r(s_{t+k}, \mathbf{a}_{t+k}) \mid s_t = s, \mathbf{a}_t = \mathbf{a} \right]$ is the continuous state-action value function.

A.6.2 Deep deterministic policy gradient (DDPG)

For high-dimensional continuous actuator spaces, stochastic sampling in policy gradients introduces substantial variance. The **Deterministic Policy Gradient (DPG)** theorem (introduced by Silver and colleagues in 2014) establishes a closed form for a deterministic policy $\mu_\theta : \mathcal{S} \to \mathcal{A}$. The policy gradient is the expected gradient of the action-value function along the policy's chosen direction:

$$\nabla_\theta J(\mu_\theta) = \frac{1}{1-\gamma} \mathbb{E}_{s \sim d^{\mu_\theta}} \left[\nabla_{\mathbf{a}} Q^{\mu_\theta}(s, \mathbf{a}) \Big|_{\mathbf{a} = \mu_\theta(s)} \nabla_\theta \mu_\theta(s) \right]$$

Here d^{μ_θ} is the normalized discounted visitation distribution and the theorem uses the true policy value Q^{μ_θ}; DDPG substitutes a learned critic. In discrete Q-learning (such as DQN), selecting the optimal greedy action requires solving an exhaustive search $\arg\max_a Q(s, a)$. In continuous control where action space $\mathcal{A} \subseteq \mathbb{R}^{d_a}$ has many dimensions (such as a 7-DoF arm or 12-DoF quadruped), solving an inner non-convex optimization at every control cycle is potentially too costly for the control

DRAFT

deadline. DPG circumvents this bottleneck by replacing the inner argmax with a differentiable continuous actor network $\mu_\theta(s)$. Applying the chain rule, the actor is updated directly in the direction of the critic's action gradient $\nabla_{\mathbf{a}} Q_\phi(s, \mathbf{a})$.

Deep Deterministic Policy Gradient (DDPG, introduced by Lillicrap and colleagues in 2015) parameterizes both actor μ_θ and critic Q_ϕ with deep neural networks. The continuous critic $Q_\phi(s, \mathbf{a})$ is trained via off-policy temporal difference learning by minimizing Bellman residual error on transitions $(s, \mathbf{a}, r, s')$ sampled from an experience replay buffer $\mathcal{D}$:

$$\mathcal{L}(\phi) = \mathbb{E}_{(s,\mathbf{a},r,s')\sim\mathcal{D}}\left[\left(Q_\phi(s,\mathbf{a}) - \left(r + \gamma Q_{\phi'}(s', \mu_{\theta'}(s'))\right)\right)^2\right]$$

Target networks (ϕ', θ') track active networks via slow Polyak averaging $\phi' \leftarrow \tau\phi + (1-\tau)\phi'$ with tracking rate $\tau \ll 1$ (e.g., $\tau = 0.005$). Polyak tracking converts an unstable, moving regression target into a quasi-stationary target, slowing target drift without guaranteeing convergence under function approximation.

A.6.3 Twin delayed DDPG (TD3) and overestimation bias

Standard continuous actor-critic algorithms like DDPG suffer from **overestimation bias**. Because the critic uses deep function approximation, target values evaluate with nonzero approximation error $\epsilon(s', \mathbf{a}')$. In continuous Q-learning, the policy maximizes over estimated values.

The **Maximization Bias Lemma** formalizes this phenomenon: let $Q_{\phi_1}(s', \mathbf{a}')$ and $Q_{\phi_2}(s', \mathbf{a}')$ be two noisy estimators of true value $Q^*(s', \mathbf{a}')$ subject to zero-mean estimation error $\mathbb{E}[\epsilon_i] = 0$. Because the maximum operator is convex, Jensen's inequality proves:

$$\mathbb{E}\left[\max_{\mathbf{a}'} Q_{\phi_i}(s', \mathbf{a}')\right] \geq \max_{\mathbf{a}'} \mathbb{E}\left[Q_{\phi_i}(s', \mathbf{a}')\right] = \max_{\mathbf{a}'} Q^*(s', \mathbf{a}')$$

The bias is nonnegative, and can be zero; strict positivity requires errors that sometimes change which action wins. When present, maximization bias can propagate through recursive Bellman backups: overestimating value at step $t+1$ inflates target values at step t and can favor suboptimal, physically destructive actuator proposals.

Introduced by Fujimoto and colleagues in 2018, **Twin Delayed DDPG (TD3)** reduces overestimation through three architectural mechanisms:

1. **Clipped Double Q-learning:** TD3 maintains two separately parameterized critic networks Q_{ϕ_1} and Q_{ϕ_2}, computing the Bellman target using the minimum of both critics:

   $$y = r + \gamma \min_{i=1,2} Q_{\phi_i'}(s', \tilde{\mathbf{a}}')$$

   Because the expected minimum satisfies $\mathbb{E}[\min(X, Y)] \leq \min(\mathbb{E}[X], \mathbb{E}[Y])$, taking the minimum introduces a conservative *underestimation bias*. A lower reward estimate is not a clearance or stability bound. Underestimation can change which action wins without making that action physically safer.

2. **Target policy smoothing:** To prevent the policy from exploiting sharp, non-physical peaks in the learned critic, TD3 injects clipped Gaussian noise into the target action:

   $$\tilde{\mathbf{a}}' = \text{clip}\left(\mu_{\theta'}(s') + \text{clip}(\epsilon, -c, c), \mathbf{a}_{\min}, \mathbf{a}_{\max}\right), \quad \epsilon \sim \mathcal{N}(\mathbf{0}, \sigma^2\mathbf{I})$$

   This regularizes value estimation over a local actuator ball. Doing so enforces the physical prior that similar motor commands should yield similar expected returns while smoothing the optimization landscape.

3. **Delayed policy updates:** Updating the policy network on every critic step causes the actor to chase an inaccurate, rapidly shifting value landscape. TD3 updates actor parameters θ and target networks once every d critic updates (typically delay ratio $d = 2$), giving the critics additional updates before actor weights shift, without guaranteeing stabilization.

DRAFT

A.6.4 Soft actor-critic (SAC) and maximum entropy control

While TD3 provides a deterministic policy, physical autonomy requires stochastic exploration to discover viable contact modes and avoid getting trapped in local contact minima (such as a quadruped foot wedged against an obstacle). **Soft Actor-Critic (SAC, developed by Haarnoja and colleagues in 2018)** formulates continuous control under the **Maximum Entropy Reinforcement Learning** framework. The objective augments task rewards with the differential entropy of the policy:

$$J(\pi_\theta) = \sum_{t=0}^{\infty} \mathbb{E}_{(s_t,\mathbf{a}_t)\sim\rho_{\pi_\theta}} \left[\gamma^t \left(r(s_t,\mathbf{a}_t) + \alpha\mathcal{H}(\pi_\theta(\cdot \mid s_t))\right)\right]$$

where $\mathcal{H}(\pi_\theta(\cdot \mid s_t)) = -\mathbb{E}_{\mathbf{a}\sim\pi_\theta}[\ln \pi_\theta(\mathbf{a} \mid s_t)]$ is the policy entropy, and temperature parameter $\alpha > 0$ controls the trade-off between reward maximization and stochastic exploration.

A.6.4.1 Soft Bellman backups and squashed Gaussian policy

The soft state-action value satisfies the soft Bellman equation:

$$Q(s,\mathbf{a}) = r(s,\mathbf{a}) + \gamma\mathbb{E}_{s'\sim p}[V(s')], \quad \text{where } V(s) = \mathbb{E}_{\mathbf{a}\sim\pi}[Q(s,\mathbf{a}) - \alpha \ln \pi(\mathbf{a} \mid s)]$$

To enforce physical actuator limits $\mathbf{a} \in [-a_{\max}, a_{\max}]^{d_a}$, SAC parameterizes the policy as an invertible squashed Gaussian distribution. The network outputs mean $\mu_\theta(s)$ and log-standard-deviation $\ln\sigma_\theta(s)$. An unbounded latent action is sampled via the reparameterization trick:

$$\mathbf{u} = \mu_\theta(s) + \sigma_\theta(s) \odot \epsilon, \quad \epsilon \sim \mathcal{N}(\mathbf{0},\mathbf{I})$$

The following density is for normalized actions. Applying the non-linear squashing function $\mathbf{a} = \tanh(\mathbf{u})$ bounds actions strictly within $(-1,1)^{d_a}$.

By the change-of-variables theorem for probability densities, the log-likelihood of the bounded action $\mathbf{a}$ requires correcting for the Jacobian determinant of the tanh mapping:

$$\pi_\theta(\mathbf{a} \mid s) = \mu(\mathbf{u} \mid s) \left|\det \frac{d\mathbf{a}}{d\mathbf{u}}\right|^{-1}$$

Because the squashing operator acts element-wise ($a_i = \tanh(u_i)$), the Jacobian matrix is diagonal: $\frac{da_i}{du_i} = 1 - \tanh^2(u_i)$. The determinant factors into a product:

$$\det \frac{d\mathbf{a}}{d\mathbf{u}} = \prod_{i=1}^{d_a} \left(1 - \tanh^2(u_i)\right)$$

Taking the natural logarithm yields the exact closed-form log-density correction:

$$\ln \pi_\theta(\mathbf{a} \mid s) = \ln \mu(\mathbf{u} \mid s) - \sum_{i=1}^{d_a} \ln\left(1 - \tanh^2(u_i)\right)$$

Physical limits require a further scale and offset; their Jacobian must also be included if densities are expressed in physical units. Here $\ln \mu(\mathbf{u} \mid s) = -\frac{1}{2}\sum_{i=1}^{d_a}\left(\left(\frac{u_i - \mu_i^\pi(s)}{\sigma_i^\pi(s)}\right)^2 + 2\ln\sigma_i^\pi(s) + \ln(2\pi)\right)$.

A.6.4.2 Dual gradient descent for automatic entropy tuning

Fixed temperature α fails across phases of robot learning: early exploration requires high entropy ($\alpha \gg 0$), while fine precision assembly requires low entropy ($\alpha \to 0$). SAC formulates temperature adaptation as a constrained optimization problem: maximizing expected return subject to a minimum average entropy constraint $\mathbb{E}[\mathcal{H}(\pi_t)] \geq \overline{\mathcal{H}}$, where target entropy is commonly set to $\overline{\mathcal{H}} = -d_a$.

Solving the dual Lagrangian formulation yields the exact update for temperature α:

$$\mathcal{L}(\alpha) = \mathbb{E}_{s_t\sim\mathcal{D},\mathbf{a}_t\sim\pi_t}\left[-\alpha \ln \pi_t(\mathbf{a}_t \mid s_t) - \alpha\overline{\mathcal{H}}\right]$$

Differentiating with respect to α gives the dual gradient update rule:

$$\alpha \leftarrow \alpha - \lambda_\alpha \nabla_\alpha \mathcal{L}(\alpha) = \alpha - \lambda_\alpha\left(-\ln \pi_t(\mathbf{a}_t \mid s_t) - \overline{\mathcal{H}}\right)$$

DRAFT

When expected policy entropy drops below target $\overline{\mathcal{H}}$, $\mathbb{E}[-\ln \pi_t] < \overline{\mathcal{H}}$, the expected gradient is negative and gradient descent raises α. Individual samples need not have that sign. Implementations preserve $\alpha > 0$, for example by optimizing its logarithm. When entropy exceeds target, α decreases to sharpen exploitation.

A.6.5 Proximal policy optimization (PPO) and GPU simulation

While off-policy algorithms (TD3, SAC) maximize sample efficiency from replay buffers, on-policy **Proximal Policy Optimization (PPO)** (Schulman et al. 2017) is the common choice when thousands of simulated robots run in parallel on one GPU. The Isaac Gym benchmarks and legged-locomotion training that learns to walk in minutes both follow this pattern (Makoviychuk et al. 2021; Rudin et al. 2022). PPO clips the incentive for large probability-ratio changes in its surrogate objective; clipping does not impose a hard trust region on the resulting policy:

$$\mathcal{L}^{\text{CLIP}}(\theta) = \hat{\mathbb{E}}_t \left[\min \left(\rho_t(\theta)\hat{A}_t, \text{clip}(\rho_t(\theta), 1-\epsilon_{\text{clip}}, 1+\epsilon_{\text{clip}})\hat{A}_t \right) \right]$$

where the probability ratio is $\rho_t(\theta) = \frac{\pi_\theta(\mathbf{a}_t|s_t)}{\pi_{\theta_{\text{old}}}(\mathbf{a}_t|s_t)}$, clipping parameter $\epsilon_{\text{clip}} \approx 0.2$, and advantage estimates $\hat{A}_t$ are computed via Generalized Advantage Estimation (GAE):

$$\widehat{A}_t^{\text{GAE}} = \sum_{l=0}^{\infty} (\gamma\lambda)^l \delta_{t+l}^V, \quad \text{where } \delta_t^V = r(s_t, \mathbf{a}_t) + \gamma V_\phi(s_{t+1}) - V_\phi(s_t)$$

The parameter $\lambda \in [0, 1]$ trades bootstrapping against longer sampled returns. At $\lambda = 0$ the estimate is a one-step TD residual and depends directly on critic error. At $\lambda = 1$, a complete episode gives the discounted Monte Carlo return minus the baseline; truncated rollouts retain bootstrap error. Terminal transitions omit the continuation value in all Bellman targets above.

A.6.5.1 Massively parallel GPU simulation physics and memory hierarchy

On-policy training consumes fresh rollouts, while off-policy methods reuse a replay buffer. Parallel simulation can make fresh experience inexpensive by keeping physics state, observations, policy inference, and rollout storage on the same accelerator. This reduces host-device copies when the complete pipeline supports device-resident execution.

The storage comparison depends on transition size as well as count. If each stored transition takes b_{tr} bytes, a rollout with n_{env} environments and h steps needs approximately $n_{\text{env}} h b_{\text{tr}}$ bytes, while a replay buffer with n_{replay} transitions needs $n_{\text{replay}} b_{\text{tr}}$. Images, privileged state, and training scratch space can dominate either budget. No utilization percentage or training duration follows from choosing PPO; simulation fidelity, contact workload, network shape, and convergence requirements determine throughput and total cost.

A.6.6 Asymmetric actor-critic for sim-to-real transfer

Deploying policies trained in physics simulators to physical hardware encounters the **reality gap**: unmodeled actuator latency, mechanical compliance, gear backlash, motor thermal derating, and sensor noise cause policies to stumble or destabilize on physical testbeds. An **asymmetric actor-critic** gives the training critic more information than the deployed actor. A related but distinct technique, Rapid Motor Adaptation (RMA) (Kumar et al. 2021), trains a privileged actor and then predicts its environment latent from onboard history. The distinction determines what must run on the robot:

1. **Privileged centralized critic:** In training simulation, the critic network $V_\phi(s_{\text{priv}})$ or $Q_\phi(s_{\text{priv}}, \mathbf{a})$ conditions on the complete, privileged simulation state $s_{\text{priv}} \in \mathbb{R}^{d_{\text{priv}}}$. This privileged vector can contain quantities that are unavailable or measured only imperfectly onboard:
   - True surface contact friction coefficients μ;
   - Exact link masses, payload inertia matrices, and center-of-mass offsets $\Delta\mathbf{c}$;
   - Ground-truth contact force vectors $\mathbf{f}$ and normal impulses at each foot/finger;
   - Unoccluded 3D ground-truth obstacle positions and complete terrain heightmaps;
   - Motor winding temperatures and dynamic back-EMF constants.

A sufficiently complete privileged state can make the critic's prediction problem Markov and reduce estimation uncertainty. It does not make the actor's observation complete or remove model error.

2. **Two-phase adaptation and onboard actor:** To transfer privileged knowledge to physical hardware where s_{priv} cannot be measured, modern architectures use a two-phase distillation pipeline:
   - *Phase 1 (Privileged policy training):* The actor $\pi_\theta(\mathbf{a}_t \mid \mathbf{o}_t, \mathbf{z}_t)$ receives deployable onboard observations $\mathbf{o}_t$ and an environment latent vector $\mathbf{z}_t = E(s_{\text{priv}})$, where encoder E compresses the privileged state into a low-dimensional manifold ($d_z \approx 8$–16).
   - *Phase 2 (Temporal adaptation module):* A lightweight 1D temporal convolutional or MLP adaptation module $g_\psi(\mathbf{o}_{t-H_{\text{hist}}:t})$ is trained via supervised regression to predict the latent vector $\hat{\mathbf{z}}_t$ purely from a sliding window history of recent proprioceptive observations (joint positions $\mathbf{q}$, velocities $\dot{\mathbf{q}}$, and commanded actions $\mathbf{a}$).
3. **Deployment cost:** A plain asymmetric actor-critic discards the privileged critic at deployment and runs only the actor. An RMA-style design also runs its history encoder or adaptation module. That module has a real compute and memory cost and can infer hidden parameters only when the observation history makes them identifiable. Critic access to simulator state does not give the actor access to that state.

Domain randomization varies physical parameters during training to expose the policy to a broader range of dynamics. It can improve transfer within the represented conditions, but neither randomization nor privileged training guarantees successful deployment on new terrain.

A.6.7 Bellman optimality and out-of-distribution overestimation

The optimal state-action value function $Q^*(s, \mathbf{a})$ satisfies the Bellman optimality equation:

$$Q^*(s, \mathbf{a}) = r(s, \mathbf{a}) + \gamma \mathbb{E}_{s' \sim p(\cdot|s,\mathbf{a})} \left[\max_{\mathbf{a}' \in \mathcal{A}} Q^*(s', \mathbf{a}') \right]$$

When learning offline from static pre-collected datasets $\mathcal{D}_{\text{offline}}$ without interactive physical exploration, evaluating the maximization $\max_{\mathbf{a}' \in \mathcal{A}} Q^*(s', \mathbf{a}')$ queries the learned critic on counterfactual actions that were never attempted in the dataset. Outside the dataset's state-action support, function approximation errors can produce value overestimation on out-of-distribution (OOD) actions. An offline policy can favor these spuriously high values and propose destructive motor setpoints unless the permission path rejects them.

Modern offline continuous RL counters this instability through **Conservative Q-Learning (CQL)** (Kumar et al. 2020), which adds an explicit regularization term that penalizes Q-values on out-of-distribution actions while maximizing Q-values on logged demonstrator actions:

$$\min_{Q_\phi} \alpha_{\text{CQL}} \left(\mathbb{E}_{s \sim \mathcal{D}_{\text{offline}}, \mathbf{a} \sim \mu(\cdot|s)} [Q_\phi(s, \mathbf{a})] - \mathbb{E}_{(s,\mathbf{a}) \sim \mathcal{D}_{\text{offline}}} [Q_\phi(s, \mathbf{a})] \right) + \frac{1}{2} \mathcal{L}_{\text{Bellman}}(Q_\phi)$$

Under its stated coverage, estimation, and regularization assumptions, CQL provides lower-bound results for expected policy value. The displayed regularizer does not guarantee a pointwise bound below Q^* for every unseen state-action pair, and reward conservatism does not prevent actuator runaway. Policy proposals still require runtime permission checks.

A.6.8 SayCan affordance-grounded skill selection

The SayCan framework (Ahn et al. 2022) integrates semantic knowledge from high-capacity language models with physical affordance constraints from trained policies. Let c_{instr} represent high-level language instruction and a represent an available low-level skill. SayCan ranks candidate skills by multiplying a language relevance score and an estimated skill-success score, then normalizing if a selection distribution is needed:

$$p(a \mid s, c_{\text{instr}}) \propto p_{\text{LLM}}(a \mid c_{\text{instr}}) \cdot V_{\text{policy}}(s, a)$$

Here the two factors separate semantic relevance from physical feasibility:

DRAFT

- $p_{\text{LLM}}(a \mid c_{\text{instr}})$ represents the **semantic prior**, evaluating whether skill a contributes logically to completing instruction c_{instr}.
- $V_{\text{policy}}(s, a) \in [0, 1]$ represents the **physical affordance probability**, modeled by a learned value function that predicts the probability of successfully executing skill a from current state s.

If the learned value correctly assigns a near-zero score to an unavailable skill, the product deprioritizes it. The learned score estimates success; it bounds no path, contact force, or clearance, so a separate motion-permission check is needed.

A.6.9 Comparing policy architectures by compute and distribution

An MLP point regressor computes one action in a single forward pass but averages ambiguous demonstrations into a single path; a diffusion decoder preserves separate path modes at the cost of N_{eval} sequential network evaluations per chunk. Deploying continuous control policies on physical robots requires selecting an architecture whose computational profile, memory traffic, and latency fit the control loop deadlines of the physical plant (table A.1).

Table A.1: Architectural Trade-offs Across Continuous Control Policies: These are mechanisms, not hardware benchmark ranges. Observation encoding and permission checks add costs beyond the proposal decoder.

Policy component	Evaluations per proposal	Main resource question	Distribution and execution limit
MLP point regressor	One	Do weights and scratch buffers remain resident?	Squared-error output averages ambiguous targets
ConvNet with action head	One encoder and head evaluation	How much spatial reuse survives the memory mapping?	The head, not convolution, determines multimodality
ACT decoder	One decoder evaluation after observation encoding	What do visual tokens and action queries cost?	Fixed latent selects one output; chunk execution delays feedback
Diffusion decoder	N_{eval} sequential denoising evaluations	Are weights and activations transferred each step?	Sampling quality depends on model, solver, and N_{eval}
Flow-matching decoder	Solver-dependent sequential evaluations	How many field evaluations meet the action-quality target?	Straight conditional paths do not guarantee an exact low-step solution
RL actor	Usually one actor evaluation	What actor, history encoder, and preprocessing execute?	RL is a training method; the selected head determines the output family

For a concrete choice, count model parameters and activations, identify the memory level serving each operation, and compare the complete measured execution path with the deadline. The worked decoder budget in section A.5.2 makes those assumptions explicit. Sample efficiency also depends on task coverage and recovery data; it cannot be ranked from the decoder family alone.

A.7 Signal Temporal Logic and Continuous Robustness

A boolean pass/fail flag tells an engineer whether a mobile base stayed at least 0.30 m from an aisle rack during a 10 s run, but not whether it cleared the rack by 0.25 m or 0.2 mm. Verifying whether a physical autonomous system satisfies dynamic safety requirements requires moving beyond instantaneous boolean assertions to continuous temporal specifications that score how much margin remained across the interval.

A.7.1 Syntax and semantics of signal temporal logic

A **Signal Temporal Logic (STL)** specification evaluates a continuous-time physical signal $s(t)$ against temporal requirements defined over time intervals $[a, b]$:

$$\phi ::= \top \mid \pi \mid \neg\phi \mid \phi_1 \wedge \phi_2 \mid \Box_{[a,b]}\phi \mid \Diamond_{[a,b]}\phi \mid \phi_1 \mathcal{U}_{[a,b]}\phi_2$$

where $\pi = (f(s(t)) \geq 0)$ is an atomic predicate (e.g., clearance $d(t) - d_{\text{safe}} \geq 0$), $\Box_{[a,b]}$ denotes the **Always** operator, $\Diamond_{[a,b]}$ denotes the **Eventually** operator, and $\mathcal{U}_{[a,b]}$ denotes the **Until** operator. The symbols match those of section 15.9.1.

A.7.2 Quantitative robustness degree

Beyond a boolean satisfaction verdict ($s \models \phi$), STL admits a signed **quantitative robustness metric** $\rho(\phi, s, t)$.[7] For a formula combining pressure, speed, and force, first define dimensionless atomic margins $\bar{f}_i(s) = f_i(s)/c_i$, where each positive scale c_i has the same SI unit as its predicate. Then the minimum and maximum below compare like quantities:

$$\begin{aligned}
\rho(\pi, s, t) &= \bar{f}(s(t)) \\
\rho(\neg\phi, s, t) &= -\rho(\phi, s, t) \\
\rho(\phi_1 \wedge \phi_2, s, t) &= \min\left(\rho(\phi_1, s, t), \rho(\phi_2, s, t)\right) \\
\rho(\Box_{[a,b]}\phi, s, t) &= \min_{t' \in [t+a, t+b]} \rho(\phi, s, t') \\
\rho(\Diamond_{[a,b]}\phi, s, t) &= \max_{t' \in [t+a, t+b]} \rho(\phi, s, t')
\end{aligned}$$

A strictly positive ρ establishes satisfaction and a negative value establishes violation under the stated semantics. Zero is a boundary case that needs the predicate convention. The normalized magnitude is dimensionless and depends on the declared scales. Preserve each raw physical margin and unit separately in the fault record; a single minimum of meters, newtons, and kilopascals has no physical meaning.

The until operator requires ϕ_1 to hold until a time when ϕ_2 holds. Its robustness is

$$\rho(\phi_1 \mathcal{U}_{[a,b]} \phi_2, s, t) = \sup_{t' \in [t+a, t+b]} \min\left(\rho(\phi_2, s, t'), \inf_{t'' \in [t, t')} \rho(\phi_1, s, t'')\right),$$

with the infimum over an empty interval taken as $+\infty$. Infimum and supremum replace minimum and maximum when extrema are not attained. A sampled trace establishes continuous-time satisfaction only with a justified interpolation or intersample variation bound and sufficient margin for measurement error.

[7] **Signal Temporal Logic Robustness**: Quantitative semantics map a trace and formula to a signed score. Its magnitude inherits the atomic predicate's units only when all combined predicates use commensurate units; otherwise a declared normalization gives a dimensionless score. Negative scores identify violations for falsification searches, subject to sampled-time and measurement limits.

A.8 Zero-Failure Testing and the Exposure Wall

In digital software machine learning, validation benchmarks evaluate millions of inference queries or generated tokens in parallel across cloud accelerators within minutes. In physical AI systems, one hour of physical robot operation takes one hour of real wall-clock time and inflicts mechanical wear on actuators, gearboxes, and structural linkages. Section 7.6 uses the zero-failure bound and the Rule of Three to price the running machine's evaluation campaigns. This section derives the discrete and continuous forms that chapter cites. It also shows why the normal approximation fails when zero failures have been observed.

A.8.1 Derivation of the discrete rule of three

Consider an operational test consisting of n independent, identically distributed Bernoulli trials (such as autonomous navigation missions or pick-and-place cycles), where each trial has an unknown catastrophic failure probability $p_{\text{fail}} \in [0, 1]$. Let the test observe zero catastrophic failures ($k = 0$). Under the hypothesis of failure probability p_{fail}, the probability of observing zero failures across n independent trials is:

$$\Pr(\text{zero failures} \mid p_{\text{fail}}) = (1 - p_{\text{fail}})^n$$

To exclude hypothesis p_{fail} at a one-sided confidence level $1 - \alpha_{\text{sig}}$ (e.g., 95 percent confidence with $\alpha_{\text{sig}} = 0.05$), the likelihood of observing zero failures under that hypothesis must not exceed α_{sig}:

$$(1 - p_{\text{fail}})^n \leq \alpha_{\text{sig}}$$

Taking the natural logarithm of both sides:

$$n \ln(1 - p_{\text{fail}}) \leq \ln \alpha_{\text{sig}}$$

For rare catastrophic events where failure probability is small ($p_{\text{fail}} \ll 1$), the first-order Taylor series expansion $\ln(1 - p_{\text{fail}}) = -p_{\text{fail}} - \frac{p_{\text{fail}}^2}{2} - \cdots \approx -p_{\text{fail}}$ yields:[8]

[8] **Statistical Rule of Three**: Zero events in n independent Bernoulli trials yield the exact one-sided 95 percent upper probability $1 - 0.05^{1/n} \approx 3/n$ for small probabilities. In continuous time, a stationary Poisson process requires $T \geq 3.0/\lambda$. Neither bound covers retrained models, modified firmware, or unobserved hazard classes without configuration-equivalence proofs.

DRAFT

$$-np_{\text{fail}} \leq \ln \alpha_{\text{sig}} \iff p_{\text{fail}} \geq \frac{-\ln \alpha_{\text{sig}}}{n} = \frac{\ln(1/\alpha_{\text{sig}})}{n}$$

Inverting this approximation gives a conservative sample count n required to bound the failure probability below p_{fail} at confidence $1-\alpha_{\text{sig}}$:

$$n \geq \frac{\ln(1/\alpha_{\text{sig}})}{p_{\text{fail}}}$$

For standard 95 percent confidence ($\alpha_{\text{sig}} = 0.05$):

$$n \geq \frac{-\ln(0.05)}{p_{\text{fail}}} = \frac{2.99573}{p_{\text{fail}}} \approx \frac{3}{p_{\text{fail}}}$$

This classical result is the **discrete Rule of Three**: observing zero failures across n trials bounds the per-trial failure probability to $p_{\text{fail}} \leq 3/n$ at 95 percent confidence. The exact inversion without Taylor approximation is $p_{\text{fail, upper}} = 1-\alpha_{\text{sig}}^{1/n}$; for small $p_{\text{fail, upper}}$, the approximation $-\ln(\alpha_{\text{sig}})/n$ slightly exceeds $p_{\text{fail, upper}}$, making the approximation conservative. For a target p_*, the exact required integer count is $\lceil \ln \alpha_{\text{sig}} / \ln(1-p_*) \rceil$.

A.8.2 Full derivation of the continuous Poisson exposure wall

Autonomous robots operate continuously in time rather than in discrete trials. Let catastrophic events follow a stationary homogeneous Poisson process with constant failure rate $\lambda > 0$ (failures per operating hour), which emerges naturally from the discrete Bernoulli model via the **Poisson Limit Theorem** (the law of rare events). Subdividing total fleet operating duration T into n infinitesimal intervals of duration $\Delta t = T/n$, the per-interval failure probability is $p = \lambda \Delta t = \lambda T/n$. In the limit as $\Delta t \to 0$ ($n \to \infty$), the binomial probability of observing exactly k failures converges to the Poisson distribution:

$$\lim_{n\to\infty} \binom{n}{k} \left(\frac{\lambda T}{n}\right)^k \left(1-\frac{\lambda T}{n}\right)^{n-k} = \frac{(\lambda T)^k e^{-\lambda T}}{k!}$$

Let $N(T)$ denote the cumulative count of catastrophic incidents observed across cumulative fleet operating duration $T = \sum_{j=1}^{N_{\text{fleet}}} T_j$ across N_{fleet} robots. The probability of recording exactly k incidents in duration T is:

$$\Pr(N(T) = k) = \frac{(\lambda T)^k e^{-\lambda T}}{k!}$$

Equivalently, the inter-arrival time t_1 to the first catastrophic incident follows an exponential distribution $t_1 \sim \text{Exponential}(\lambda)$ with survival probability $\Pr(t_1 > T) = e^{-\lambda T}$. When a physical fleet qualification campaign completes with zero observed incidents ($k = 0$):

$$\Pr(N(T) = 0) = \frac{(\lambda T)^0 e^{-\lambda T}}{0!} = e^{-\lambda T}$$

To test whether the operational failure rate is below an acceptable target rate λ_{target}, we formulate the statistical hypothesis test:

$$H_0 : \lambda \geq \lambda_{\text{target}} \quad \text{versus} \quad H_1 : \lambda < \lambda_{\text{target}}$$

Under null hypothesis H_0 with rate λ_{target}, the probability of observing the zero-failure test outcome is $\Pr(N(T) = 0 \mid \lambda_{\text{target}}) = e^{-\lambda_{\text{target}} T}$. To reject H_0 at significance level α_{sig} (achieving confidence level $1-\alpha_{\text{sig}}$):

$$p\text{-value} = \Pr(N(T) \leq 0 \mid \lambda_{\text{target}}) = e^{-\lambda_{\text{target}} T} \leq \alpha_{\text{sig}}$$

Taking the natural logarithm of both sides:

$$-\lambda_{\text{target}} T \leq \ln \alpha_{\text{sig}} \iff T \geq \frac{-\ln \alpha_{\text{sig}}}{\lambda_{\text{target}}} = \frac{\ln(1/\alpha_{\text{sig}})}{\lambda_{\text{target}}}$$

DRAFT

For standard 95 percent confidence ($\alpha_{\text{sig}} = 0.05$), $-\ln(0.05) = \ln(20) \approx 2.99573227$. This yields the **continuous Rule of Three**:

$$T \geq \frac{2.99573}{\lambda_{\text{target}}} \approx \frac{3.0}{\lambda_{\text{target}}}$$

Unlike the discrete Bernoulli derivation which required a Taylor approximation for $\ln(1-p_{\text{fail}})$, the continuous Poisson bound $T \geq \frac{\ln(1/\alpha_{\text{sig}})}{\lambda_{\text{target}}}$ is **mathematically exact** across all values of $\lambda_{\text{target}} > 0$.

A.8.2.1 Systems arithmetic of the exposure wall

For an illustrative target of 1×10^{-9} failures per operating hour, the one-sided 95 percent bound requires 2.996×10^{9} zero-failure operating hours. At the less stringent hypothetical target of 1×10^{-6} per hour, it still requires 2.996×10^{6} hours. These are scenario targets, not rates assigned by a software assurance level or a functional-safety classification.

Parallelism reduces calendar time but not total exposure. Even 1,000 independent, configuration-equivalent robots operating continuously need 342.0 365-day calendar years at the stricter target. Shared environmental hazards and common software faults can invalidate that independence assumption. Pooling fleet hours requires a justified common rate and representative exposure.

The **Poisson Exposure Wall** limits what zero-event testing alone can establish. A change to policy weights, firmware, sensors, or the operating domain can alter the event process, so earlier hours do not automatically qualify the changed configuration. Reuse requires evidence that the relevant event rate and conditions remain applicable.

Architectural constraints, fault analysis, and runtime monitors therefore carry evidence that a feasible test campaign cannot supply. They are not unconditional guarantees either: a barrier filter or interlock depends on its plant model, sensing validity, fault assumptions, and timing contract. Section 7.7 uses the exposure bound to separate these evidence obligations.

A.8.3 Wald normal confidence interval breakdown and Clopper-Pearson exact bounds

In standard machine learning benchmarks, empirical success or failure rates are commonly summarized using the asymptotic Wald normal approximation. For k observed failures across N independent Bernoulli trials, the sample failure proportion is $\hat{p} = k/N$. The two-sided $(1-\alpha_{\text{sig}})$ Wald confidence interval is:

$$\text{CI}_{\text{Wald}} = \hat{p} \pm z_{1-\alpha_{\text{sig}}/2}\sqrt{\frac{\hat{p}(1-\hat{p})}{N}}$$

where $z_{1-\alpha_{\text{sig}}/2}$ is the standard normal critical value ($z_{1-\alpha_{\text{sig}}/2} \approx 1.96$ for 95 percent confidence).

A.8.3.1 The asymptotic collapse at zero failures ($k = 0$)

In physical autonomy qualification, candidate systems undergo zero-failure validation tests ($k = 0$). When $k = 0$, the sample proportion is $\hat{p} = 0$, causing the estimated variance $\hat{p}(1-\hat{p})/N$ to collapse to zero:

$$\text{CI}_{\text{Wald}}\Big|_{k=0} = 0 \pm z_{1-\alpha_{\text{sig}}/2}\sqrt{\frac{0(1-0)}{N}} = [0, 0]$$

The Wald interval asserts, at 95 percent confidence, that the failure probability is exactly zero after a finite test run. It ignores finite-sample uncertainty, and this particular interval excludes every nonzero failure rate. Repeated-sampling coverage of the Wald procedure is not identically zero, but can fall far below its nominal level near the boundary.

For a small nonzero true failure probability, $(1-p_{\text{fail}})^n$ can remain substantial, so a zero-failure campaign is not evidence of impossibility. The degenerate Wald interval confuses an estimated zero variance with zero uncertainty. Near the opposite boundary it has the same defect, and interior intervals can extend outside the valid probability range.

DRAFT

A.8.3.2 Clopper-Pearson exact binomial inversion

To maintain non-asymptotic statistical rigor, physical autonomy qualification can use **Clopper-Pearson exact binomial confidence intervals** (Clopper and Pearson 1934). The Clopper-Pearson interval $[p_L, p_U]$ inverts the exact binomial cumulative distribution function without normal approximations:

$$\sum_{x=k}^{N} \binom{N}{x} p_L^x (1-p_L)^{N-x} = \frac{\alpha_{\text{sig}}}{2}, \quad \sum_{x=0}^{k} \binom{N}{x} p_U^x (1-p_U)^{N-x} = \frac{\alpha_{\text{sig}}}{2}$$

By the identity connecting binomial sums to the regularized incomplete Beta function $I_{p_{\text{fail}}}(a,b)$:

$$\sum_{x=k}^{N} \binom{N}{x} p_{\text{fail}}^x (1-p_{\text{fail}})^{N-x} = I_{p_{\text{fail}}}(k, N-k+1) = \frac{1}{\text{B}(k, N-k+1)} \int_0^{p_{\text{fail}}} t^{k-1}(1-t)^{N-k}\, dt$$

for $0 < k < N$, these exact boundaries can be computed using quantiles of the Beta distribution:

$$p_L = \text{BetaQuantile}\left(\frac{\alpha_{\text{sig}}}{2}; k, N-k+1\right), \quad p_U = \text{BetaQuantile}\left(1-\frac{\alpha_{\text{sig}}}{2}; k+1, N-k\right)$$

At the endpoints, set $p_L = 0$ for $k = 0$ and $p_U = 1$ for $k = N$; the corresponding Beta distribution with a zero shape parameter is not defined.

A.8.3.3 Exact bounds at zero failures ($k = 0$)

When zero failures occur in physical testing ($k = 0$), the lower bound is $p_L = 0$. For a one-sided $(1-\alpha_{\text{sig}})$ upper confidence bound, the exact binomial condition simplifies to:

$$\Pr(X = 0) = \binom{n}{0} p_U^0 (1-p_U)^n = (1-p_U)^n = \alpha_{\text{sig}}$$

Solving directly for p_U:

$$1 - p_U = \alpha_{\text{sig}}^{1/n} \iff p_U = 1 - \alpha_{\text{sig}}^{1/n} = 1 - \exp\left(\frac{1}{n} \ln \alpha_{\text{sig}}\right)$$

Applying the Taylor expansion $e^u = 1 + u + \frac{u^2}{2} + \ldots$ with $u = \frac{\ln \alpha_{\text{sig}}}{n}$:

$$p_U = 1 - \left(1 + \frac{\ln \alpha_{\text{sig}}}{n} + \mathcal{O}(n^{-2})\right) = \frac{-\ln \alpha_{\text{sig}}}{n} + \mathcal{O}(n^{-2})$$

For $\alpha_{\text{sig}} = 0.05$, $-\ln(0.05) \approx 2.99573$, rigorously recovering the discrete Rule of Three: $p_U \approx 3/n$. For a two-sided 95 percent interval ($\alpha_{\text{sig}} = 0.05$, tail probability $\alpha_{\text{sig}}/2 = 0.025$):

$$p_U = 1 - (0.025)^{1/n} \approx \frac{-\ln(0.025)}{n} = \frac{3.68888}{n} \approx \frac{3.69}{n}$$

Unlike the degenerate Wald interval, the Clopper-Pearson interval guarantees exact non-asymptotic coverage of at least $1-\alpha_{\text{sig}}$ for every finite sample size $N \geq 1$.

A.9 Sequential Probability Ratio Test

Evaluating embodied physical policies on physical hardware is expensive and induces mechanical wear. A fixed-sample design predeclares sample count N for its planned acceptance decision and inference. A predeclared rejection rule may stop a failing campaign early, and physical safety can require termination at any time; neither decision requires continued exposure to an unsafe candidate. Early acceptance is different. Stopping when an accumulating result looks favorable and reporting the fixed-sample error guarantee can inflate false acceptance. Valid early acceptance requires a stopping rule with its own error calibration.

Abraham Wald's **Sequential Probability Ratio Test (SPRT)** (Wald 1945) handles optional stopping for two predeclared simple hypotheses by updating a likelihood ratio after each rollout and comparing it with stopping boundaries. Section 7.7.3 applies the test to the running machine's campaign in the same convention used here. The convention uses per-trial failure probability p, k failures in m trials, statistic Λ_m, null hypothesis the unacceptable p_0, and error allowances α_{sig} and β.

DRAFT

A.9.1 Log-likelihood ratio and Bernoulli updates

Across consecutive physical rollouts with independent trial outcomes $x_1, x_2, \ldots, x_m$, sequential testing compares two competing operational hypotheses:

- Null hypothesis H_0: The system failure probability is unacceptable ($p = p_0$).
- Alternative hypothesis H_1: The system failure probability meets the safety target ($p = p_1 < p_0$).

After observing m trials, the cumulative log-likelihood ratio Λ_m is:

$$\Lambda_m = \sum_{i=1}^{m} \ln \frac{\Pr(x_i \mid H_1)}{\Pr(x_i \mid H_0)}$$

For discrete Bernoulli trials where $x_i \in \{0,1\}$ (with $x_i = 1$ denoting task failure and $x_i = 0$ denoting task success), let $k = \sum_{i=1}^{m} x_i$ be the cumulative failure count across m runs. The log-likelihood ratio simplifies to the exact closed-form evaluation:

$$\Lambda_m = k \ln\left(\frac{p_1}{p_0}\right) + (m-k)\ln\left(\frac{1-p_1}{1-p_0}\right)$$

A.9.2 Wald stopping boundaries and decision rules

Wald's stopping rule rests on declared error rates. The Type I error rate α_{sig} is the maximum allowable probability of falsely accepting H_1 when H_0 is true. The Type II error rate β is the maximum allowable probability of falsely rejecting H_1 when H_1 is true. Testing then proceeds according to Wald's stopping rule:

$$\Lambda_{\text{lo}} < \Lambda_m < \Lambda_{\text{up}}$$

where the usual Wald boundary approximations are:

$$\Lambda_{\text{up}} = \ln\left(\frac{1-\beta}{\alpha_{\text{sig}}}\right), \quad \Lambda_{\text{lo}} = \ln\left(\frac{\beta}{1-\alpha_{\text{sig}}}\right)$$

At each evaluation step m:

1. If $\Lambda_m \geq \Lambda_{\text{up}}$: Halt and favor H_1 over the specified H_0 under the trial model; this is not a general safety certification.
2. If $\Lambda_m \leq \Lambda_{\text{lo}}$: Halt and favor H_0 over the specified H_1; do not release on this evidence.
3. If $\Lambda_{\text{lo}} < \Lambda_m < \Lambda_{\text{up}}$: The accumulated evidence remains inconclusive; execute rollout $m+1$.

Wald's approximate thresholds need calibration because the discrete log-likelihood increments can overshoot a boundary. Conservative alternatives are $\Lambda_{\text{up}} = \ln(1/\alpha_{\text{sig}})$ and $\Lambda_{\text{lo}} = \ln\beta$: the likelihood-ratio martingale under H_0 bounds false acceptance by α_{sig}, and the reciprocal under H_1 bounds false rejection by β. These guarantees apply to the declared simple hypotheses and observation model, not arbitrary deployment shifts.

A.9.3 Average sample number optimality

For Bernoulli failure probability p, the expected log-likelihood increment is

$$m(p) = p \ln\frac{p_1}{p_0} + (1-p)\ln\frac{1-p_1}{1-p_0}.$$

Let N_{stop} be the stopping sample count. Ignoring boundary overshoot and using the nominal endpoint error rates gives Wald's approximate average sample numbers

$$\mathbb{E}_{p_0}[N_{\text{stop}}] \approx \frac{\alpha_{\text{sig}}\Lambda_{\text{up}} + (1-\alpha_{\text{sig}})\Lambda_{\text{lo}}}{m(p_0)}, \qquad \mathbb{E}_{p_1}[N_{\text{stop}}] \approx \frac{(1-\beta)\Lambda_{\text{up}} + \beta\Lambda_{\text{lo}}}{m(p_1)}.$$

The denominators are the evidence gained per trial, negative under H_0 and positive under H_1. As the hypotheses approach each other, their magnitudes shrink and the required exposure grows.

DRAFT

For calibrated boundaries, use the actual operating characteristics and terminal overshoot rather than substituting nominal errors. A predeclared trial cap also changes the protocol and requires an explicit inconclusive outcome or recalibrated terminal rule.

For independent identically distributed outcomes under these two simple hypotheses, SPRT has an average-sample-number efficiency result relative to comparable tests.[9] Actual machine-hour savings depend on the two event probabilities, error allowances, overshoot at the stopping boundaries, and trial cost. The displayed thresholds are approximations; a finite-sample operating-characteristic calculation or calibrated simulation is needed for the chosen protocol.

[9] **Wald Sequential Probability Ratio Test**: The efficiency result assumes the specified simple hypotheses and independent, identically distributed outcomes. A sequential design can stop an unpromising test early without claiming a fixed percentage of saved robot hours.

A.10 Extreme Value Theory and Tail Risk

Average behavior does not determine the largest disturbance or latency spike a controller will encounter. The central limit theorem concerns normalized sums under conditions such as finite variance; it does not imply that individual observations or their far tails are Gaussian. Even a good Gaussian fit near the center can misstate rare exceedances.

For a genuinely Gaussian variable, a one-sided exceedance above k standard deviations has probability $1-\Phi(k)$, where Φ is the standard normal cumulative distribution function. Under independent samples at rate f, its mean waiting time is $1/[f(1-\Phi(k))]$. Correlation changes the clustering and waiting-time distribution, so a control-loop frequency alone does not establish an independent-trial rate.

A.10.1 Physical mechanisms that motivate tail analysis

Disturbances affecting structural survival and controller timing can arise from nonlinear or correlated mechanisms that a Gaussian sensor-noise model does not represent:

1. **Contact impact dynamics:** When an autonomous manipulator or mobile robot collides unexpectedly with a rigid obstacle, Hertzian contact mechanics govern the compressive force along the normal of each contact. This force is $f_{k,\perp} = k_c \delta^{3/2}$, where δ is deformation and the subscripts name the contact and its normal direction. When compliant protective covers bottom out against rigid metal chassis, contact stiffness shoots up discontinuously ($k_c \to k_\infty$), converting residual kinetic energy into sharp loads. The relation $F_{\text{unbraked}} = v\sqrt{mk_{\text{contact}}}$ applies to an ideal linear spring of stiffness k_{contact} absorbing kinetic energy, not to the Hertzian stiffness coefficient k_c.
2. **Mechanical friction transitions:** Stick-slip friction instability, drivetrain gear backlash, and structural resonance modes inject multiplicative, non-Gaussian torque transients into actuator gearboxes during rapid reversals.
3. **Real-time execution jitter:** On embedded systems, shared PCIe buses, memory cache thrashing, interrupt storms, and memory reclamation pauses produce tail latency spikes in control loops that break temporal determinism. Head-of-line blocking can amplify latency tails, but a Pareto service-time model requires evidence; bounded service times and arrival processes can produce different waiting-time tails.

These mechanisms motivate inspecting the measured tail; they do not prove a Pareto law. Bounded disturbances, exponential tails, lognormal tails, and power-law tails are all possible. **Extreme Value Theory (EVT)** supplies limiting models for maxima and threshold exceedances, with tail family and parameter uncertainty estimated from representative data. A positive shape parameter supports a power-law model over the validated range, not an assertion that every physical shock has infinite variance.

A.10.2 The Fisher-Tippett-Gnedenko theorem

While the Central Limit Theorem describes the limiting behavior of normalized sums, the **Fisher-Tippett-Gnedenko theorem** (Coles 2001) establishes the asymptotic behavior of normalized block maxima:

$$M_n = \max\{X_1, X_2, \ldots, X_n\}$$

Let $X_1, X_2, \ldots, X_n$ be a sequence of independent and identically distributed random variables with cumulative distribution function $F(x)$. If there exist normalizing sequences of real constants

$a_n > 0$ and $b_n \in \mathbb{R}$ such that the normalized block maximum converges to a non-degenerate limiting distribution $G(z)$:

$$\lim_{n\to\infty} \Pr\left(\frac{M_n - b_n}{a_n} \le z\right) = \lim_{n\to\infty} F^n(a_n z + b_n) = G(z)$$

then $G(z)$ belongs exclusively to the **Generalized Extreme Value (GEV)** family:[10]

$$G(z) = \exp\left(-\left[1+\xi\left(\frac{z-\mu}{\sigma}\right)\right]^{-1/\xi}\right)$$

defined on $\{z : 1+\xi(z-\mu)/\sigma > 0\}$, with location parameter $\mu \in \mathbb{R}$, scale parameter $\sigma > 0$, and shape parameter $\xi \in \mathbb{R}$. The shape parameter ξ partitions extreme behavior into three distinct tail regimes:

1. **Gumbel (Type I, $\xi = 0$):** The continuous limit as $\xi \to 0$:
$$G(z) = \exp\left(-\exp\left(-\frac{z-\mu}{\sigma}\right)\right)$$
including several unbounded tail forms, rather than only exponential tails. The maximum domain of attraction MDA(Gumbel) includes Gaussian, exponential, lognormal, and Gamma distributions.
2. **Fréchet (Type II, $\xi > 0$, with tail index $\alpha_{\text{tail}} = 1/\xi$):** The heavy-tailed regime where survival probabilities decay according to a polynomial power law: $\Pr(X > x) \sim x^{-\alpha_{\text{tail}}}$. The domain of attraction MDA(Fréchet) includes Pareto, Cauchy, and Student's t distributions. For a power-law density $p(x) \sim \alpha_{\text{tail}} x^{-\alpha_{\text{tail}}-1}$, the k-th raw moment evaluates to:
$$\mathbb{E}[X^k] = \int_{x_0}^{\infty} x^k p(x)\,dx \sim \alpha_{\text{tail}} \int_{x_0}^{\infty} x^{k-\alpha_{\text{tail}}-1}\,dx$$
This integral converges if and only if $k - \alpha_{\text{tail}} - 1 < -1 \iff k < \alpha_{\text{tail}} = 1/\xi$. For any moment order $k \ge 1/\xi$, the moment diverges to infinity ($\mathbb{E}[X^k] = \infty$). A direct mathematical consequence is that for $\xi \ge 0.5$ ($\alpha_{\text{tail}} \le 2$), the unbounded power-law model has **infinite variance** ($\text{Var}(X) = \infty$). The usual finite-variance central limit theorem then does not apply, and sample variance cannot converge to a finite population variance. For $\xi \ge 1.0$, the distribution has infinite mean. These are properties of an unbounded fitted model. Finite physical limits can truncate the tail, and a finite dataset cannot establish literal infinite moments.
3. **Weibull (Type III, $\xi < 0$):** Bounded distributions with a finite physical upper endpoint ($z \le \mu - \sigma/\xi$). The domain MDA(Weibull) includes Uniform and Beta distributions, applicable when hard physical limits (such as mechanically positive endstops) strictly bound the disturbance.

[10] **Tail Family Is an Empirical Claim**: A positive fitted GEV shape parameter ($\xi > 0$) provides formal evidence of heavy-tailed physical risk. It does not replace physical instrumentation: block size, temporal autocorrelation, threshold selection, and parameter uncertainty must be validated against real machine rollouts.

A.10.3 Peaks-over-threshold and generalized Pareto distribution

Block maxima analysis discards valuable extreme observations occurring within the same block (e.g., secondary collision shocks) and retains uninformative low maxima from quiescent blocks. The **Peaks-Over-Threshold (POT)** approach, formalized by the Pickands-Balkema-de Haan theorem (Coles 2001), analyzes all excess values $Y = X - u$ exceeding a sufficiently high physical threshold u:

$$F_u(y) = \Pr(X - u \le y \mid X > u) = \frac{F(u+y) - F(u)}{1 - F(u)}, \quad y \ge 0$$

The **Pickands-Balkema-de Haan theorem** proves that for a broad class of underlying physical distributions $F \in \text{MDA}(\text{GEV}_\xi)$, as threshold u approaches the right endpoint x_F:

$$\lim_{u\to x_F} \sup_{0\le y<x_F-u} |F_u(y) - H(y;\tilde{\sigma}(u),\xi)| = 0$$

where, for $\xi \neq 0$, $H(y)$ is the **Generalized Pareto Distribution (GPD)**:

$$H(y) = 1 - \left(1 + \frac{\xi y}{\tilde{\sigma}}\right)^{-1/\xi}$$

defined for $y \ge 0$ with $1 + \xi y/\tilde{\sigma} > 0$, with scale parameter $\tilde{\sigma} > 0$ and shape parameter ξ identical to the GEV shape parameter. For $\xi = 0$, take the continuous limit $H(y) = 1 - \exp(-y/\tilde{\sigma})$; for $\xi < 0$, the upper endpoint is $-\tilde{\sigma}/\xi$.

DRAFT

A.10.3.1 Threshold stability and mean residual life

A key property of the GPD is **threshold stability**. If the exceedances over threshold u_0 follow GPD$(\tilde{\sigma}_0, \xi)$, then for any higher threshold $u > u_0$ below the upper endpoint, the exceedances over u also follow a GPD with the *same* shape ξ and linearly shifted scale:

$$\tilde{\sigma}(u) = \tilde{\sigma}_0 + \xi(u - u_0)$$

The **Mean Residual Life (MRL)** evaluates the expected excess conditional on exceeding threshold u:

$$\mathbb{E}[X - u \mid X > u] = \int_0^{y_{\max}} [1 - H(y)]\, dy = \frac{\tilde{\sigma}(u)}{1 - \xi} \quad (\xi < 1),$$

where $y_{\max} = \infty$ for $\xi \geq 0$ and $y_{\max} = -\tilde{\sigma}(u)/\xi$ for $\xi < 0$. The exponential limit at $\xi = 0$ has mean $\tilde{\sigma}(u)$.

Substituting the threshold stability relation yields a strictly linear function of threshold u:

$$\mathbb{E}[X - u \mid X > u] = \frac{\tilde{\sigma}_0 + \xi(u - u_0)}{1 - \xi}$$

Systems engineers plot empirical mean excess against candidate thresholds u (the MRL plot); approximate linearity helps choose a candidate threshold, alongside parameter stability, dependence diagnostics, and uncertainty. It does not certify a unique mathematically valid threshold.

Given N_u exceedances $\{y_1, \ldots, y_{N_u}\}$ where $y_i = x_i - u > 0$, parameters $(\tilde{\sigma}, \xi)$ can be estimated via Maximum Likelihood Estimation (MLE), with the following expression for $\xi \neq 0$ and valid support:

$$\ln L(\tilde{\sigma}, \xi) = -N_u \ln \tilde{\sigma} - \left(1 + \frac{1}{\xi}\right) \sum_{i=1}^{N_u} \ln\left(1 + \frac{\xi y_i}{\tilde{\sigma}}\right)$$

Under the GPD model and regularity conditions, including $\xi > -1/2$, maximum-likelihood estimates have asymptotic normality and efficiency properties. Finite-sample bias, threshold choice, and clustered exceedances still affect the estimate.

A.10.4 Hardware margin and high-quantile sizing

Sizing physical hardware margins against an ultra-rare catastrophic event probability ϵ (e.g., $\epsilon = 10^{-7}$ per control cycle) requires extrapolating from N total operational cycles and N_u recorded threshold exceedances $(X > u)$. With empirical exceedance fraction $\hat{\zeta}_u = N_u/N > \epsilon$, the **high-quantile return level** z_ϵ satisfies $\Pr(X > z_\epsilon) = \epsilon$:

$$\begin{aligned} \Pr(X > z_\epsilon) &= \Pr(X > u) \Pr(X > z_\epsilon \mid X > u) \\ &= \hat{\zeta}_u [1 - H(z_\epsilon - u)] \\ &= \frac{N_u}{N} \left(1 + \frac{\xi(z_\epsilon - u)}{\tilde{\sigma}}\right)^{-1/\xi} = \epsilon \end{aligned}$$

Inverting this relation for z_ϵ:

$$\left(1 + \frac{\xi(z_\epsilon - u)}{\tilde{\sigma}}\right)^{-1/\xi} = \frac{N\epsilon}{N_u} \iff 1 + \frac{\xi(z_\epsilon - u)}{\tilde{\sigma}} = \left(\frac{N_u}{N\epsilon}\right)^{\xi}$$

Rearranging yields the closed-form return level formula:

$$z_\epsilon = u + \frac{\tilde{\sigma}}{\xi} \left[\left(\frac{N_u}{N\epsilon}\right)^{\xi} - 1 \right] \quad (\xi \neq 0)$$

Taking the continuous limit as $\xi \to 0$ using L'Hôpital's rule ($\lim_{\xi \to 0} \frac{a^\xi - 1}{\xi} = \ln a$):

$$z_\epsilon = u + \tilde{\sigma} \ln\left(\frac{N_u}{N\epsilon}\right) \quad (\xi = 0)$$

DRAFT

A.10.4.1 Systems engineering sizing rules

For a fitted positive shape parameter, the return level grows as a power of $1/\epsilon$; the exponential limit grows logarithmically. Those rates do not yield a numerical ratio between shock loads without matching thresholds, scales, and exceedance frequencies. Report parameter and model uncertainty with the return level, and keep the target unit explicit: a probability per sampled cycle is not a rate per operating hour.

A force quantile can inform spring travel through $\delta = z_\epsilon / k_{\text{spring}}$ only under a valid linear spring model; energy capacity and bottoming-out dynamics still require separate checks. A latency quantile can inform availability analysis, but a watchdog timeout must remain inside the plant's maximum tolerable delay even when some valid computations exceed it. If that interval is infeasible, the scheduling or fallback design must change.

Queue depth requires an arrival-and-service model converting a delay into accumulated packets or frames; taking the ceiling of a time-valued quantile is dimensionally invalid. Thermal sizing likewise needs the energy and repetition rate of braking events, not a peak-force quantile alone. EVT estimates a tail under stated assumptions; it supplies neither a deterministic maximum nor a guarantee against all future physical failures.

A.11 Further Reading

For a deeper foundational understanding of machine learning theory, sequential statistics, and extreme value modeling, consult the following authoritative references:

- **Deep Learning** (Goodfellow et al. 2016) provides a comprehensive treatment of neural network optimization, regularized representation learning, and Lipschitz sensitivity bounds.
- **An Introduction to Statistical Modeling of Extreme Values** (Coles 2001) establishes the definitive mathematical foundations for GEV, GPD, and tail risk quantification.
- **Sequential Tests of Statistical Hypotheses** (Wald 1945) develops the first-principles mathematical framework and average sample number optimality proofs for the Sequential Probability Ratio Test.
- **A Reduction of Imitation Learning and Structured Prediction to No-Regret Online Learning** (Ross et al. 2011) establishes the theoretical foundations of compounding error in imitation learning and derives the DAgger algorithm.

DRAFT

B

Control and Dynamics

This appendix collects the models needed to reason from a robot command to the motion it can produce. It develops state-space dynamics, feedback stability, trajectory continuity, stopping and contact bounds, and state-estimation uncertainty. Each result identifies the assumptions under which it can support a tracking or containment decision in the main text.

B.1 How to Use This Appendix

Use the table to enter at the physical question being checked. For a first encounter with control theory, start with state-space models and PID before consulting stability or constrained control. The longer Riccati, Lie-derivative, and differential-game derivations supply optional depth; the local model, assumptions, and resulting bound are the reference tools needed by the main text.

B.2 Classical and Modern State-Space Control

A robot moving toward a target retains velocity when a new command arrives. A state-space model records that memory explicitly: its state contains enough information to predict subsequent motion from the current state and future inputs. A learned policy can propose an input, but the plant dynamics determine how that input changes position, velocity, and stored energy.

The physical body is the **plant**, the system a controller acts on (section 2.4). Its state $\mathbf{x}(t)$ can include joint positions, velocities, winding currents, and temperatures. These quantities are physically constrained, but they are not all conserved. Actuators change their rates of change; they do not overwrite the state instantaneously. For a mass driven by force, for example, the state contains both position and velocity because force changes acceleration before it changes either of them.

B.2.1 Linear and nonlinear state-space representations

State-space equations track how a plant's internal state evolves under actuator commands and what sensors observe from that state. In the notation below, a dot denotes a time derivative, bold symbols collect coordinates into vectors or matrices, and matrix multiplication describes how one coordinate affects another. An eigenvalue describes the growth, decay, or oscillation of a linear mode; a negative real part means decay in continuous time, while discrete-time decay requires magnitude below one. A positive-definite matrix assigns a positive quadratic measure to every nonzero vector. These interpretations connect the algebra below to motion and stored energy.

A continuous-time Linear Time-Invariant (LTI) dynamic system is represented in canonical state-space form as:

$$\dot{\mathbf{x}}(t) = \mathbf{A}_{\text{sys}}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t)$$

$$\mathbf{y}(t) = \mathbf{H}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t)$$

where $\mathbf{x}(t) \in \mathbb{R}^n$ denotes the internal state vector (e.g., joint angles and velocities, motor winding currents, or vehicle pose and velocity), $\mathbf{u}(t) \in \mathbb{R}^m$ is the control input vector (e.g., commanded motor currents, voltages, or torques), and $\mathbf{y}(t) \in \mathbb{R}^p$ represents the measured output vector produced by physical sensors. The system matrix $\mathbf{A}_{\text{sys}} \in \mathbb{R}^{n\times n}$ governs unforced internal system dynamics (the natural drift vector field). The input matrix $\mathbf{B} \in \mathbb{R}^{n\times m}$ models control authority over state rates. The output matrix $\mathbf{H} \in \mathbb{R}^{p\times n}$ maps internal states to sensor measurements. The feedthrough matrix $\mathbf{D} \in \mathbb{R}^{p\times m}$ represents direct feedthrough, which vanishes in strictly proper physical plants ($\mathbf{D} = \mathbf{0}$).

When physical dynamics include kinematic nonlinearities, centrifugal couplings, or configuration-dependent gravity (section B.6.1), the dynamics generalize to the control-affine nonlinear form:

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)) + \mathbf{g}(\mathbf{x}(t))\mathbf{u}(t)$$

where $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^n$ is the unforced drift vector field and $\mathbf{g} : \mathbb{R}^n \to \mathbb{R}^{n\times m}$ is the state-dependent control effectiveness matrix.

B.2.1.1 Discrete-time equivalent under zero-order hold

Digital microcontrollers and real-time operating systems execute periodic control loops at sampling frequency $f_s = 1/T_s$ (e.g., 1 kHz, $T_s = 1$ ms; see section 4.3). When the actuator driver holds control

inputs constant across each clock tick using a Zero-Order Hold ($\mathbf{u}(t) = \mathbf{u}_k$ for $t \in [kT_s, (k+1)T_s)$), the continuous LTI dynamics integrate into the exact discrete-time recurrence:

$$\mathbf{x}_{k+1} = \mathbf{A}_d \mathbf{x}_k + \mathbf{B}_d \mathbf{u}_k$$

where the discrete transition operators evaluate via the continuous matrix exponential:

$$\mathbf{A}_d = e^{\mathbf{A}_{\text{sys}} T_s} = \mathbf{I} + \mathbf{A}_{\text{sys}} T_s + \frac{1}{2!}\mathbf{A}_{\text{sys}}^2 T_s^2 + \dots$$

$$\mathbf{B}_d = \int_0^{T_s} e^{\mathbf{A}_{\text{sys}} t'} dt' \, \mathbf{B} = \left(\mathbf{I} T_s + \frac{1}{2!}\mathbf{A}_{\text{sys}} T_s^2 + \dots \right) \mathbf{B}$$

When $\mathbf{A}_{\text{sys}}$ is non-singular, the discrete input matrix simplifies to $\mathbf{B}_d = \mathbf{A}_{\text{sys}}^{-1}(e^{\mathbf{A}_{\text{sys}} T_s} - \mathbf{I})\mathbf{B}$. This recurrence is exact for the stated LTI model with a held input. A nonlinear plant generally requires numerical integration or a local linear model; its discretization error must enter the prediction bound.

B.2.1.2 Discretization pathologies: Why forward Euler destabilizes physical models

To an ML engineer, a forward Euler discretization $\mathbf{x}_{k+1} \approx (\mathbf{I} + \mathbf{A}_{\text{sys}} T_s)\mathbf{x}_k + \mathbf{B} T_s \mathbf{u}_k = \mathbf{x}_k + T_s(\mathbf{A}_{\text{sys}} \mathbf{x}_k + \mathbf{B}\mathbf{u}_k)$ appears structurally identical to a Residual Network (ResNet) skip connection $\mathbf{x}_{k+1} = \mathbf{x}_k + \mathcal{F}(\mathbf{x}_k)$. However, in physical dynamical systems, Euler truncation introduces spurious numerical energy that can artificially destabilize the model or ruin gradient propagation in backpropagation through time.

Consider an undamped harmonic physical oscillator $\ddot{q} + \omega^2 q = 0$ with state $\mathbf{x} = [q, \dot{q}]^\top$ and continuous system matrix $\mathbf{A}_{\text{sys}} = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix}$. The continuous eigenvalues are purely imaginary: $\lambda = \pm j\omega$. Analyzing how common numerical discretization schemes map these eigenvalues to the complex z-plane illustrates their stability properties:

1. **Exact Zero-Order Hold (Matrix Exponential):** The discrete transition operator is $\mathbf{A}_d = e^{\mathbf{A}_{\text{sys}} T_s}$. Its eigenvalues lie on the unit circle:

   $$|\lambda(\mathbf{A}_d)| = |e^{\pm j\omega T_s}| = 1$$

   This preserves the physical total energy $E = \frac{1}{2}\dot{q}^2 + \frac{1}{2}\omega^2 q^2$ over infinite horizons without artificial growth or decay. Phase rotates at the true angular rate ωT_s per step.

2. **Forward Euler Discretization:** Approximating the transition as $\mathbf{A}_{\text{FE}} = \mathbf{I} + \mathbf{A}_{\text{sys}} T_s = \begin{bmatrix} 1 & T_s \\ -\omega^2 T_s & 1 \end{bmatrix}$ yields eigenvalues $\lambda_{\text{FE}} = 1 \pm j\omega T_s$. Their complex modulus is:

   $$|\lambda_{\text{FE}}| = \sqrt{1 + \omega^2 T_s^2} > 1 \quad \forall T_s > 0$$

   Because the spectral radius strictly exceeds unity, forward Euler simulation injects artificial numerical energy at every step, converting an intrinsically conservative physical oscillator into an exponentially diverging explosion. In differentiable simulation and policy learning, this causes exploding gradients during backpropagation through time.

3. **Backward (Implicit) Euler Discretization:** Approximating transitions via $\mathbf{x}_{k+1} = \mathbf{x}_k + T_s \mathbf{A}_{\text{sys}} \mathbf{x}_{k+1}$ yields $\mathbf{A}_{\text{BE}} = (\mathbf{I} - \mathbf{A}_{\text{sys}} T_s)^{-1}$. The discrete eigenvalues evaluate to $\lambda_{\text{BE}} = \frac{1}{1 \mp j\omega T_s}$, with modulus:

   $$|\lambda_{\text{BE}}| = \frac{1}{\sqrt{1 + \omega^2 T_s^2}} < 1 \quad \forall T_s > 0$$

   While unconditionally stable, backward Euler introduces artificial numerical dissipation (numerical damping) that bleeds energy from the physical system. In unrolled optimization, that artificial contraction causes gradient vanishing over long horizons.

DRAFT

4. **Bilinear (Tustin / Crank-Nicolson) Discretization:** Employing the trapezoidal integration operator $s \approx \frac{2}{T_s}\frac{z-1}{z+1}$ yields:

$$\mathbf{A}_{\text{Tustin}} = \left(\mathbf{I} - \frac{T_s}{2}\mathbf{A}_{\text{sys}}\right)^{-1}\left(\mathbf{I} + \frac{T_s}{2}\mathbf{A}_{\text{sys}}\right)$$

For purely imaginary continuous poles $s = \pm j\omega$, the discrete eigenvalues evaluate to $\lambda_{\text{Tustin}} = \frac{1 \pm j\omega T_s/2}{1 \mp j\omega T_s/2}$. Their modulus is identically unity:

$$|\lambda_{\text{Tustin}}| = \left|\frac{1 \pm j\omega T_s/2}{1 \mp j\omega T_s/2}\right| = \frac{\sqrt{1 + (\omega T_s/2)^2}}{\sqrt{1 + (\omega T_s/2)^2}} = 1 \quad \forall T_s > 0$$

The bilinear transform maps the continuous imaginary axis directly onto the discrete unit circle, preserving energy conservation without matrix exponentials. Higher frequencies undergo frequency warping, however, because $\arctan(\omega T_s/2)$ compresses the phase advance per step.

5. **Semi-Implicit (Symplectic) Euler Discretization:** Staggering state updates by updating velocity with current acceleration and then updating position with the updated velocity:

$$v_{k+1} = v_k - \omega^2 T_s q_k, \quad q_{k+1} = q_k + T_s v_{k+1} = (1 - \omega^2 T_s^2) q_k + T_s v_k$$

yields the discrete transition matrix:

$$\mathbf{A}_{\text{symp}} = \begin{bmatrix} 1 - \omega^2 T_s^2 & T_s \\ -\omega^2 T_s & 1 \end{bmatrix}$$

The determinant evaluates to $\det(\mathbf{A}_{\text{symp}}) = (1 - \omega^2 T_s^2)(1) - (T_s)(-\omega^2 T_s) = 1$ identically for all $T_s > 0$. For this oscillator, the method is symplectic and preserves phase-space area. It conserves a modified quadratic energy rather than the original energy exactly; determinant one alone does not establish symplecticity in higher dimensions. For stable step sizes ($\omega T_s < 2$), physical energy oscillates within bounded limits over infinite horizons rather than exploding or vanishing. The bounded energy error makes this method useful for conservative mechanical models, although contact, damping, and solver choices require separate analysis.

The integrator and step size must preserve the behavior needed by the application. Forward Euler can be adequate for sufficiently resolved dissipative dynamics; this undamped oscillator shows why a small step alone does not guarantee long-horizon energy fidelity. Sampling adds a separate phase effect (section B.5.5).

B.2.2 Controllability and the Kalman rank condition

In deep learning, model capacity measures whether a neural architecture possesses the expressivity to represent a desired target function class. In physical systems, **controllability** addresses a more basic structural question, namely whether the physical actuator allocation $\mathbf{B}$ provides sufficient authority to steer the plant's internal state $\mathbf{x}$ to an arbitrary target configuration across the continuous dynamic transition graph $\mathbf{A}_{\text{sys}}$.

An LTI system $(\mathbf{A}_{\text{sys}}, \mathbf{B})$ is **controllable** if, for any initial state $\mathbf{x}(0) = \mathbf{x}_0$ and any desired target state $\mathbf{x}_f$, there exists a finite time $T > 0$ and an unconstrained input trajectory $\mathbf{u}(t)$ that transfers the state from $\mathbf{x}_0$ to $\mathbf{x}_f$. This test does not impose actuator, state, or path limits. Under that unconstrained LTI model, the condition holds if and only if the **controllability matrix** $\mathbf{C}_{\text{ctrb}}$ has full row rank:

$$\mathbf{C}_{\text{ctrb}} = \begin{bmatrix} \mathbf{B} & \mathbf{A}_{\text{sys}}\mathbf{B} & \mathbf{A}_{\text{sys}}^2\mathbf{B} & \dots & \mathbf{A}_{\text{sys}}^{n-1}\mathbf{B} \end{bmatrix} \in \mathbb{R}^{n \times nm}, \quad \text{rank}(\mathbf{C}_{\text{ctrb}}) = n$$

Each column block $\mathbf{A}_{\text{sys}}^k\mathbf{B}$ represents the directional reach of the control input after k steps of dynamic diffusion through the unforced system matrix $\mathbf{A}_{\text{sys}}$. The column space $\text{im}(\mathbf{C}_{\text{ctrb}})$ defines the **controllable subspace**, mathematically equivalent to the n-th order Krylov subspace $\mathcal{K}_n(\mathbf{A}_{\text{sys}}, \text{im}(\mathbf{B})) = \text{span}\{\mathbf{B}, \mathbf{A}_{\text{sys}}\mathbf{B}, \dots, \mathbf{A}_{\text{sys}}^{n-1}\mathbf{B}\}$.

DRAFT

The matrix sequence terminates at power $n-1$ because the **Cayley-Hamilton theorem** states that every square matrix $\mathbf{A}_{\text{sys}} \in \mathbb{R}^{n\times n}$ satisfies its own characteristic polynomial $p(\mathbf{A}_{\text{sys}}) = \mathbf{0}$, where:

$$p(\lambda) = \det(\lambda\mathbf{I} - \mathbf{A}_{\text{sys}}) = \lambda^n + c_{n-1}\lambda^{n-1} + \cdots + c_1\lambda + c_0$$

Substituting $\mathbf{A}_{\text{sys}}$ into its polynomial yields:

$$\mathbf{A}_{\text{sys}}^n = -c_{n-1}\mathbf{A}_{\text{sys}}^{n-1} - c_{n-2}\mathbf{A}_{\text{sys}}^{n-2} - \cdots - c_1\mathbf{A}_{\text{sys}} - c_0\mathbf{I}$$

Multiplying repeatedly by $\mathbf{A}_{\text{sys}}$ demonstrates that every higher power $\mathbf{A}_{\text{sys}}^k$ for $k \geq n$ can be expressed as a linear combination of the lower powers $\{\mathbf{I}, \mathbf{A}_{\text{sys}}, \ldots, \mathbf{A}_{\text{sys}}^{n-1}\}$. Consequently, adding higher powers $\mathbf{A}_{\text{sys}}^k\mathbf{B}$ for $k \geq n$ cannot increase the dimension of the subspace spanned by the columns of $\mathbf{C}_{\text{ctrb}}$.

If $\text{rank}(\mathbf{C}_{\text{ctrb}}) < n$, the state space decomposes into a controllable subspace and an uncontrollable component in suitable coordinates. The controllability matrix $\mathbf{C}_{\text{ctrb}}$ evaluates whether control inputs can reach all n state dimensions through powers of $\mathbf{A}_{\text{sys}}$. It is exactly dual to the observability matrix $\mathbf{O}_{\text{obs}}$ (section B.8), which evaluates whether sensor outputs can distinguish all n state dimensions.

The Popov-Belevitch-Hautus (PBH) test provides an equivalent spectral condition: the pair $(\mathbf{A}_{\text{sys}}, \mathbf{B})$ is controllable if and only if:

$$\text{rank}\left(\begin{bmatrix}\lambda\mathbf{I} - \mathbf{A}_{\text{sys}} & \mathbf{B}\end{bmatrix}\right) = n \quad \forall\lambda \in \mathbb{C}$$

If $\text{rank}([\lambda\mathbf{I} - \mathbf{A}_{\text{sys}}, \mathbf{B}]) < n$ for some eigenvalue λ, the dynamic mode associated with λ cannot be excited or influenced by any control input. If that uncontrollable mode is unstable ($\text{Re}(\lambda) \geq 0$), the physical plant is un-stabilizable, an unyielding physical limitation that no learned policy, foundation model, or reinforcement learning algorithm can overcome. Underactuation alone does not imply uncontrollability. Dynamic coupling can make an indirectly actuated state controllable; floating-base systems additionally depend on the available contacts (section B.9).

B.2.3 Proportional-integral-derivative control as closed-loop error dissipation

When an arm link sags 4 mm below its target height under a 3 kg payload, position feedback pulls the joint toward the target, velocity feedback bleeds off overshoot, and accumulated-error feedback builds the extra torque needed to hold the load at zero steady-state offset. A joint-level **Proportional-Integral-Derivative (PID)** controller combines position error, accumulated error, and error rate to generate effort. For a simple mechanical plant, these terms act as a restoring spring, bias compensation, and damping. This interpretation explains their roles; PID is not generally an optimal controller, and positive gains alone do not guarantee stability.

In this subsection, let $\mathbf{x}^*(t)$ and $\mathbf{x}(t)$ denote desired and measured joint positions, rather than the full position-velocity state. Their difference defines the instantaneous tracking error:

$$\mathbf{e}(t) = \mathbf{x}^*(t) - \mathbf{x}(t)$$

The continuous PID control law synthesizes commanded control effort $\mathbf{u}(t)$ (e.g., motor drive current, electromagnetic torque, or hydraulic valve pressure) as:

$$\mathbf{u}(t) = \mathbf{K}_p\mathbf{e}(t) + \mathbf{K}_i\int_0^t \mathbf{e}(t')\,dt' + \mathbf{K}_d\dot{\mathbf{e}}(t)$$

where $\mathbf{K}_p, \mathbf{K}_i, \mathbf{K}_d \in \mathbb{R}^{n\times n}$ are symmetric, positive-definite gain matrices. For the energy argument below, assume a fixed setpoint, a constant scalar inertia $m > 0$, and no saturation. Each term has a distinct role:

1. **Proportional Term ($\mathbf{K}_p\mathbf{e}$): Conservative Restoring Force / Gradient Descent:** Consider an artificial quadratic potential loss landscape $\mathcal{L}_{\text{pos}}(\mathbf{e}) = \frac{1}{2}\mathbf{e}^\top\mathbf{K}_p\mathbf{e}$. Because $\mathbf{e} = \mathbf{x}^* - \mathbf{x}$, the restoring force is the negative gradient with respect to position, $-\nabla_{\mathbf{x}}\mathcal{L}_{\text{pos}} = \mathbf{K}_p\mathbf{e}$. Proportional feedback behaves as an elastic spring or continuous negative gradient step that pulls the physical coordinates toward the reference setpoint. However, on an undamped second-order plant ($m\ddot{\mathbf{x}} = \mathbf{u}$), proportional feedback alone generates an undamped harmonic oscillator $m\ddot{\mathbf{e}} + \mathbf{K}_p\mathbf{e} = \mathbf{0}$. The system conserves total mechanical energy $E = \frac{1}{2}m\|\dot{\mathbf{e}}\|^2 + \frac{1}{2}\mathbf{e}^\top\mathbf{K}_p\mathbf{e}$, orbiting closed level curves indefinitely with zero asymptotic convergence.

DRAFT

2. **Derivative Term ($\mathbf{K}_d\dot{\mathbf{e}}$): Rayleigh Dissipation / Momentum Damping:** To force convergence to the origin, kinetic energy must be extracted from the closed loop. The derivative term introduces an artificial viscous damper or Rayleigh dissipation function $\mathcal{D}(\dot{\mathbf{e}}) = \frac{1}{2}\dot{\mathbf{e}}^\top \mathbf{K}_d \dot{\mathbf{e}}$. Differentiating the closed-loop mechanical energy $E(\mathbf{e}, \dot{\mathbf{e}})$ along plant trajectories under PD feedback yields:

$$\dot{E} = m\dot{\mathbf{e}}^\top \ddot{\mathbf{e}} + \dot{\mathbf{e}}^\top \mathbf{K}_p \mathbf{e} = \dot{\mathbf{e}}^\top \left(-\mathbf{K}_p \mathbf{e} - \mathbf{K}_d \dot{\mathbf{e}}\right) + \dot{\mathbf{e}}^\top \mathbf{K}_p \mathbf{e} = -\dot{\mathbf{e}}^\top \mathbf{K}_d \dot{\mathbf{e}} \leq 0$$

   Because $\mathbf{K}_d \succ \mathbf{0}$, the derivative term converts tracking kinetic energy into continuous dissipation, damping oscillations and, for this plant, steering closed-loop poles into the open left-half complex plane. In machine learning optimization, this is analogous to the friction term in the continuous heavy-ball model used to stabilize gradient oscillations across steep ravines.

3. **Integral Term ($\mathbf{K}_i \int_0^t \mathbf{e}(t')\, dt'$): Online Disturbance / Unmodeled Bias Estimation:** In physical deployments, constant external loads $\mathbf{d}_{\text{ext}}$, such as gravitational sagging on robot arm links, cable friction, or payload offsets, induce a steady-state standoff. At rest ($\dot{\mathbf{e}} = \mathbf{0}, \ddot{\mathbf{e}} = \mathbf{0}$), a PD controller yields $\mathbf{K}_p \mathbf{e}_{\text{ss}} + \mathbf{d}_{\text{ext}} = \mathbf{0}$, leaving a persistent tracking error $\mathbf{e}_{\text{ss}} = -\mathbf{K}_p^{-1}\mathbf{d}_{\text{ext}}$. The integral term introduces an internal dynamic state variable:

$$\dot{\mathbf{z}}(t) = \mathbf{e}(t), \quad \mathbf{u}_{\text{int}}(t) = \mathbf{K}_i \mathbf{z}(t)$$

   Accumulating tracking error over time forces $\mathbf{z}(t)$ to integrate until $\mathbf{K}_i \mathbf{z}_{\text{ss}} = -\mathbf{d}_{\text{ext}}$, counteracting the disturbance and driving steady-state position error to zero ($\mathbf{e}_{\text{ss}} \to \mathbf{0}$). In optimization terms, the integral term acts as an online running bias estimator that dynamically learns and cancels constant model mismatch.

For a scalar single-degree-of-freedom mechanical plant with mass m, the closed-loop error equation under PD control evaluates to:

$$\ddot{e}(t) + 2\zeta\omega_n \dot{e}(t) + \omega_n^2 e(t) = 0$$

where the undamped natural frequency is $\omega_n = \sqrt{K_p/m}$ and the dimensionless damping ratio is $\zeta = \frac{K_d}{2\sqrt{mK_p}}$. The characteristic roots $s_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{\zeta^2 - 1}$ partition the closed-loop tracking response into three physical regimes:

- **Underdamped ($0 < \zeta < 1$):** Complex conjugate poles; fast initial rise time but decaying ringing oscillations and overshoot that can damage mechanical gearboxes.
- **Critically Damped ($\zeta = 1$):** Repeated real negative root $s = -\omega_n$; for fixed ω_n, gives the fastest nonoscillatory step response from rest in this second-order model.
- **Overdamped ($\zeta > 1$):** Distinct negative real roots; gives a slower nonoscillatory step response from rest. Other initial velocities can still produce a setpoint crossing.

B.2.3.1 Practical firmware implementation: Anti-windup and derivative filtering

While textbook PID assumes infinite actuator authority and continuous differentiation, deploying PID loops on physical robot joints exposes two cyber-physical pathologies:

1. **Derivative Kick and Noise Amplification:** In textbook PID, the derivative term evaluates error rate $\mathbf{u}_d = \mathbf{K}_d\dot{\mathbf{e}} = \mathbf{K}_d(\dot{\mathbf{q}}^* - \dot{\mathbf{q}})$. When a learned policy or planner issues a step setpoint or hands over between action chunks (section 14.4), the sudden change in reference setpoint $\mathbf{q}^*$ creates an impulsive derivative spike $\dot{\mathbf{q}}^* \approx \infty$ (derivative kick). The spike commands explosive actuator torques and can trigger current limiting or an inverter fault. Furthermore, discrete differentiation of quantized encoder signals amplifies high-frequency measurement noise as $\mathcal{O}(\omega)$. Production firmware resolves this by differentiating *solely on the measured plant state* ($\mathbf{u}_d = -\mathbf{K}_d\dot{\mathbf{q}}$) and routing the velocity through a first-order low-pass filter:

$$\mathbf{u}_d(s) = -\frac{\mathbf{K}_d s}{T_f s + 1}\mathbf{q}(s)$$

   where $T_f > 0$ sets the derivative filter roll-off frequency, preserving damping in the control band while limiting the high-frequency gain that an ideal differentiator would amplify without bound.

DRAFT

2. **Actuator Saturation and Integral Windup:** Physical actuators are strictly bounded by torque and thermal current limits ($\tau_{\text{min}} \leq \tau \leq \tau_{\text{max}}$). When a large disturbance or aggressive maneuver pushes commanded torque past physical limits, the physical plant cannot accelerate fast enough to eliminate tracking error. Meanwhile, the integral term continues accumulating error unhindered, winding up the internal dynamic state $\mathbf{z}(t)$ to excessive values. Once the plant finally reaches the setpoint, the stored integrator charge forces the actuator to remain saturated in the forward direction, causing violent overshoot, severe limit-cycle hunting, and structural collisions. Real-time motor firmware implements **anti-windup circuitry**: clamping the integrator state whenever actuator limits are reached, or employing back-calculation:

$$\dot{\mathbf{z}}(t) = \mathbf{e}(t) + \frac{1}{T_t}\mathbf{K}_i^{-1}\left(\tau_{\text{act}}(t) - \tau_{\text{cmd}}(t)\right)$$

where $\mathbf{u} = \tau$, the invertible integral gain converts the torque mismatch back to error-integral units, $T_t > 0$ is a tracking time constant and $\tau_{\text{act}} = \text{clip}(\tau_{\text{cmd}}, \tau_{\text{min}}, \tau_{\text{max}})$. When the actuator is unsaturated ($\tau_{\text{act}} = \tau_{\text{cmd}}$), standard integration proceeds. When the actuator is saturated, the mismatch feeds back to discharge the integrator dynamically, reducing the excess stored integral command upon desaturation. With integral action, stability must be checked again: for the scalar mass model, positive gains must also satisfy $K_d K_p > m K_i$.

B.2.4 Feedback linearization: Transforming nonlinear dynamics into decoupled double integrators

Swinging a manipulator's elbow outward changes the shoulder's effective inertia and injects centrifugal torque into the shoulder joint, so fixed linear gains tuned with the arm tucked become sluggish or oscillatory when the arm extends. Multi-body robotic plants are governed by coupled, configuration-dependent equations of motion (section 2.4):

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \tau$$

where $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{n \times n}$ is the configuration-dependent mass matrix, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}$ collects velocity-dependent generalized forces, $\mathbf{g}(\mathbf{q})$ is gravity, and $\tau \in \mathbb{R}^n$ is the joint torque vector.

To cancel those configuration-dependent couplings, **feedback linearization** (implemented here as **computed torque control**) uses a model of inertia, velocity coupling, and gravity to turn a requested joint acceleration into torque. The cancellation below assumes a fully actuated rigid-link model, valid joint coordinates, exact parameters, and sufficient actuator authority. It does not apply unchanged to a floating base or to saturated drives.

Because the physical inertia matrix $\mathbf{M}(\mathbf{q})$ is symmetric and strictly positive definite everywhere on the configuration space ($\mathbf{M}(\mathbf{q}) = \mathbf{M}(\mathbf{q})^\top \succ \mathbf{0}$), it is globally invertible. We define the nonlinear state-feedback control law:

$$\tau = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}}^* + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})$$

where $\ddot{\mathbf{q}}^* \in \mathbb{R}^n$ is a synthetic, virtual acceleration command. Substituting this control law directly into the physical equations of motion yields:

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}}^* + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})$$

Subtracting the identical Coriolis and gravity vectors from both sides isolates:

$$\mathbf{M}(\mathbf{q})\left(\ddot{\mathbf{q}} - \ddot{\mathbf{q}}^*\right) = \mathbf{0}$$

Because $\mathbf{M}(\mathbf{q})$ is non-singular, multiplying by $\mathbf{M}(\mathbf{q})^{-1}$ collapses the coupled nonlinear plant into n decoupled, linear double-integrator channels:

$$\ddot{\mathbf{q}} = \ddot{\mathbf{q}}^* \iff \ddot{q}_i = \ddot{q}_i^* \quad \forall i \in \{1, \ldots, n\}$$

Over these decoupled channels, linear tracking control laws synthesize virtual acceleration commands with global exponential stability:

$$\ddot{\mathbf{q}}^* = \ddot{\mathbf{q}}^{\text{ref}} + \mathbf{K}_p(\mathbf{q}^{\text{ref}} - \mathbf{q}) + \mathbf{K}_d(\dot{\mathbf{q}}^{\text{ref}} - \dot{\mathbf{q}})$$

DRAFT

Substituting $\ddot{\mathbf{q}}^*$ back into the double-integrator dynamics reveals that the tracking error $\mathbf{e}(t) = \mathbf{q}^{\text{ref}}(t) - \mathbf{q}(t)$ satisfies the linear error ODE:

$$\ddot{\mathbf{e}} + \mathbf{K}_d \dot{\mathbf{e}} + \mathbf{K}_p \mathbf{e} = \mathbf{0}$$

Choosing positive-diagonal gain matrices $\mathbf{K}_p$ and $\mathbf{K}_d$ guarantees that tracking errors in every joint coordinate decouple and decay to zero independently at the designer-specified rate. Each joint then behaves as an independent second-order oscillator whose natural frequency and damping ratio follow directly from its diagonal gain pair.

B.2.4.1 Lie-derivative formulation for general control-affine systems

A general control-affine nonlinear dynamical system has a state rate $\dot{\mathbf{x}}$ that is a drift field $\mathbf{f}(\mathbf{x})$ plus an input matrix field applied linearly to $\mathbf{u}$, and an output $\mathbf{y} = \mathbf{h}(\mathbf{x})$. For such systems, feedback linearization differentiates each output channel y_ℓ with respect to continuous time until the control input $\mathbf{u}$ appears explicitly:

$$y_\ell^{(r_\ell)} = L_{\mathbf{f}}^{r_\ell} h_\ell(\mathbf{x}) + L_{\mathbf{g}} L_{\mathbf{f}}^{r_\ell - 1} h_\ell(\mathbf{x}) \mathbf{u}$$

where r_ℓ is the relative degree of output ℓ. Collecting all output channels into vector form:

$$\mathbf{y}^{(r)} = \mathbf{b}(\mathbf{x}) + \mathbf{E}(\mathbf{x}) \mathbf{u}$$

where $\mathbf{E}(\mathbf{x}) \in \mathbb{R}^{p \times m}$ is the **decoupling matrix** whose entries are Lie derivatives $E_{\ell,j}(\mathbf{x}) = L_{\mathbf{g}_j} L_{\mathbf{f}}^{r_\ell - 1} h_\ell(\mathbf{x})$. If $\mathbf{E}(\mathbf{x})$ is square ($p = m$) and non-singular across the operating envelope, the state-feedback law:

$$\mathbf{u} = \mathbf{E}(\mathbf{x})^{-1} \left(\mathbf{v} - \mathbf{b}(\mathbf{x}) \right)$$

cancels the modeled nonlinearities in the output equations, yielding $\mathbf{y}^{(r)} = \mathbf{v}$. Here $L_{\mathbf{f}} h = \nabla h^\top \mathbf{f}$ is the rate of change of h along $\mathbf{f}$, and repeated Lie derivatives differentiate that rate again. If $\sum_\ell r_\ell$ is less than the dimension of $\mathbf{x}$, internal states remain outside this input-output description; their zero dynamics must also be stable.

Unlike deep learning architectures where model inaccuracies are accommodated by statistical loss minimization, computed torque control assumes perfect knowledge of physical parameters ($\mathbf{M}, \mathbf{C}, \mathbf{g}$). In real hardware, parametric inaccuracies (uncertain link masses, payload variations) leave residual nonlinear perturbations $\Delta\mathbf{f} = (\mathbf{M} - \hat{\mathbf{M}})\ddot{\mathbf{q}} + (\mathbf{C} - \hat{\mathbf{C}})\dot{\mathbf{q}} + (\mathbf{g} - \hat{\mathbf{g}})$. Physical AI architectures resolve this by pairing feedback linearization with robust inner loops (sliding-mode control or H_∞ disturbance observers) or online adaptive parameter estimators.

In modern physical AI architectures, computed torque control also provides an analytical, differentiable physics inductive bias for learned policies. Rather than forcing a high-capacity neural network to learn the entire multi-body dynamics from scratch, the system splits torque synthesis into a nominal analytical dynamics model and a learned residual policy:

$$\tau = \hat{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}}^* + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \hat{\mathbf{g}}(\mathbf{q}) + \tau_{\text{res},\theta}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}^*)$$

The baseline physics model cancels the dominant, known multi-body nonlinearities, while the neural network $\tau_{\text{res},\theta}$ is trained via reinforcement learning or imitation learning to capture unmodeled physical effects: joint cable friction, transmission backlash, hydrodynamic drag, and payload variations. This hybrid formulation can reduce the dynamics a policy must learn, but does not preserve baseline stability automatically. The residual needs an amplitude or energy bound compatible with the nominal controller, and the combined command must satisfy actuator limits.

B.2.5 Linear quadratic regulator and algebraic Riccati equations

In reinforcement learning (section 6.2.1), policy optimization searches for an action policy $\pi_\theta(\mathbf{a} \mid s)$ that maximizes expected cumulative reward via trial-and-error sampling or learned critic networks $V_\phi(s)$ / $Q_\phi(s, \mathbf{a})$. This search frequently struggles with high gradient variance, non-convex loss landscapes, and empirical stability failures. In contrast, for linear-quadratic physical dynamics, the **Linear Quadratic Regulator (LQR)** provides the exact, analytical solution to the continuous-state Bellman optimality equation over an infinite time horizon, as summarized against reinforcement learning below:

DRAFT

Dimension	Reinforcement Learning (Actor-Critic / Policy Gradient)	Linear Quadratic Regulator (LQR)
Value Function (Critic)	Parameterized deep neural network $V_\phi(s)$ or $Q_\phi(s,\mathbf{a})$	Exact quadratic potential $V^*(\mathbf{x}) = \mathbf{x}^\top \mathbf{P}\mathbf{x}$
Policy (Actor)	Parameterized neural network $\mathbf{a} \sim \pi_\theta(\cdot \mid s)$	Optimal linear state feedback $\mathbf{u}^* = -\mathbf{K}_{\text{lqr}}\mathbf{x}$
Bellman Optimality	Dynamic programming fixed point: $V^*_{\text{RL}}(s) = \max_{\mathbf{a}}[r(s,\mathbf{a}) + \gamma \mathbb{E}[V^*_{\text{RL}}(s')]]$	Continuous Algebraic Riccati Equation (ARE fixed point)
Solution Method	Stochastic gradient descent (PPO, SAC), TD learning	Direct algebraic factorizations (Schur decomposition, ARE solvers)
Stability Guarantees	Not supplied by empirical reward optimization alone	Stable under the stated model and rank conditions; ideal full-state margins below
Sample Complexity	Requires task- and algorithm-dependent training data	No policy-training samples once $(\mathbf{A}_{\text{sys}}, \mathbf{B}, \mathbf{Q}_x, \mathbf{R}_u)$ are specified; identifying the model still needs evidence

Given the controllable continuous LTI system $\dot{\mathbf{x}} = \mathbf{A}_{\text{sys}}\mathbf{x} + \mathbf{B}\mathbf{u}$, the infinite-horizon regulator minimizes the quadratic performance objective:

$$J = \int_0^\infty \left(\mathbf{x}(t)^\top \mathbf{Q}_x \mathbf{x}(t) + \mathbf{u}(t)^\top \mathbf{R}_u \mathbf{u}(t)\right) dt$$

Here the two weighting matrices price state error against actuator effort:

- $\mathbf{Q}_x \in \mathbb{R}^{n\times n}$ is a symmetric positive semi-definite state penalty matrix ($\mathbf{Q}_x \succeq \mathbf{0}$), penalizing deviations from the target state $\mathbf{x}^* = \mathbf{0}$.
- $\mathbf{R}_u \in \mathbb{R}^{m\times m}$ is a symmetric positive definite control penalty matrix ($\mathbf{R}_u \succ \mathbf{0}$), penalizing control effort.

The weights express a trade-off, not hard physical limits. Increasing $\mathbf{R}_u$ discourages effort, while increasing $\mathbf{Q}_x$ discourages state error. Neither guarantees a current ceiling, a torque slew rate, or a position bound. Those requirements need explicit constraints, such as the MPC formulation below, or a separate admissibility check (section 2.4).

B.2.5.1 Dynamic programming derivation of continuous LQR

In continuous time, Bellman's principle of optimality (Bellman 1957; Åström and Murray 2021) states that the optimal cost-to-go from state $\mathbf{x}(t)$ across an infinitesimal time step $\Delta t \to 0$ satisfies:

$$V^*(\mathbf{x}(t)) = \min_{\mathbf{u}_{[t,t+\Delta t]}} \left\{ \int_t^{t+\Delta t} \left(\mathbf{x}(t')^\top \mathbf{Q}_x \mathbf{x}(t') + \mathbf{u}(t')^\top \mathbf{R}_u \mathbf{u}(t')\right) dt' + V^*(\mathbf{x}(t+\Delta t)) \right\}$$

Expanding the integral to first order in Δt and applying a first-order Taylor expansion to the terminal cost gives:

$$V^*(\mathbf{x}(t+\Delta t)) = V^*(\mathbf{x}(t)) + \nabla V^*(\mathbf{x}(t))^\top \dot{\mathbf{x}}(t)\Delta t + \mathcal{O}(\Delta t^2)$$

Substituting the plant dynamics $\dot{\mathbf{x}} = \mathbf{A}_{\text{sys}}\mathbf{x} + \mathbf{B}\mathbf{u}$, subtracting $V^*(\mathbf{x}(t))$ from both sides, dividing by Δt, and taking the limit $\Delta t \to 0$ yields the continuous-time **Hamilton-Jacobi-Bellman (HJB)** equation:

$$0 = \min_{\mathbf{u}} \left[\mathbf{x}^\top \mathbf{Q}_x \mathbf{x} + \mathbf{u}^\top \mathbf{R}_u \mathbf{u} + \nabla V^*(\mathbf{x})^\top (\mathbf{A}_{\text{sys}}\mathbf{x} + \mathbf{B}\mathbf{u})\right]$$

Postulating a quadratic value function ansatz (the optimal continuous critic) $V^*(\mathbf{x}) = \mathbf{x}^\top \mathbf{P}\mathbf{x}$ with symmetric matrix $\mathbf{P} = \mathbf{P}^\top$ (positive definite under the controllability and observability assumptions stated below), its spatial gradient evaluates to:

$$\nabla V^*(\mathbf{x}) = 2\mathbf{P}\mathbf{x}$$

DRAFT

Differentiating the expression inside the bracket with respect to control input $\mathbf{u}$ and setting the derivative to zero yields the stationarity condition:

$$2\mathbf{R}_u\mathbf{u} + 2\mathbf{B}^\top\mathbf{P}\mathbf{x} = \mathbf{0} \implies \mathbf{u}^*(t) = -\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}\mathbf{x}(t) = -\mathbf{K}_{\text{lqr}}\mathbf{x}(t)$$

The optimal state-feedback control law (the optimal actor policy) is strictly linear in the state, with constant optimal gain matrix $\mathbf{K}_{\text{lqr}} = \mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}$. Substituting this optimal control law $\mathbf{u}^*$ back into the HJB equation eliminates the minimization:

$$\mathbf{x}^\top\mathbf{Q}_x\mathbf{x} + \mathbf{x}^\top\mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}\mathbf{x} + 2\mathbf{x}^\top\mathbf{P}\mathbf{A}_{\text{sys}}\mathbf{x} - 2\mathbf{x}^\top\mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}\mathbf{x} = 0$$

Combining quadratic terms and using the matrix transpose identity $2\mathbf{x}^\top\mathbf{P}\mathbf{A}_{\text{sys}}\mathbf{x} = \mathbf{x}^\top(\mathbf{A}_{\text{sys}}^\top\mathbf{P} + \mathbf{P}\mathbf{A}_{\text{sys}})\mathbf{x}$ reveals:

$$\mathbf{x}^\top\left(\mathbf{A}_{\text{sys}}^\top\mathbf{P} + \mathbf{P}\mathbf{A}_{\text{sys}} - \mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P} + \mathbf{Q}_x\right)\mathbf{x} = 0 \quad \forall\mathbf{x} \in \mathbb{R}^n$$

Because this equality must hold identically for all states $\mathbf{x}$, the bracketed matrix equation must vanish, yielding the canonical **Continuous Algebraic Riccati Equation (ARE)**:

$$\mathbf{A}_{\text{sys}}^\top\mathbf{P} + \mathbf{P}\mathbf{A}_{\text{sys}} - \mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P} + \mathbf{Q}_x = \mathbf{0}$$

Substituting the control law into the plant dynamics yields the closed-loop system $\dot{\mathbf{x}} = (\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})\mathbf{x}$. When $(\mathbf{A}_{\text{sys}}, \mathbf{B})$ is controllable and $(\mathbf{A}_{\text{sys}}, \mathbf{Q}_x^{1/2})$ is observable, all closed-loop eigenvalues are strictly Hurwitz ($\text{Re}(\lambda_i(\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})) < 0$), guaranteeing exponential convergence to the origin.

B.2.5.2 LQR as an optimal closed-loop error dissipator

Beyond minimizing quadratic cost, the Riccati solution $\mathbf{P} \succ \mathbf{0}$ provides a Lyapunov function for the nominal closed loop. With a positive-definite running cost it also supplies a strict decrease certificate. Differentiating $V^*(\mathbf{x}) = \mathbf{x}^\top\mathbf{P}\mathbf{x}$ along the closed-loop trajectories of $\dot{\mathbf{x}} = (\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})\mathbf{x}$ gives:

$$\begin{aligned}\dot{V}^*(\mathbf{x}) &= \dot{\mathbf{x}}^\top\mathbf{P}\mathbf{x} + \mathbf{x}^\top\mathbf{P}\dot{\mathbf{x}} = \mathbf{x}^\top\left[(\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})^\top\mathbf{P} + \mathbf{P}(\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})\right]\mathbf{x} \\ &= \mathbf{x}^\top\left[\mathbf{A}_{\text{sys}}^\top\mathbf{P} + \mathbf{P}\mathbf{A}_{\text{sys}} - 2\mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}\right]\mathbf{x}\end{aligned}$$

Substituting the Algebraic Riccati Equation $\mathbf{A}_{\text{sys}}^\top\mathbf{P} + \mathbf{P}\mathbf{A}_{\text{sys}} = \mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P} - \mathbf{Q}_x$ into this expression yields:

$$\dot{V}^*(\mathbf{x}) = \mathbf{x}^\top\left[-\mathbf{Q}_x - \mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top\mathbf{P}\right]\mathbf{x} = -\mathbf{x}^\top\left[\mathbf{Q}_x + \mathbf{K}_{\text{lqr}}^\top\mathbf{R}_u\mathbf{K}_{\text{lqr}}\right]\mathbf{x} \leq 0$$

The derivative is strictly negative when the running-cost matrix is positive definite; with semidefinite $\mathbf{Q}_x$ it can vanish at a nonzero state, even though observability establishes asymptotic convergence. The equality identifies the dissipated quantity as cost, not necessarily physical energy. The value function decreases at a rate matching the instantaneous running cost $\mathbf{x}^\top\mathbf{Q}_x\mathbf{x} + \mathbf{u}^\top\mathbf{R}_u\mathbf{u}$.

B.2.5.3 Robustness margins of continuous LQR

Continuous-time full-state LQR has a useful robustness property (Åström and Murray 2021) under the ideal full-state assumptions, expressed by the frequency-domain **Kalman return difference equality**:

$$(\mathbf{I} + \mathbf{L}(j\omega))^*\,\mathbf{R}_u\,(\mathbf{I} + \mathbf{L}(j\omega)) = \mathbf{R}_u + \mathbf{B}^\top(-j\omega\mathbf{I} - \mathbf{A}_{\text{sys}}^\top)^{-1}\mathbf{Q}_x(j\omega\mathbf{I} - \mathbf{A}_{\text{sys}})^{-1}\mathbf{B}$$

where * denotes conjugate transpose and $\mathbf{L}(j\omega) = \mathbf{K}_{\text{lqr}}(j\omega\mathbf{I} - \mathbf{A}_{\text{sys}})^{-1}\mathbf{B}$ is the open-loop frequency response broken at the plant input. Because $\mathbf{Q}_x \succeq \mathbf{0}$, the second term on the right-hand side is positive semi-definite at frequencies where the resolvents exist. For a single-input system with scalar $\mathbf{R}_u > 0$, this establishes:

$$|1 + L(j\omega)| \geq 1 \quad \forall\omega \in \mathbb{R}$$

Geometrically on the Nyquist plane, the loop transfer locus $L(j\omega)$ never enters the open unit disk centered at $-1 + j0$. This property confers two guaranteed stability margins:

1. **Infinite Gain Margin:** The closed loop remains asymptotically stable under scalar gain scaling $\kappa \in (1/2, \infty)$ inserted into the control loop.

DRAFT

2. **Phase Margin Guarantee:** The distance from -1 to the Nyquist curve is at least 1, which by elementary trigonometry guarantees at least 60° of phase margin for the single-input loop:

$$\Phi_m \geq 2\arcsin(1/2) = 60^\circ$$

These are continuous-time, full-state, nominal-model margins at the specified loop break. They are not an unrestricted guarantee against actuator dynamics, structural resonances, or simultaneous multivariable perturbations. Digital sampling and transport add phase lag; section B.5.5 gives the low-frequency delay approximation used to budget that loss.

B.2.5.4 Discrete-time LQR

For digital microcontrollers executing at sampling period T_s, the discrete-time LQR formulation minimizes:

$$J_d = \sum_{k=0}^{\infty} \left(\mathbf{x}_k^\top \mathbf{Q}_x \mathbf{x}_k + \mathbf{u}_k^\top \mathbf{R}_u \mathbf{u}_k\right)$$

subject to $\mathbf{x}_{k+1} = \mathbf{A}_d \mathbf{x}_k + \mathbf{B}_d \mathbf{u}_k$. The matrix $\mathbf{P}$ satisfies the **Discrete Algebraic Riccati Equation (DARE)**:

$$\mathbf{P} = \mathbf{A}_d^\top \mathbf{P} \mathbf{A}_d - \mathbf{A}_d^\top \mathbf{P} \mathbf{B}_d \left(\mathbf{R}_u + \mathbf{B}_d^\top \mathbf{P} \mathbf{B}_d\right)^{-1} \mathbf{B}_d^\top \mathbf{P} \mathbf{A}_d + \mathbf{Q}_x$$

yielding the discrete optimal state-feedback gain:

$$\mathbf{K}_{\text{lqr},d} = \left(\mathbf{R}_u + \mathbf{B}_d^\top \mathbf{P} \mathbf{B}_d\right)^{-1} \mathbf{B}_d^\top \mathbf{P} \mathbf{A}_d, \quad \mathbf{u}_k^* = -\mathbf{K}_{\text{lqr},d} \mathbf{x}_k$$

B.2.6 The separation principle and linear quadratic Gaussian control

In physical deployments, full-state access is rarely available; controllers must estimate $\hat{\mathbf{x}}$ from noisy sensor observations $\mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{v}_{\text{meas}}$. Under a linear model with independent Gaussian white process and measurement noises of intensities $\mathbf{Q}$ and $\mathbf{R}_{\text{cont}}$, the optimal continuous state estimator is the continuous-time **Kalman-Bucy filter** (section B.8; the discrete filter the machine runs is in section 9.2):

$$\dot{\hat{\mathbf{x}}}(t) = \mathbf{A}_{\text{sys}} \hat{\mathbf{x}}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{L}\left(\mathbf{y}(t) - \mathbf{H}\hat{\mathbf{x}}(t)\right)$$

where $\mathbf{y}(t) - \mathbf{H}\hat{\mathbf{x}}(t)$ is the **innovation** (the measurement residual), and the optimal Kalman observer gain is:

$$\mathbf{L} = \mathbf{P}_{\text{est}} \mathbf{H}^\top \mathbf{R}_{\text{cont}}^{-1}$$

At steady state, $\mathbf{P}_{\text{est}} = \mathbb{E}[(\mathbf{x} - \hat{\mathbf{x}})(\mathbf{x} - \hat{\mathbf{x}})^\top]$ is the state estimation error covariance matrix, which solves the dual filter algebraic Riccati equation under the usual stabilizability and detectability conditions:

$$\mathbf{A}_{\text{sys}} \mathbf{P}_{\text{est}} + \mathbf{P}_{\text{est}} \mathbf{A}_{\text{sys}}^\top - \mathbf{P}_{\text{est}} \mathbf{H}^\top \mathbf{R}_{\text{cont}}^{-1} \mathbf{H} \mathbf{P}_{\text{est}} + \mathbf{Q} = \mathbf{0}$$

To an ML practitioner, the Kalman filter is the exact recursive Bayesian Minimum Mean Square Error (MMSE) estimator. It continuously updates the posterior state distribution $\mathcal{N}(\hat{\mathbf{x}}, \mathbf{P}_{\text{est}})$ by balancing dynamic model propagation (growing uncertainty via process noise $\mathbf{Q}$) against empirical sensor evidence (contracting uncertainty via inverse continuous measurement-noise intensity $\mathbf{R}_{\text{cont}}^{-1}$). For discrete measurements, the analogous update uses the per-sample measurement covariance Σ_{meas}, not the continuous noise intensity. With invertible prior and measurement covariances, it evaluates as:

$$\mathbf{P}_{k|k}^{-1} = \mathbf{P}_{k|k-1}^{-1} + \mathbf{H}^\top \Sigma_{\text{meas}}^{-1} \mathbf{H}, \quad \mathbf{P}_{k|k}^{-1} \hat{\mathbf{x}}_{k|k} = \mathbf{P}_{k|k-1}^{-1} \hat{\mathbf{x}}_{k|k-1} + \mathbf{H}^\top \Sigma_{\text{meas}}^{-1} \mathbf{y}_k$$

In information (precision) space, the posterior precision is the linear addition of prior dynamic precision $\mathbf{P}_{k|k-1}^{-1}$ and measurement evidence precision $\mathbf{H}^\top \Sigma_{\text{meas}}^{-1} \mathbf{H}$. This reveals the Kalman filter as the exact recursive, online counterpart of Bayesian linear regression and Gaussian process conditioning, and highlights the mathematical duality between optimal control (LQR) and optimal estimation (Kalman filter):

DRAFT

Duality Attribute	Optimal Regulator (LQR)	Optimal Estimator (Kalman Filter)
System Operator	Drift matrix $\mathbf{A}_{\text{sys}}$	Adjoint drift matrix $\mathbf{A}_{\text{sys}}^{\top}$
Control / Sensor Map	Actuator input matrix $\mathbf{B}$	Sensor output matrix transpose $\mathbf{H}^{\top}$
Weighting / Noise Covariance	State weight $\mathbf{Q}_x \succeq \mathbf{0}$, control effort $\mathbf{R}_u \succ \mathbf{0}$	Process noise $\mathbf{Q} \succeq \mathbf{0}$, measurement noise $\mathbf{R}_{\text{cont}} \succ \mathbf{0}$
Riccati Solution	Control Riccati matrix $\mathbf{P}$	Estimation covariance matrix $\mathbf{P}_{\text{est}}$
Optimal Gain	Feedback gain $\mathbf{K}_{\text{lqr}} = \mathbf{R}_u^{-1}\mathbf{B}^{\top}\mathbf{P}$	Observer gain $\mathbf{L} = \mathbf{P}_{\text{est}}\mathbf{H}^{\top}\mathbf{R}_{\text{cont}}^{-1}$
Optimality Criterion	Minimizes quadratic state and action penalty	Minimizes trace of estimation error covariance $\mathbb{E}[\|\mathbf{x}-\hat{\mathbf{x}}\|^2]$

The **Linear Quadratic Gaussian (LQG)** controller cascades this optimal estimator with the optimal LQR regulator by applying feedback directly to the estimated state:

$$\mathbf{u}(t) = -\mathbf{K}_{\text{lqr}}\hat{\mathbf{x}}(t)$$

The **Separation Principle** (Åström and Murray 2021) proves that under linear-Gaussian assumptions, observer design and state-feedback controller design are completely decoupled. Specifically, the poles of the closed-loop LQG system are strictly the union of the controller poles $\text{eig}(\mathbf{A}_{\text{sys}} - \mathbf{B}\mathbf{K}_{\text{lqr}})$ and the observer poles $\text{eig}(\mathbf{A}_{\text{sys}} - \mathbf{L}\mathbf{H})$.

Systems Perspective B.1: The Doyle warning: LQG robustness margins

While full-state LQR provides guaranteed 60° phase margins and infinite gain margins, John Doyle's classic 1978 paper demonstrated that output-feedback LQG controllers possess **no guaranteed stability margins whatsoever** (Åström and Murray 2021). When an observer is inserted into the loop, unmodeled plant parameter variations couple estimation error $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ directly back into the control actuation channel. Even infinitesimal parameter perturbations can then push the closed-loop poles across the imaginary axis into the unstable right-half plane.

For physical AI systems, this carries a warning. Cascading a high-capacity neural perception system (e.g., an end-to-end vision model estimating 6D object poses or end-effector coordinates) with an optimal tracking controller does not inherit the controller's nominal robustness. Dynamic perception lag, out-of-distribution observation errors, and high-frequency sensor noise degrade feedback phase margin rapidly. An implementation must evaluate the combined estimator-controller dynamics and its safety bounds; loop transfer recovery is one design technique, not a universal requirement (section 12.1).

B.3 Stability Theory and Model Predictive Control

An arm controller that converges exponentially to a target grasp pose can still swing its elbow through a cage-door post along the way. Stability concerns whether trajectories remain near, or converge to, an equilibrium; set invariance concerns whether they stay inside a safe region at every instant. These are separate claims, each conditional on a model, an initial-state domain, and the implementation assumptions.

B.3.1 Lyapunov stability and invariant sets

Continuous gradient flow provides a useful analogy for Lyapunov analysis. It evolves parameter weights according to $\dot{\theta} = -\nabla_{\theta}\mathcal{L}(\theta)$. Along this parameter trajectory, the empirical loss decreases monotonically via the multivariable chain rule:

$$\dot{\mathcal{L}}(\theta) = \nabla_{\theta}\mathcal{L}(\theta)^{\top}\dot{\theta} = -\nabla_{\theta}\mathcal{L}(\theta)^{\top}\nabla_{\theta}\mathcal{L}(\theta) = -\|\nabla_{\theta}\mathcal{L}(\theta)\|^2 \leq 0$$

In parameter optimization, the software program has unconstrained, direct write access to the parameter velocity vector $\dot{\theta}$, allowing the optimizer to force loss descent along the negative gradient direction. In physical control, the robot's physical state $\mathbf{x}(t) \in \mathbb{R}^n$ evolves in physical state space according to continuous differential equations $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$. Unlike software network weights θ, physical coordinates $\mathbf{x}$ cannot be updated by arbitrary gradient descent: actuators cannot command arbitrary velocity vectors $\dot{\mathbf{x}}$, because physical momentum, mass inertia, unforced drift, and kinematic constraints govern the system. By Newton's second law, motor actuators modulate second-order accelerations ($\ddot{\mathbf{q}} = \mathbf{M}(\mathbf{q})^{-1}(\tau - \mathbf{h})$), which must be integrated through continuous time against centrifugal forces, Coriolis couplings, and gravitational fields.

Instead, a **Lyapunov function** $V(\mathbf{x})$ acts as an analytical, continuous state-space loss function that certifies the asymptotic convergence of the physical plant's continuous trajectories without simulating every rollout to infinity. In mechanical systems, $V(\mathbf{x})$ often corresponds to the physical or synthetic Hamiltonian energy of the plant: kinetic energy stored in moving mass plus potential energy stored in gravitational elevation or virtual elastic springs.

Consider an autonomous nonlinear dynamical system:

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)), \quad \mathbf{f}(\mathbf{0}) = \mathbf{0}$$

where $\mathbf{x}^* = \mathbf{0}$ is an isolated equilibrium point, and $\mathbf{f} : \mathcal{D} \to \mathbb{R}^n$ is locally Lipschitz on an open domain $\mathcal{D} \subset \mathbb{R}^n$ containing the origin.

A continuously differentiable scalar function $V : \mathcal{D} \to \mathbb{R}$ is a **candidate Lyapunov function** if it is positive definite on $\mathcal{D}$:

$$V(\mathbf{0}) = 0, \quad V(\mathbf{x}) > 0 \quad \forall \mathbf{x} \in \mathcal{D} \setminus \{\mathbf{0}\}$$

The directional derivative of V along the trajectories of $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ evaluates via the multivariable chain rule:

$$\dot{V}(\mathbf{x}) = \nabla V(\mathbf{x})^\top \dot{\mathbf{x}} = \nabla V(\mathbf{x})^\top \mathbf{f}(\mathbf{x}) = \nabla V(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x})$$

Control theory traditionally denotes this inner product as the **Lie derivative** $L_{\mathbf{f}} V(\mathbf{x}) = \nabla V(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x})$. In computational terms, this is the **directional derivative** or forward-mode **Jacobian-vector product (JVP)** of the scalar loss V evaluated in the direction of the physical drift vector field $\mathbf{f}(\mathbf{x})$:

$$\text{JVP}(V, \mathbf{x}, \mathbf{f}(\mathbf{x})) = \frac{d}{d\epsilon} V(\mathbf{x} + \epsilon \mathbf{f}(\mathbf{x}))\Big|_{\epsilon=0} = \nabla V(\mathbf{x})^\top \mathbf{f}(\mathbf{x}) = L_{\mathbf{f}} V(\mathbf{x})$$

Automatic differentiation can evaluate this directional derivative without forming a full Jacobian. Computing it at sampled states, however, does not verify its sign everywhere in a region.

Alexander Lyapunov established three foundational stability tiers (Slotine and Li 1991):

1. **Stability in the Sense of Lyapunov:** If $\dot{V}(\mathbf{x}) \leq 0$ for all $\mathbf{x} \in \mathcal{D}$, the origin is stable. Trajectories starting arbitrarily close to the origin remain trapped within bounded neighborhood contours for all $t \geq 0$.
2. **Asymptotic Stability:** If $\dot{V}(\mathbf{x}) < 0$ for all $\mathbf{x} \in \mathcal{D} \setminus \{\mathbf{0}\}$, the origin is asymptotically stable: $\lim_{t\to\infty} \mathbf{x}(t) = \mathbf{0}$. The system is guaranteed to descend the energy landscape toward the origin.
3. **Exponential Stability:** If there exist positive constants $k_1, k_2, k_3 > 0$ such that $k_1\|\mathbf{x}\|^2 \leq V(\mathbf{x}) \leq k_2\|\mathbf{x}\|^2$ and $\dot{V}(\mathbf{x}) \leq -k_3\|\mathbf{x}\|^2$, trajectories converge exponentially:

$$\|\mathbf{x}(t)\| \leq \sqrt{\frac{k_2}{k_1}} \|\mathbf{x}_0\| e^{-\frac{k_3}{2k_2} t} \quad \forall t \geq 0$$

For mechanical systems with friction and viscous damping, $\dot{V}(\mathbf{x})$ often vanishes on a subspace (for example, when velocities are zero while position errors remain nonzero: $\dot{V}(\mathbf{q}, \dot{\mathbf{q}}) = -\dot{\mathbf{q}}^\top \mathbf{D} \dot{\mathbf{q}} = 0$ whenever $\dot{\mathbf{q}} = \mathbf{0}$). Standard Lyapunov theorems only certify stability in the sense of Lyapunov, failing to prove asymptotic convergence. **LaSalle's Invariance Principle** (Slotine and Li 1991) resolves this. If $\dot{V}(\mathbf{x}) \leq 0$ on a compact, positively invariant set Ω, all trajectories starting in Ω asymptotically converge to the largest invariant set $\mathcal{M}$ contained within $\{\mathbf{x} \in \Omega \mid \dot{V}(\mathbf{x}) = 0\}$. Because any trajectory trapped on $\mathcal{M}$ with $\dot{\mathbf{q}} \equiv \mathbf{0}$ must also satisfy zero acceleration ($\ddot{\mathbf{q}} \equiv \mathbf{0}$), the equations of motion force

DRAFT

position errors to vanish ($\mathbf{K}_p\mathbf{e} = \mathbf{0} \implies \mathbf{e} = \mathbf{0}$). LaSalle's principle proves that the only trajectory that can remain indefinitely in the zero-dissipation manifold is the origin itself, certifying asymptotic convergence.

A compact sublevel set $\Omega_c = \{\mathbf{x} \in \mathcal{D} \mid V(\mathbf{x}) \leq c\}$ contained in $\mathcal{D}$ is positively invariant when $\dot{V} \leq 0$ throughout it. It is an inner estimate of the **domain of attraction (DOA)** only when trajectories there also converge to the equilibrium, for example by strict descent or the LaSalle argument. Invariance alone does not imply convergence.

A neural network can parameterize a candidate Lyapunov function and search for a stabilizing policy. For example, $V(\mathbf{x}) = \mathbf{x}^\top \mathbf{L}_\phi(\mathbf{x})\mathbf{L}_\phi(\mathbf{x})^\top \mathbf{x} + \epsilon_{\text{pos}}\|\mathbf{x}\|^2$, with $\epsilon_{\text{pos}} > 0$, guarantees positivity away from the origin. Convexity alone does not guarantee this property. Penalizing violations of $\dot{V} < 0$ during training produces a candidate; a certificate requires verifying the derivative condition throughout the claimed region, including the model and implementation uncertainty.

B.3.2 Control Lyapunov functions and stabilization

For a controlled system $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$, the directional derivative along the closed-loop dynamics splits linearly into unforced drift and control effectiveness:

$$\dot{V}(\mathbf{x}, \mathbf{u}) = \nabla V(\mathbf{x}) \cdot (\mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}) = L_{\mathbf{f}} V(\mathbf{x}) + L_{\mathbf{g}} V(\mathbf{x})\mathbf{u}$$

where $L_{\mathbf{f}} V(\mathbf{x}) = \nabla V(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x}) \in \mathbb{R}$ is the unforced directional drift and $L_{\mathbf{g}} V(\mathbf{x}) = \nabla V(\mathbf{x})^\top \mathbf{g}(\mathbf{x}) \in \mathbb{R}^{1\times m}$ is the control effectiveness gradient. A candidate Lyapunov function $V(\mathbf{x})$ is a **Control Lyapunov Function (CLF)** (Ames et al. 2014; Slotine and Li 1991) if there exists an admissible control input $\mathbf{u} \in \mathcal{U}_{\text{adm}}$ that forces V to decrease at every non-equilibrium state:

$$\inf_{\mathbf{u}\in\mathcal{U}_{\text{adm}}} \left[L_{\mathbf{f}} V(\mathbf{x}) + L_{\mathbf{g}} V(\mathbf{x})\mathbf{u} + \alpha_V(V(\mathbf{x})) \right] \leq 0 \quad \forall \mathbf{x} \in \mathcal{D} \setminus \{\mathbf{0}\}$$

where α_V is an extended class $\mathcal{K}$ function (a strictly increasing function with $\alpha_V(0) = 0$). For ML practitioners, $\alpha_V(V(\mathbf{x}))$ acts as a state-dependent convergence rate floor: the larger the current error $V(\mathbf{x})$, the steeper the required rate of descent. Geometrically, the CLF inequality defines a closed affine half-space in control space $\mathcal{U}_{\text{CLF}}(\mathbf{x}) = \{\mathbf{u} \in \mathcal{U}_{\text{adm}} \mid L_{\mathbf{g}} V(\mathbf{x})\mathbf{u} \leq -L_{\mathbf{f}} V(\mathbf{x}) - \alpha_V(V(\mathbf{x}))\}$; any control input chosen inside this half-space guarantees monotonic descent of the continuous state-space loss.

B.3.2.1 Sontag's universal stabilizing formula

For an unconstrained control-affine system, a smooth CLF admits the following stabilizing feedback construction (Slotine and Li 1991):

$$\mathbf{u}_{\text{Sontag}}(\mathbf{x}) = \begin{cases} -\left(\frac{L_{\mathbf{f}} V(\mathbf{x}) + \sqrt{(L_{\mathbf{f}} V(\mathbf{x}))^2 + \|L_{\mathbf{g}} V(\mathbf{x})\|^4}}{\|L_{\mathbf{g}} V(\mathbf{x})\|^2} \right) \left(L_{\mathbf{g}} V(\mathbf{x})\right)^\top & \text{if } L_{\mathbf{g}} V(\mathbf{x}) \neq \mathbf{0} \\ \mathbf{0} & \text{if } L_{\mathbf{g}} V(\mathbf{x}) = \mathbf{0} \end{cases}$$

The formula makes $\dot{V} < 0$ away from the origin when the CLF condition holds. Continuity at the origin additionally requires the *small control property*: arbitrarily small states can be stabilized with arbitrarily small inputs. The condition $L_{\mathbf{f}} V < 0$ wherever $L_{\mathbf{g}} V = 0$ is the CLF's uncontrollable-direction condition, not the small control property itself. The formula does not impose actuator limits; clipping its output can destroy the decrease condition.

B.3.2.2 The duality between CLFs and CBFs

Control Lyapunov Functions and Control Barrier Functions (section B.4) form the central duality of modern safety-critical control:

DRAFT

Dimension	Control Lyapunov Function (CLF)	Control Barrier Function (CBF)
Objective	Performance tracking / Goal convergence	Safety guarantee / Set invariance
Geometry	Positive-definite potential well ($V(\mathbf{x}^*) = 0$)	Superlevel safe set $\mathcal{C} = \{\mathbf{x} \mid h(\mathbf{x}) \geq 0\}$
Trajectory Dynamic	Pulls trajectories **inward** toward the origin ($V \to 0$)	Prevents outward crossing; may permit approach to the boundary
Differential Inequality	$L_{\mathbf{f}}V(\mathbf{x}) + L_{\mathbf{g}}V(\mathbf{x})\mathbf{u} \leq -\alpha_V(V(\mathbf{x}))$	$L_{\mathbf{f}}h(\mathbf{x}) + L_{\mathbf{g}}h(\mathbf{x})\mathbf{u} \geq -\kappa(h(\mathbf{x}))$
Optimization Priority	Soft constraint (relaxed via slack $\delta \geq 0$)	Hard constraint (strictly non-negotiable)

When combining performance tracking (such as following an uncertified trajectory proposed by a vision-language-action policy) with guaranteed collision avoidance, the enforcer solves a unified **CLF-CBF Quadratic Program (CLF-CBF-QP)**:

$$\begin{aligned} \min_{\mathbf{u}\in\mathcal{U},\delta\geq 0} \quad & \frac{1}{2}\|\mathbf{u}-\mathbf{u}_{\text{nom}}\|^2 + p\delta^2 \\ \text{subject to:} \quad & L_{\mathbf{f}}h(\mathbf{x}) + L_{\mathbf{g}}h(\mathbf{x})\mathbf{u} \geq -\kappa(h(\mathbf{x})) \quad \text{(hard safety constraint)} \\ & L_{\mathbf{f}}V(\mathbf{x}) + L_{\mathbf{g}}V(\mathbf{x})\mathbf{u} \leq -\alpha_V(V(\mathbf{x})) + \delta \quad \text{(soft tracking constraint)} \end{aligned}$$

where $p \gg 1$ heavily penalizes the tracking relaxation slack $\delta \geq 0$. The slack can relax tracking while leaving the modeled barrier condition hard. This only helps when at least one admissible input satisfies the barrier; tracking relaxation cannot repair an infeasible safety constraint.

B.3.3 Constrained model predictive control and recursive feasibility

While LQR and CLF feedback laws operate reactively on instantaneous state feedback, **Model Predictive Control (MPC)** optimizes trajectories over a predictive finite horizon N_{mpc}, explicitly enforcing hard inequality constraints on physical boundaries, motor voltages, and actuator torques. Numerical MPC and learned generative policies play complementary roles:

Attribute	Classical Numerical MPC	Learned Action Chunking (Diffusion, ACT)
Input Modality	Low-dimensional numerical states $\mathbf{x} \in \mathbb{R}^n$	High-dimensional perception (RGB images, point clouds, language)
Plant Model	Explicit analytical equations $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$	Implicit behavioral distribution learned from demonstration
Inference Time	Iterative solve; deadline depends on size, structure, and solver	Model-dependent inference, possibly iterative denoising
Constraints	Explicit modeled limits; guarantees require feasibility and model assumptions	Empirical; proposals can penetrate obstacles or exceed limits
Contact Discontinuities	Combinatorial branch stalling across non-smooth contacts	Learned contact behaviors; physical consistency requires validation
System Role	Deterministic Execution Gatekeeper / Tracking Enforcer	Generative Proposal Engine (long-horizon action chunking)

DRAFT

B.3.3.1 Discrete-time MPC formulation

At discrete sampling tick k, given current state measurement $\mathbf{x}_k = \mathbf{x}(t_k)$, the MPC controller solves a constrained finite-horizon optimal control problem over horizon N_{mpc}:

$$\begin{aligned}
\min_{\mathbf{u}_{0:N_{\text{mpc}}-1}} \quad & \mathbf{x}_{N_{\text{mpc}}}^\top \mathbf{P}_{N_{\text{mpc}}} \mathbf{x}_{N_{\text{mpc}}} + \sum_{i=0}^{N_{\text{mpc}}-1} \left(\mathbf{x}_i^\top \mathbf{Q}_x \mathbf{x}_i + \mathbf{u}_i^\top \mathbf{R}_u \mathbf{u}_i\right) \\
\text{subject to:} \quad & \mathbf{x}_{i+1} = \mathbf{A}_d \mathbf{x}_i + \mathbf{B}_d \mathbf{u}_i, \quad \mathbf{x}_0 = \mathbf{x}_k \\
& \mathbf{x}_i \in \mathcal{X}_{\text{safe}} \subset \mathbb{R}^n \quad \forall i \in \{0, \dots, N_{\text{mpc}}\} \\
& \mathbf{u}_i \in \mathcal{U}_{\text{adm}} \subset \mathbb{R}^m \quad \forall i \in \{0, \dots, N_{\text{mpc}}-1\} \\
& \mathbf{x}_{N_{\text{mpc}}} \in \mathcal{X}_f \subset \mathcal{X}_{\text{safe}}
\end{aligned}$$

where $\mathcal{X}_{\text{safe}} = \{\mathbf{x} \mid \mathbf{H}_x \mathbf{x} \leq \mathbf{b}_x\}$ represents state clearance constraints (joint limits, obstacle margins), $\mathcal{U}_{\text{adm}} = \{\mathbf{u} \mid \mathbf{u}_{\min} \leq \mathbf{u} \leq \mathbf{u}_{\max}\}$ bounds actuator torque authority, $\mathcal{X}_f$ is a terminal invariant set, and $\mathbf{P}_{N_{\text{mpc}}}$ is the terminal cost matrix.

B.3.3.2 The receding-horizon principle and closed-loop stability

MPC executes in a receding-horizon closed loop:

1. Solve the constrained QP at step k, obtaining optimal sequence $\mathbf{u}^*_{0:N_{\text{mpc}}-1} = [\mathbf{u}^*_0, \mathbf{u}^*_1, \dots, \mathbf{u}^*_{N_{\text{mpc}}-1}]$.
2. Apply only the first control setpoint to physical hardware: $\mathbf{u}(t_k) = \mathbf{u}^*_0$.
3. Advance the hardware clock by T_s, discard the remaining trajectory $\mathbf{u}^*_{1:N_{\text{mpc}}-1}$, obtain updated state $\mathbf{x}_{k+1}$, and re-solve across the shifted horizon.

For the exact discrete model, an initially feasible state, and successful on-time solves, closed-loop stability can be established by choosing the terminal cost $\mathbf{P}_{N_{\text{mpc}}}$ and terminal set $\mathcal{X}_f$ to satisfy the classical Rawlings-Mayne stability conditions (Åström and Murray 2021; Wabersich and Zeilinger 2021):

1. **Terminal Invariance:** There exists a local linear feedback law $\mathbf{u} = -\mathbf{K}_f \mathbf{x}$ such that for all $\mathbf{x} \in \mathcal{X}_f$, $(\mathbf{A}_d - \mathbf{B}_d \mathbf{K}_f)\mathbf{x} \in \mathcal{X}_f$ and $-\mathbf{K}_f \mathbf{x} \in \mathcal{U}_{\text{adm}}$.
2. **Terminal Lyapunov Descent:** $\mathbf{P}_{N_{\text{mpc}}}$ satisfies the discrete Lyapunov inequality:

$$(\mathbf{A}_d - \mathbf{B}_d \mathbf{K}_f)^\top \mathbf{P}_{N_{\text{mpc}}} (\mathbf{A}_d - \mathbf{B}_d \mathbf{K}_f) - \mathbf{P}_{N_{\text{mpc}}} \leq -\left(\mathbf{Q}_x + \mathbf{K}_f^\top \mathbf{R}_u \mathbf{K}_f\right)$$

Under these conditions, the optimal cost function $J^*(\mathbf{x}_k)$ acts as a discrete Lyapunov function:

$$J^*(\mathbf{x}_{k+1}) - J^*(\mathbf{x}_k) \leq -(\mathbf{x}_k^\top \mathbf{Q}_x \mathbf{x}_k + \mathbf{u}_k^{*\top} \mathbf{R}_u \mathbf{u}_k^*) \leq 0$$

Strict descent away from the origin follows from a positive-definite state cost. With semidefinite cost, convergence instead requires an appropriate detectability argument. Under those assumptions, the nominal closed loop converges while respecting the modeled constraints.

B.3.3.3 Recursive feasibility and avoidance of dynamic traps

A hazard in constrained physical control is dynamic trap entry. A naive controller drives the system into a state where, due to physical inertia, finite stopping distance, and actuator saturation, no control sequence can prevent constraint violation N_{mpc} steps in the future, which renders the QP instantaneously infeasible. For example, a mobile robot cruising at high velocity toward a wall may have a feasible solution over horizon N_{mpc}. If the horizon terminates before braking completes, however, step $k+1$ encounters an unavoidable collision, because available deceleration cannot overcome kinetic momentum within the remaining distance.

A controller possesses **recursive feasibility** if the existence of a feasible solution at step k guarantees that the optimization problem remains feasible at step $k+1$ for all time. With the terminal invariant set $\mathcal{X}_f$ and exact nominal dynamics, the candidate shifted sequence:

$$\tilde{\mathbf{u}}_{0:N_{\text{mpc}}-1} = [\mathbf{u}^*_1, \mathbf{u}^*_2, \dots, \mathbf{u}^*_{N_{\text{mpc}}-1}, -\mathbf{K}_f \mathbf{x}_{N_{\text{mpc}}}]$$

DRAFT

is guaranteed to satisfy all dynamics, state, input, and terminal constraints at step $k+1$. The shifted sequence proves nominal recursive feasibility and can supply a warm start. Bounded disturbances alone do not preserve this proof: robust MPC must tighten constraints or propagate disturbance tubes and use a compatible robust terminal set. Solver failure and missed deadlines still require a reserved fallback.

B.3.3.4 Classical numerical MPC vs. learned action chunking

As framed in section 11.6, modern physical AI embodies a direct trade-off between numerical MPC and learned generative action chunking:

- **Model Accuracy vs. Semantic Ingestion:** Classical MPC relies on analytical differential equations ($\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k, \mathbf{u}_k)$). Its stated low-dimensional formulation requires an upstream perception system to convert images, point clouds, or language into state estimates and goals. Modeling contact-mode changes creates an additional difficulty (section B.7). In contrast, generative action chunking policies (Diffusion Policy, Action Chunking with Transformers (ACT), Flow Matching) learn complex, multimodal behavioral distributions directly from human demonstrations.
- **Computational Scaling:** Dense optimization can become expensive as the horizon and state dimension grow; sparse and structured solvers can exploit the trajectory structure. No universal cubic runtime or control frequency follows from the MPC label. Learned action chunking moves much of the optimization into training, but its inference deadline still depends on model size, decoding steps, and hardware.
- **The Physical AI Synthesis:** Learned policies can propose action chunks while a model-based controller checks their physical feasibility. Determinism, recursive feasibility, and collision avoidance remain properties to establish for the selected model, constraints, solver, timing, and fallback. Neither MPC nor a CBF-QP provides them merely by being placed below the proposal boundary (section 12.1).

B.4 Safety and Control Barrier Functions

When a learned policy commands an arm toward a rack post at $1.0\,\mathrm{m/s}$, a position check that triggers only at contact is too late because inertia carries the link into the post. An independent enforcer can instead check a control barrier constraint before actuation. In reliable software systems, safety properties are proven using inductive loop invariants: if an invariant holds initially and is preserved across every state transition, it holds for all executions. A Control Barrier Function (CBF) lifts this principle to continuous physical systems, framing safety as an inductive loop invariant over continuous state trajectories:

Let the system state be $\mathbf{x} \in \mathcal{X} \subset \mathbb{R}^n$ and the control input be $\mathbf{u} \in \mathcal{U} \subset \mathbb{R}^m$. Suppose we define a safe operating set $\mathcal{C}$ as the superlevel set of a continuously differentiable scalar certificate function $h(\mathbf{x})$, with a nonzero gradient on its zero-level boundary:

$$\mathcal{C} = \{\mathbf{x} \in \mathcal{X} \mid h(\mathbf{x}) \geq 0\}, \quad \partial\mathcal{C} = \{\mathbf{x} \in \mathcal{X} \mid h(\mathbf{x}) = 0\}$$

- $h(\mathbf{x}) > 0$ when the system is strictly inside the safe interior.
- $h(\mathbf{x}) = 0$ on the boundary of the safe set.
- $h(\mathbf{x}) < 0$ when the system violates safety.

Invariant Concept	Formal Software Verification (Dafny, TLA+)	Safety-Critical Control (CBF)
State Space	Discrete variable states $s \in \Sigma$	Continuous state $\mathbf{x} \in \mathcal{X} \subset \mathbb{R}^n$
Base Step	Precondition assertion: $\{P(s_0)\}$	Safe initialization: $h(\mathbf{x}_0) \geq 0$
Transition Rule	Discrete program statement: $s_{k+1} = \mathrm{eval}(s_k, \mathrm{stmt})$	Differential equation: $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$

Invariant Concept	Formal Software Verification (Dafny, TLA+)	Safety-Critical Control (CBF)
Inductive Invariant	Invariant preservation: $P(s) \implies P(\text{eval}(s))$	Barrier condition: $\dot{h}(\mathbf{x}, \mathbf{u}) \geq -\kappa(h(\mathbf{x}))$
Proof Technique	SMT solvers (Z3, CVC5), structural induction	Grönwall-Bellman comparison lemma
Enforcement Layer	Runtime guard assertion / exception handler	Inline minimal-intervention QP projection

1. **Base Case:** The system initializes within the safe operating envelope: $h(\mathbf{x}_0) \geq 0$.
2. **Inductive Step:** Along all continuous transitions governed by plant dynamics and control inputs $\mathbf{u}_t \in \mathcal{U}$, the instantaneous rate of change satisfies:
$$\dot{h}(\mathbf{x}_t, \mathbf{u}_t) \geq -\kappa(h(\mathbf{x}_t))$$
where $\kappa(\cdot)$ is an extended class $\mathcal{K}_\infty$ function (or linear decay $\kappa(h) = \gamma_{\text{cbf}} h$ with design bandwidth $\gamma_{\text{cbf}} > 0$).
3. **Continuous Induction via Comparison Lemma:** For the linear choice $\kappa(h) = \gamma_{\text{cbf}} h$, consider the scalar comparison differential equation:
$$\dot{z}(t) = -\gamma_{\text{cbf}} z(t), \quad z(0) = h(\mathbf{x}_0) \geq 0$$
whose exact analytical solution is $z(t) = h(\mathbf{x}_0) e^{-\gamma_{\text{cbf}} t}$. Because $h(\mathbf{x}_0) \geq 0$ and $e^{-\gamma_{\text{cbf}} t} > 0$ for all finite $t \geq 0$, the comparison trajectory remains non-negative: $z(t) \geq 0$. By the Grönwall-Bellman comparison lemma (Slotine and Li 1991), the condition $\dot{h}(\mathbf{x}_t, \mathbf{u}_t) \geq -\gamma_{\text{cbf}} h(\mathbf{x}_t)$ guarantees:
$$h(\mathbf{x}_t) \geq z(t) = h(\mathbf{x}_0) e^{-\gamma_{\text{cbf}} t} \geq 0 \quad \forall t \geq 0$$
4. **Conclusion:** By induction over continuous time, $h(\mathbf{x}_t) \geq 0$ for all $t \geq 0$, guaranteeing forward invariance of the safe set $\mathcal{C}$. As the state approaches the boundary ($h(\mathbf{x}_t) \to 0^+$), the permissible rate of decrease $-\kappa(h)$ contracts to zero, enforcing $\dot{h}(\mathbf{x}_t, \mathbf{u}_t) \geq 0$. Consequently, $h(\mathbf{x}_t)$ can never cross zero with a negative slope.

B.4.1 Lie derivatives and forward invariance

Forward invariance means a trajectory starting in $\mathcal{C}$ remains in $\mathcal{C}$ for all future time. For a control-affine continuous dynamical system $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$, the total time derivative $\dot{h}$ evaluates via the multivariate chain rule as directional derivatives along system dynamics:[1]

$$\dot{h}(\mathbf{x}, \mathbf{u}) = \nabla h(\mathbf{x})^\top \dot{\mathbf{x}} = \nabla h(\mathbf{x})^\top \mathbf{f}(\mathbf{x}) + \left(\nabla h(\mathbf{x})^\top \mathbf{g}(\mathbf{x})\right) \mathbf{u} = L_{\mathbf{f}} h(\mathbf{x}) + L_{\mathbf{g}} h(\mathbf{x}) \mathbf{u}$$

In modern computational terminology, the Lie derivatives $L_{\mathbf{f}} h(\mathbf{x})$ and $L_{\mathbf{g}} h(\mathbf{x})$ are Jacobian-vector products (JVPs) of the scalar safety function h evaluated along the drift and control vector fields:

$$L_{\mathbf{f}} h(\mathbf{x}) = \nabla h(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x}) \in \mathbb{R}, \quad L_{\mathbf{g}} h(\mathbf{x}) = \nabla h(\mathbf{x})^\top \mathbf{g}(\mathbf{x}) \in \mathbb{R}^{1 \times m}$$

where $L_{\mathbf{f}} h(\mathbf{x})$ captures the unforced directional drift of clearance (passive momentum, centrifugal forces, gravity), and $L_{\mathbf{g}} h(\mathbf{x})$ is the directional control effectiveness row vector mapping control inputs into instantaneous safety margin growth.

[1] **Boundary Viability**: Nagumo's tangent-cone condition characterizes invariance under regularity assumptions. The displayed CBF inequality is a sufficient design condition for the stated smooth control-affine model. A sampled implementation needs a separate bound for state error, computation, hold interval, and actuator response; failure of one candidate inequality does not prove contact within one integration step.

DRAFT

B.4.2 Nagumo's viability theorem and contingent cones

Whether a trajectory can remain inside a closed safe set $\mathcal{C} \subset \mathbb{R}^n$ depends on which velocity directions point inward or tangent along its boundary, a geometric condition formalized by Nagumo's Viability Theorem (Blanchini 1999). The **Bouligand contingent cone** (or tangent cone) $T_{\mathcal{C}}(\mathbf{x})$ to $\mathcal{C}$ at a point $\mathbf{x} \in \mathcal{C}$ is defined as:

$$T_{\mathcal{C}}(\mathbf{x}) = \left\{ \mathbf{v} \in \mathbb{R}^n \;\middle|\; \liminf_{\tau \to 0^+} \frac{\operatorname{dist}(\mathbf{x}+\tau\mathbf{v}, \mathcal{C})}{\tau} = 0 \right\}$$

where $\operatorname{dist}(\mathbf{y}, \mathcal{C}) = \inf_{\mathbf{z}\in\mathcal{C}} \|\mathbf{y}-\mathbf{z}\|$. For trajectories that exist for the interval considered, Nagumo's theorem proves that an autonomous system $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ with locally Lipschitz vector field $\mathbf{f}$ keeps $\mathcal{C}$ forward-invariant if and only if the velocity vector satisfies the **subtangentiality condition**:

$$\mathbf{f}(\mathbf{x}) \in T_{\mathcal{C}}(\mathbf{x}) \quad \forall \mathbf{x} \in \mathcal{C}$$

In the interior $\operatorname{int}(\mathcal{C})$, $T_{\mathcal{C}}(\mathbf{x}) = \mathbb{R}^n$, so the condition is trivially satisfied. On the boundary $\partial\mathcal{C}$ of a smooth set defined by the zero-superlevel set of $h(\mathbf{x})$ ($\mathcal{C} = \{\mathbf{x} \mid h(\mathbf{x}) \geq 0\}$ with $\nabla h(\mathbf{x}) \neq \mathbf{0}$), the inward normal is $\nabla h(\mathbf{x})$. The contingent cone becomes the closed half-space of inward or tangent velocities:

$$T_{\mathcal{C}}(\mathbf{x}) = \left\{ \mathbf{v} \in \mathbb{R}^n \;\middle|\; \nabla h(\mathbf{x})^\top \mathbf{v} \geq 0 \right\} \quad \forall \mathbf{x} \in \partial\mathcal{C}$$

Consequently, the system cannot exit the set if and only if the directional derivative satisfies $\dot{h}(\mathbf{x}) = \nabla h(\mathbf{x})^\top \mathbf{f}(\mathbf{x}) \geq 0$ whenever $h(\mathbf{x}) = 0$. Control Barrier Functions (Ames et al. 2019) extend Nagumo's subtangentiality to controlled affine systems $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$. For safety, there must exist an admissible control $\mathbf{u} \in \mathcal{U}$ such that $\mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u} \in T_{\mathcal{C}}(\mathbf{x})$. By introducing an extended class $\mathcal{K}_\infty$ decay rate $\kappa(h(\mathbf{x}))$ satisfying $\kappa(0) = 0$, the CBF inequality:

$$\dot{h}(\mathbf{x}, \mathbf{u}) = L_{\mathbf{f}} h(\mathbf{x}) + L_{\mathbf{g}} h(\mathbf{x})\mathbf{u} \geq -\kappa(h(\mathbf{x}))$$

ensures that as the state approaches the boundary ($h(\mathbf{x}) \to 0$), the admissible decay rate contracts to zero ($-\kappa(h(\mathbf{x})) \to 0$). At the boundary $h(\mathbf{x}) = 0$, it strictly enforces $\dot{h}(\mathbf{x}, \mathbf{u}) \geq 0$, directly preserving Nagumo's subtangentiality invariant and preventing trajectory exit into the unsafe set.

B.4.3 Relative degree and kinetic stopping insets

Position clearance cannot change instantaneously when a motor drive updates its torque command, because torque acts on acceleration rather than position. The **relative degree** r of a barrier function $h(\mathbf{x})$ counts how many times h must be differentiated with respect to continuous time before the control input $\mathbf{u}$ explicitly appears:

$$L_{\mathbf{g}} L_{\mathbf{f}}^k h(\mathbf{x}) = \mathbf{0} \quad \forall k < r-1, \quad \text{and} \quad L_{\mathbf{g}} L_{\mathbf{f}}^{r-1} h(\mathbf{x}) \neq \mathbf{0}$$

For a one-dimensional approach to a stationary obstacle, let raw spatial clearance be $h_{\text{raw}} = D_{\text{clear}}$, approach speed $v > 0$, and commanded approach acceleration a_{cmd}. Differentiating reveals:

$$\dot{D}_{\text{clear}} = -v, \quad \ddot{D}_{\text{clear}} = -a_{\text{cmd}}$$

Because acceleration enters raw clearance only at the second time derivative ($L_{\mathbf{g}} h_{\text{raw}} = 0$ and $L_{\mathbf{g}} L_{\mathbf{f}} h_{\text{raw}} \neq 0$), raw clearance has **relative degree two** ($r = 2$) with respect to force or acceleration inputs. An actuator torque command cannot instantaneously change position or velocity. Commanding maximum braking at the boundary $D_{\text{clear}} = 0$ is futile because momentum carries the system across the boundary before velocity can reach zero.

For systems with general relative degree $r \geq 2$, **High-Order Control Barrier Functions (HOCBFs)** construct a cascaded sequence of barrier certificates:

$$\begin{aligned}
\psi_0(\mathbf{x}) &= h(\mathbf{x}) \\
\psi_1(\mathbf{x}) &= \dot{\psi}_0(\mathbf{x}) + \alpha_1(\psi_0(\mathbf{x})) \\
&\vdots \\
\psi_r(\mathbf{x}) &= \dot{\psi}_{r-1}(\mathbf{x}) + \alpha_r(\psi_{r-1}(\mathbf{x})) = L_{\mathbf{f}}^r h(\mathbf{x}) + L_{\mathbf{g}} L_{\mathbf{f}}^{r-1} h(\mathbf{x})\mathbf{u} + \ldots \geq 0
\end{aligned}$$

DRAFT

The high-order condition also requires safe initialization of all intermediate certificates $\psi_0, \ldots, \psi_{r-1}$ and a feasible control throughout their intersection. In physical robotics, rather than tuning abstract class $\mathcal{K}$ functions across multiple derivatives, we can augment the barrier coordinate with kinetic energy and available stopping capacity. In a one-dimensional approach to a stationary obstacle, let D_{clear} be measured clearance, $v > 0$ approach speed, and $a_{\text{brake}} > 0$ a validated lower bound on available braking deceleration for the operating state. Defining the **kinetic stopping inset**:

$$h_{\text{kinetic}}(D_{\text{clear}}, v) = D_{\text{clear}} - \frac{v^2}{2a_{\text{brake}}}, \qquad \dot{D}_{\text{clear}} = -v, \quad \dot{v} = a_{\text{cmd}}$$

Differentiating $h_{\text{kinetic}}(D_{\text{clear}}, v)$ along the system dynamics yields:

$$\dot{h}_{\text{kinetic}} = \dot{D}_{\text{clear}} - \frac{v}{a_{\text{brake}}}\dot{v} = -v - \frac{v}{a_{\text{brake}}}a_{\text{cmd}}$$

Commanded acceleration a_{cmd} now appears directly in the first time derivative ($r = 1$). The CBF condition $\dot{h}_{\text{kinetic}} + \gamma_{\text{cbf}} h_{\text{kinetic}} \geq 0$ (with gain $\gamma_{\text{cbf}} > 0$) enforces the linear affine inequality on commanded acceleration:

$$a_{\text{cmd}} \leq \frac{a_{\text{brake}}}{v}\left(\gamma_{\text{cbf}} h_{\text{kinetic}} - v\right) \quad \text{for } v > 0$$

At standstill ($v \to 0$), a separate static clearance rule must be evaluated. State estimation error, digital sampling, and brake-onset delay require additional clearance reserves; the continuous kinematic calculation alone does not cover them.

B.4.4 Minimal-intervention quadratic program

The Control Barrier Function Quadratic Program (CBF-QP) changes a nominal command only as much as needed to satisfy the modeled barrier and actuator constraints. At a fixed state, the barrier condition is affine in the control input, so the filter solves a convex projection problem:

$$\begin{aligned} \mathbf{u}^* = \arg\min_{\mathbf{u} \in \mathcal{U}} \frac{1}{2}\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2 \\ \text{subject to:} \quad L_{\mathbf{f}} h(\mathbf{x}) + L_{\mathbf{g}} h(\mathbf{x})\mathbf{u} \geq -\kappa(h(\mathbf{x})), \quad \mathbf{u}_{\min} \leq \mathbf{u} \leq \mathbf{u}_{\max} \end{aligned}$$

To a machine learning engineer, the CBF-QP is the continuous physical counterpart of **projection operators** used in optimization:

- In deep learning optimization, **Projected Gradient Descent (PGD)** enforces hard weight or adversarial perturbation constraints by projecting updated parameters back onto an ϵ-ball: $\mathbf{w}_{k+1} = \text{proj}_{\mathcal{C}}(\mathbf{w}_k - \eta \mathbf{g})$. In multi-task gradient learning (such as PCGrad or MGDA), conflicting task gradients $\nabla \mathcal{L}_i$ are projected onto the normal hyperplane of $\nabla \mathcal{L}_j$ via $\nabla \mathcal{L}_i \leftarrow \nabla \mathcal{L}_i - \frac{\nabla \mathcal{L}_i^\top \nabla \mathcal{L}_j}{\|\nabla \mathcal{L}_j\|^2} \nabla \mathcal{L}_j$ whenever their inner product is negative.
- In physical AI systems, the CBF-QP projects uncertified action vectors $\mathbf{u}_{\text{nom}} \in \mathbb{R}^m$ onto the convex polyhedron of forward-invariant safe actions $\mathcal{U}_{\text{safe}}(\mathbf{x}) = \{\mathbf{u} \in \mathcal{U} \mid L_{\mathbf{f}} h(\mathbf{x}) + L_{\mathbf{g}} h(\mathbf{x})\mathbf{u} \geq -\kappa(h(\mathbf{x}))\}$.

Write the affine CBF constraint in standard half-space form $\mathbf{a}_{\text{cbf}}^\top \mathbf{u} \leq b_{\text{cbf}}$, with normal vector $\mathbf{a}_{\text{cbf}} = -L_{\mathbf{g}} h(\mathbf{x})^\top \in \mathbb{R}^m$ and scalar threshold $b_{\text{cbf}} = L_{\mathbf{f}} h(\mathbf{x}) + \kappa(h(\mathbf{x}))$. Assume $\mathbf{a}_{\text{cbf}} \neq \mathbf{0}$ and consider the unconstrained actuator case ($\mathbf{u} \in \mathbb{R}^m$):

$$\min_{\mathbf{u} \in \mathbb{R}^m} \frac{1}{2}\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2 \quad \text{subject to } \mathbf{a}_{\text{cbf}}^\top \mathbf{u} \leq b_{\text{cbf}}$$

The Lagrangian function is:

$$L_{\text{Lag}}(\mathbf{u}, \lambda) = \frac{1}{2}\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2 + \lambda(\mathbf{a}_{\text{cbf}}^\top \mathbf{u} - b_{\text{cbf}})$$

The Karush-Kuhn-Tucker (KKT) optimality conditions are:

1. **Stationarity:** $\nabla_{\mathbf{u}} L_{\text{Lag}} = \mathbf{u}^* - \mathbf{u}_{\text{nom}} + \lambda^* \mathbf{a}_{\text{cbf}} = \mathbf{0} \implies \mathbf{u}^* = \mathbf{u}_{\text{nom}} - \lambda^* \mathbf{a}_{\text{cbf}}$

DRAFT

2. **Primal Feasibility:** $\mathbf{a}_{\text{cbf}}^\top \mathbf{u}^* \leq b_{\text{cbf}}$
3. **Dual Feasibility:** $\lambda^* \geq 0$
4. **Complementary Slackness:** $\lambda^*(\mathbf{a}_{\text{cbf}}^\top \mathbf{u}^* - b_{\text{cbf}}) = 0$

These conditions yield two distinct operational regimes:

- **Permissive Pass-Through:** When the nominal neural proposal $\mathbf{u}_{\text{nom}}$ satisfies the safety constraint ($\mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} \leq b_{\text{cbf}}$), the optimal Lagrange multiplier is $\lambda^* = 0$. The filter acts as an identity pass-through:
$$\mathbf{u}^* = \mathbf{u}_{\text{nom}}$$
Zero control effort is distorted in this regime. Passing the command untouched preserves the full behavioral fidelity of the learned policy during normal task execution.
- **Active Minimal-Intervention Projection:** When the neural policy proposes an unsafe command that attempts to penetrate the barrier ($\mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} > b_{\text{cbf}}$), the safety constraint must be active ($\mathbf{a}_{\text{cbf}}^\top \mathbf{u}^* = b_{\text{cbf}}$) and $\lambda^* > 0$. Substituting the stationarity condition into the active constraint yields:
$$\mathbf{a}_{\text{cbf}}^\top (\mathbf{u}_{\text{nom}} - \lambda^* \mathbf{a}_{\text{cbf}}) = b_{\text{cbf}} \implies \mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} - \lambda^* \|\mathbf{a}_{\text{cbf}}\|^2 = b_{\text{cbf}}$$
Solving for the optimal multiplier yields:
$$\lambda^* = \frac{\mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} - b_{\text{cbf}}}{\|\mathbf{a}_{\text{cbf}}\|^2} > 0$$
The filtered control command is the exact, closed-form Euclidean projection onto the safe half-space boundary:
$$\mathbf{u}^* = \mathbf{u}_{\text{nom}} - \left(\frac{\mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} - b_{\text{cbf}}}{\|\mathbf{a}_{\text{cbf}}\|^2} \right) \mathbf{a}_{\text{cbf}}$$

Unifying both cases into a single compact projection operator:

$$\mathbf{u}^* = \text{proj}_{\mathcal{U}_{\text{safe}}}(\mathbf{u}_{\text{nom}}) = \mathbf{u}_{\text{nom}} - \frac{\max(0, \mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} - b_{\text{cbf}})}{\|\mathbf{a}_{\text{cbf}}\|^2} \mathbf{a}_{\text{cbf}}$$

Geometrically, the vector $\mathbf{a}_{\text{cbf}} = -L_{\mathbf{g}} h(\boldsymbol{x})^\top$ points outward along the gradient of safety penetration. The term $\max(0, \mathbf{a}_{\text{cbf}}^\top \mathbf{u}_{\text{nom}} - b_{\text{cbf}})$ is precisely the **hinge loss** (or ReLU activation) of safety margin penetration. When the proposal is safe, the loss is zero and the output is untouched. When the proposal is unsafe, the projection operator subtracts the exact scalar penetration depth along $\mathbf{a}_{\text{cbf}}$, leaving all orthogonal control directions untouched. To an ML engineer, this is the exact continuous-control counterpart of an analytical, one-step subgradient projection onto a Support Vector Machine margin hyperplane.

If $\mathbf{a}_{\text{cbf}} = \mathbf{0}$, division by $\|\mathbf{a}_{\text{cbf}}\|^2$ is invalid: all inputs satisfy this constraint when $b_{\text{cbf}} \geq 0$, and none do when $b_{\text{cbf}} < 0$. With actuator limits or multiple barriers, the nonempty admissible set is a convex polyhedron and the strictly convex objective has a unique projection. A numerical implementation must check feasibility, residual tolerance, and completion before its deadline. A solver name or nominal cadence supplies none of those bounds.

> Systems Perspective B.2: Check feasibility before relying on invariance
>
> The unconstrained projection formula does not solve the box-constrained problem. Clamping its result post hoc can violate $\mathbf{a}_{\text{cbf}}^\top \mathbf{u} \leq b_{\text{cbf}}$. If no command satisfies both the barrier half-space and actuator limits simultaneously ($\mathcal{U}_{\text{safe}} \cap \mathcal{U}_{\text{adm}} = \emptyset$), the modeled invariant cannot be maintained by this filter. A separately validated emergency fallback may still limit harm, but it cannot restore the lost forward-invariance claim. Admission must reserve stopping authority before the state reaches this boundary.

DRAFT

B.5 Smooth Trajectories and Bumpless Transfer

Switching directly between two action chunks that differ in velocity or acceleration commands an abrupt torque step across the gearbox. Because physical links and rotors possess inertia, a velocity step requests an ideal acceleration impulse, and an acceleration step requests an instantaneous torque jump under a rigid-inertia model. Whether a commanded seam excites drivetrain resonance or trips an inverter fault depends on the plant, load, and controller response.

B.5.1 Analytical quintic splines

A quintic (5th-degree) polynomial trajectory segment $q(t)$ over time interval $t \in [0, T]$ is defined as:

$$q(t) = a_0 + a_1 t + a_2 t^2 + a_3 t^3 + a_4 t^4 + a_5 t^5$$

The six coefficients $[a_0, \dots, a_5]$ are uniquely determined by matching six boundary conditions at $t = 0$ and $t = T$:

$$\begin{aligned} q(0) &= q_0, \quad \dot{q}(0) = \dot{q}_0, \quad \ddot{q}(0) = \ddot{q}_0 \\ q(T) &= q_1, \quad \dot{q}(T) = \dot{q}_1, \quad \ddot{q}(T) = \ddot{q}_1 \end{aligned}$$

Solving the resulting linear system yields the exact analytical formulas:

$$\begin{aligned} a_0 &= q_0 \\ a_1 &= \dot{q}_0 \\ a_2 &= \frac{1}{2}\ddot{q}_0 \\ a_3 &= \frac{10(q_1 - q_0) - (6\dot{q}_0 + 4\dot{q}_1)T - (3\ddot{q}_0 - \ddot{q}_1)\frac{T^2}{2}}{T^3} \\ a_4 &= \frac{-15(q_1 - q_0) + (8\dot{q}_0 + 7\dot{q}_1)T + (3\ddot{q}_0 - 2\ddot{q}_1)\frac{T^2}{2}}{T^4} \\ a_5 &= \frac{6(q_1 - q_0) - 3(\dot{q}_0 + \dot{q}_1)T - (\ddot{q}_0 - \ddot{q}_1)\frac{T^2}{2}}{T^5} \end{aligned}$$

Differentiating three times gives the segment's **jerk profile**, a quadratic in time that stays finite over a finite blend:

$$\dddot{q}(t) = 6a_3 + 24a_4 t + 60a_5 t^2$$

Matching position, velocity, and acceleration at the endpoints gives a C^2 join to adjacent segments with those same endpoint values and removes the commanded acceleration step at the join. The endpoint conditions say nothing about the segment's interior, so its jerk and torque extrema, and the joint's resonant response, still require a check against the machine's measured limits. Section 11.5 places this bridge at the seam between two action chunks.

B.5.1.1 Boundary value matrix formulation

The polynomial coefficients $\mathbf{a} = [a_0, a_1, a_2, a_3, a_4, a_5]^\top$ are determined by evaluating the trajectory and its first two derivatives at the temporal endpoints $t = 0$ and $t = T$. This yields the 6×6 confluent Vandermonde linear system $\mathbf{M}\mathbf{a} = \mathbf{b}$:

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 \\ 1 & T & T^2 & T^3 & T^4 & T^5 \\ 0 & 1 & 2T & 3T^2 & 4T^3 & 5T^4 \\ 0 & 0 & 2 & 6T & 12T^2 & 20T^3 \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \\ a_4 \\ a_5 \end{bmatrix} = \begin{bmatrix} q_0 \\ \dot{q}_0 \\ \ddot{q}_0 \\ q_1 \\ \dot{q}_1 \\ \ddot{q}_1 \end{bmatrix}$$

DRAFT

The top three rows trivially yield the initial boundary terms: $a_0 = q_0$, $a_1 = \dot{q}_0$, and $a_2 = \frac{1}{2}\ddot{q}_0$. Substituting these values into the bottom three rows isolates the higher-order coefficients $[a_3, a_4, a_5]^\top$ under the reduced 3×3 system:

$$\begin{bmatrix} T^3 & T^4 & T^5 \\ 3T^2 & 4T^3 & 5T^4 \\ 6T & 12T^2 & 20T^3 \end{bmatrix} \begin{bmatrix} a_3 \\ a_4 \\ a_5 \end{bmatrix} = \begin{bmatrix} q_1 - q_0 - \dot{q}_0 T - \frac{1}{2}\ddot{q}_0 T^2 \\ \dot{q}_1 - \dot{q}_0 - \ddot{q}_0 T \\ \ddot{q}_1 - \ddot{q}_0 \end{bmatrix}$$

The determinant of this 3×3 matrix is $\det(\mathbf{M}_{33}) = 2T^9 > 0$ for all strictly positive blending horizons $T > 0$, guaranteeing non-singularity and uniqueness. The analytic matrix inverse is:

$$\begin{bmatrix} T^3 & T^4 & T^5 \\ 3T^2 & 4T^3 & 5T^4 \\ 6T & 12T^2 & 20T^3 \end{bmatrix}^{-1} = \begin{bmatrix} \frac{10}{T^3} & -\frac{4}{T^2} & \frac{1}{2T} \\ -\frac{15}{T^4} & \frac{7}{T^3} & -\frac{1}{T^2} \\ \frac{6}{T^5} & -\frac{3}{T^4} & \frac{1}{2T^3} \end{bmatrix}$$

Matrix multiplication $\mathbf{a}_{3:5} = \mathbf{M}_{33}^{-1}\mathbf{b}_{\text{red}}$ directly produces the closed-form coefficients a_3, a_4, a_5 stated above. Because the inverse scales as T^{-5} in its highest-order row, shrinking the blend duration T rapidly amplifies the commanded jerk and torque peaks.

B.5.2 Cubic Hermite spline interpolation for multi-rate synchronization

When synchronizing physical sensor and state streams arriving at heterogeneous rates (such as 30 Hz camera frames against 1 kHz joint encoder trajectories), intermediate poses must be continuously interpolated while preserving velocity continuity. A cubic Hermite spline over interval $t \in [t_0, t_1]$ with segment duration $T = t_1 - t_0$ interpolates position and velocity between endpoints:

$$q(t_0) = q_0, \quad \dot{q}(t_0) = \dot{q}_0, \quad q(t_1) = q_1, \quad \dot{q}(t_1) = \dot{q}_1$$

Introducing the normalized time coordinate $s = (t - t_0)/T \in [0, 1]$, the trajectory is parameterized by the cubic Hermite basis polynomials:

$$q(s) = h_{00}(s)q_0 + h_{10}(s)T\dot{q}_0 + h_{01}(s)q_1 + h_{11}(s)T\dot{q}_1$$

where the basis functions satisfy:

$$\begin{aligned} h_{00}(s) &= 2s^3 - 3s^2 + 1 \\ h_{10}(s) &= s^3 - 2s^2 + s \\ h_{01}(s) &= -2s^3 + 3s^2 \\ h_{11}(s) &= s^3 - s^2 \end{aligned}$$

Differentiating with respect to physical time t yields the instantaneous velocity:

$$\dot{q}(t) = \frac{1}{T}\frac{dq}{ds} = \frac{1}{T}\left(h'_{00}(s)q_0 + h'_{01}(s)q_1\right) + h'_{10}(s)\dot{q}_0 + h'_{11}(s)\dot{q}_1$$

with derivative basis functions:

$$\begin{aligned} h'_{00}(s) &= 6s^2 - 6s \\ h'_{10}(s) &= 3s^2 - 4s + 1 \\ h'_{01}(s) &= -6s^2 + 6s \\ h'_{11}(s) &= 3s^2 - 2s \end{aligned}$$

Because the basis polynomials satisfy $h_{00}(0) = 1, h_{00}(1) = 0, h'_{10}(0) = 1, h'_{10}(1) = 0$, this yields a C^1-continuous trajectory matching position and velocity exactly at sample boundaries without the computational overhead of solving a 6-boundary-condition quintic system. However, the resulting acceleration $\ddot{q}(t)$ is piecewise linear and discontinuous across sample boundaries (C^1 but not C^2), producing finite torque steps $\Delta\tau = M(q)\Delta\ddot{q}$ at knot points that require further smoothing when a finite torque-slew limit must be enforced.

DRAFT

B.5.3 Bumpless transfer and smoothstep blending

For bumpless transfer (section 14.4), let $\hat{t} = (t - t_{\text{start}})/\tau_{\text{blend}} \in [0,1]$ be the normalized progress, as in equation 14.6, and use the same C^2 smoothstep $\alpha(\hat{t})$ to interpolate two commands:

$$\alpha(\hat{t}) = 6\hat{t}^5 - 15\hat{t}^4 + 10\hat{t}^3, \qquad u(t) = (1-\alpha(\hat{t}))u_{\text{prior}}(t) + \alpha(\hat{t})u_{\text{new}}(t).$$

The endpoint first and second derivatives of α vanish. If u is commanded acceleration, its time derivative is commanded-acceleration jerk:

$$j_{\text{cmd}}(t) = \frac{\alpha'(\hat{t})}{\tau_{\text{blend}}}(u_{\text{new}} - u_{\text{prior}}) + (1-\alpha(\hat{t}))\dot{u}_{\text{prior}} + \alpha(\hat{t})\dot{u}_{\text{new}}.$$

Here $\alpha'(\hat{t}) = 30\hat{t}^2(1-\hat{t})^2$ differentiates with respect to *normalized* time and peaks at 1.875. Only for two fixed, latched endpoint accelerations ($\dot{u}_{\text{prior}} = \dot{u}_{\text{new}} = 0$) does the blend contribution satisfy

$$\max|j_{\text{cmd}}| = \frac{1.875|\Delta u|}{\tau_{\text{blend}}}, \qquad \tau_{\text{blend}} \geq \frac{1.875|\Delta u|}{j_{\max}}.$$

This is a command-rate condition. Measured plant jerk, tracking error, and available stopping clearance remain separate admission checks.

B.5.4 Flexible joint dynamics and singular perturbations

Mechanical transmissions such as harmonic strain-wave drives, planetary reducers, and cable linkages introduce torsional elasticity between actuator motor rotors and robot links. Following Mark W. Spong's canonical formulation (Spong 1987), an n-degree-of-freedom manipulator with elastic joints is governed by two coupled second-order vector differential equations:

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{K}(\theta_{\text{motor}} - \mathbf{q})$$

$$\mathbf{J}_m\ddot{\theta}_{\text{motor}} + \mathbf{B}_m\dot{\theta}_{\text{motor}} + \mathbf{K}(\theta_{\text{motor}} - \mathbf{q}) = \tau$$

The coordinates and structural matrices have the following physical roles:

- $\mathbf{q} \in \mathbb{R}^n$ represents the physical link coordinates.
- $\theta_{\text{motor}} \in \mathbb{R}^n$ represents the motor rotor coordinates reflected through gear reduction N_{gear} to the link side.
- $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{n\times n}$ is the symmetric, positive-definite link inertia matrix.
- $\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} \in \mathbb{R}^n$ collects Coriolis and centripetal terms.
- $\mathbf{g}(\mathbf{q}) \in \mathbb{R}^n$ is the gravitational torque vector.
- $\mathbf{J}_m = \text{diag}(J_{m_1}, \ldots, J_{m_n})$ is the diagonal matrix of reflected rotor inertias ($J_{m_i} = {N_{\text{gear}}}_i^2 {J_{\text{rotor}}}_i$).
- $\mathbf{B}_m = \text{diag}(B_{m_1}, \ldots, B_{m_n})$ collects viscous motor damping.
- $\mathbf{K} = \text{diag}({K_{\text{joint}}}_1, \ldots, {K_{\text{joint}}}_n)$ is the diagonal joint torsional stiffness matrix (${K_{\text{joint}}}_i > 0$).
- $\tau \in \mathbb{R}^n$ is the vector of actuator torques reflected to the link side, consistent with the reflected motor coordinates and inertias.

B.5.4.1 Singular perturbation formulation and time-scale separation

Time-scale separation requires the elastic modes to be fast relative to the intended rigid-body motion. After nondimensionalizing time, inertia, and stiffness by declared reference scales, write $\mathbf{K} = \tilde{\mathbf{K}}/\epsilon^2$, where ϵ is a small dimensionless ratio of fast to slow time scales and $\tilde{\mathbf{K}} = \mathcal{O}(1)$. A comparison such as stiffness greater than one has no physical meaning before this scaling.

Define the elastic torque fast state variable $\mathbf{z} \in \mathbb{R}^n$:

$$\mathbf{z} = \frac{1}{\epsilon^2}\tilde{\mathbf{K}}(\theta_{\text{motor}} - \mathbf{q}) = \mathbf{K}(\theta_{\text{motor}} - \mathbf{q})$$

DRAFT

Differentiating $\mathbf{z}$ twice with respect to continuous time t gives:

$$\ddot{\mathbf{z}} = \mathbf{K}(\ddot{\theta}_{\text{motor}} - \ddot{\mathbf{q}}) = \mathbf{K}\left[\mathbf{J}_m^{-1}(\tau - \mathbf{B}_m\dot{\theta}_{\text{motor}} - \mathbf{z}) - \mathbf{M}(\mathbf{q})^{-1}(\mathbf{z} - \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} - \mathbf{g}(\mathbf{q}))\right]$$

Multiplying through by ϵ^2 reveals the singularly perturbed boundary layer:

$$\epsilon^2\ddot{\mathbf{z}} = \tilde{\mathbf{K}}\left[\mathbf{J}_m^{-1}\tau - (\mathbf{J}_m^{-1} + \mathbf{M}(\mathbf{q})^{-1})\mathbf{z} + \mathbf{M}(\mathbf{q})^{-1}(\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})) - \mathbf{J}_m^{-1}\mathbf{B}_m\dot{\theta}_{\text{motor}}\right]$$

For the following undamped fast-mode calculation, set $\mathbf{B}_m = \mathbf{0}$ and freeze the slow configuration. Introducing the stretched fast time variable $t_{\text{fast}} = t/\epsilon$ transforms the elastic dynamics into:

$$\frac{d^2\mathbf{z}}{dt_{\text{fast}}^2} + \tilde{\mathbf{K}}(\mathbf{J}_m^{-1} + \mathbf{M}(\mathbf{q})^{-1})\mathbf{z} = \tilde{\mathbf{K}}\mathbf{J}_m^{-1}\tau + \tilde{\mathbf{K}}\mathbf{M}(\mathbf{q})^{-1}(\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}))$$

B.5.4.2 The rigid manifold and boundary-layer resonance

In the singular limit as joint stiffness approaches infinity ($\epsilon \to 0$), the fast elastic variable $\mathbf{z}$ has the formal quasi-steady manifold $\mathbf{z}_0$:

$$\mathbf{z}_0 = (\mathbf{J}_m^{-1} + \mathbf{M}(\mathbf{q})^{-1})^{-1}\left[\mathbf{J}_m^{-1}\tau + \mathbf{M}(\mathbf{q})^{-1}(\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}))\right]$$

The undamped expression does not prove that fast oscillations decay onto this manifold. Restoring damping and imposing the rigid constraint $\theta_{\text{motor}} = \mathbf{q}$ in the original equations gives the classical rigid-body equations with aggregated inertia $\mathbf{M}(\mathbf{q}) + \mathbf{J}_m$:

$$(\mathbf{M}(\mathbf{q}) + \mathbf{J}_m)\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) + \mathbf{B}_m\dot{\mathbf{q}} = \tau$$

For finite stiffness, a torque step excites the elastic modes; it is a step forcing, not an impulse. In physical time, their squared natural frequencies are the eigenvalues of the frozen-configuration matrix $\mathbf{K}(\mathbf{J}_m^{-1} + \mathbf{M}(\mathbf{q})^{-1})$. Equivalently, the modal frequency matrix is:

$$\Omega(\mathbf{q}) = \sqrt{\mathbf{K}(\mathbf{J}_m^{-1} + \mathbf{M}(\mathbf{q})^{-1})}$$

The actual damping and resonant frequencies depend on the transmission and load. Smoothing commands and limiting torque slew can reduce excitation, but C^2 continuity alone does not establish a resonance or fatigue bound. The blend spectrum and measured closed-loop response must be checked against the flexible plant.

B.5.5 Discrete-time sampling and zero-order hold phase lag

Real-time digital controllers execute periodically at sampling period $T_s = 1/f_s$. Actuator drivers hold commanded setpoints constant between clock ticks using a **Zero-Order Hold (ZOH)**. At frequencies well below the sampling frequency, the zero-order hold's phase is equivalent to about half a sample period of delay:

$$\tau_{\text{ZOH}} = \frac{T_s}{2}$$

For a closed-loop control system operating at crossover frequency ω_c, this transport delay erodes the system's phase margin Φ_m by:[2]

$$\Delta\phi_{\text{ZOH}} = \omega_c\frac{T_s}{2} \quad \text{(radians)} \approx 28.65^\circ \cdot \left(\frac{\omega_c}{f_s}\right)$$

For fixed modeled compute and bus delays, the added phase lag near crossover is approximately $\Delta\phi_{\text{total}} = \omega_c(T_{\text{comp}} + T_{\text{bus}} + T_s/2)$. The controller must validate phase margin over the measured latency and operating envelope; the formula alone does not predict a particular contact response.

[2] **Phase Margin and Delay**: A pure delay T_d contributes phase $-\omega T_d$. The half-sample approximation applies in the baseband; actual stability depends on the sampled plant, compensation, jitter, and measured total response. Consuming modeled phase margin predicts loss of the stated stability reserve, not a specific destructive failure mode.

B.6 Dynamic Reachability, Intent Envelopes, and Differential Games

A target tote 0.60 m from the wrist is geometrically inside a 0.855 m manipulator workspace. Yet it is unreachable within a 150 ms intent lease if the arm cannot accelerate, traverse 0.60 m, and decelerate to rest within its torque and jerk limits before the lease expires. Kinematic reachability characterizes the set of configurations or end-effector poses a mechanism can reach geometrically, whereas dynamic reachability restricts that set to states attainable within the remaining time horizon and actuator bounds.

DRAFT

B.6.1 Forward kinematics and singularities

When a two-link arm stretches straight out, a small Cartesian velocity request along the extended link axis demands huge joint velocities near the singular alignment. Section 11.2 introduces forward kinematics, the Jacobian, and the singular pose on a planar two-link abstraction of the machine's arm. Section 11.4.5 turns a path into a timed trajectory under torque and jerk bounds. This section states the general n-joint form those examples specialize.

For an n-joint arm, the **forward-kinematics** map $\mathbf{FK}(\mathbf{q})$ sends joint coordinates $\mathbf{q} \in \mathbb{R}^n$ to an end-effector pose $\mathbf{T}_{WE} \in SE(3)$:

$$\mathbf{T}_{WE} = \mathbf{FK}(\mathbf{q}).$$

In a declared spatial or body twist convention, the **manipulator Jacobian** $\mathbf{J}(\mathbf{q}) \in \mathbb{R}^{6\times n}$ relates joint rates to the six-vector end-effector twist $\mathbf{V}_E$:

$$\mathbf{V}_E = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}.$$

For a six-dimensional task and $n \geq 6$, rank loss ($\det(\mathbf{J}\mathbf{J}^\top) = 0$) marks a **kinematic singularity**. Tracking a nonzero twist along a lost direction would require unbounded joint rates in the ideal inverse model; real actuators saturate first. A task-specific design may monitor $w(\mathbf{q}) = \sqrt{\det(\mathbf{J}\mathbf{J}^\top)}$ against a validated threshold.[3]

[3] **Yoshikawa Manipulability Measure**: The measure summarizes the velocity ellipsoid for a chosen task Jacobian. Near rank loss, inverse-kinematics commands can exceed joint-rate or torque limits. The actual drive response and fallback depend on the specified controller and hardware.

To an ML engineer, the geometry of a kinematic singularity is best understood through the Singular Value Decomposition (SVD) of the Jacobian:

$$\mathbf{J}(\mathbf{q}) = \mathbf{U}\Sigma\mathbf{V}^\top = \sum_{i=1}^{6} \sigma_i \mathbf{u}_i \mathbf{v}_i^\top$$

For the full-row-rank case, $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_6 > 0$ are the singular values. The Yoshikawa manipulability index evaluates to the product of these singular values: $w(\mathbf{q}) = \prod_{i=1}^{6} \sigma_i$. In unregularized differential inverse kinematics, solving for commanded joint rates yields:

$$\dot{\mathbf{q}} = \mathbf{J}(\mathbf{q})^\dagger \mathbf{V}_E = \sum_{i=1}^{6} \left(\frac{\mathbf{u}_i^\top \mathbf{V}_E}{\sigma_i} \right) \mathbf{v}_i$$

As the arm approaches a singularity, the smallest singular value vanishes ($\sigma_6 \to 0$). Any commanded task twist with a nonzero projection onto the lost direction ($\mathbf{u}_6^\top \mathbf{V}_E \neq 0$) causes the commanded joint rate $\dot{\mathbf{q}}$ to explode as $\mathcal{O}(1/\sigma_6)$, potentially exceeding motor velocity limits. The drive response depends on its current and fault logic.

Roboticists resolve this through **Damped Least Squares (DLS)** inverse kinematics (Wampler 1986; Nakamura and Hanafusa 1986):

$$\mathbf{J}_\lambda^\dagger = \mathbf{J}^\top \left(\mathbf{J}\mathbf{J}^\top + \lambda^2 \mathbf{I} \right)^{-1}$$

For a spatial task mixing translation and rotation, first declare a task scaling or metric so that the singular values and damping parameter are comparable; the velocity bound below uses that same scaled norm. For each singular mode, the effective inversion gain is regularized from $1/\sigma_i$ to $\frac{\sigma_i}{\sigma_i^2+\lambda^2} \leq \frac{1}{2\lambda}$. This is mathematically identical to ℓ_2 Tikhonov regularization (ridge regression / weight decay) in machine learning: it deliberately introduces a bounded tracking residual in exchange for strictly bounded joint velocities ($\|\dot{\mathbf{q}}\| \leq \|\mathbf{V}_E\|/(2\lambda)$).

B.6.2 Trajectory transit time and reachable distance

For a one-dimensional rest-to-rest move with symmetric available acceleration $a_{\max}$ and speed ceiling $v_{\max}$, the shortest nominal transit has two regimes:

1. **Triangular profile (acceleration-limited):** For short horizons where peak velocity $v_{\max}$ is not attained ($d \leq d_{\text{crit}} = v_{\max}^2/a_{\max}$):

$$t_{\min} = 2\sqrt{\frac{d}{a_{\max}}}, \quad d_{\text{reach}}(T_{\text{rem}}) = \frac{1}{4} a_{\max} T_{\text{rem}}^2$$

2. **Trapezoidal profile (velocity-limited):** For larger horizons ($d > d_{\text{crit}}$):

$$t_{\min} = \frac{d}{v_{\max}} + \frac{v_{\max}}{a_{\max}}, \quad d_{\text{reach}}(T_{\text{rem}}) = v_{\max}\left(T_{\text{rem}} - \frac{v_{\max}}{a_{\max}}\right)$$

Below d_{crit} the reachable distance grows with the square of the available time, and above it only linearly, because the mechanism spends the rest of the move at its speed ceiling. When jerk is also bounded by $|\dot{a}| \le j_{\max}$, reaching full acceleration from zero takes at least $a_{\max}/j_{\max}$, if the profile reaches it at all. That bound exists because an acceleration step is a torque step, which shocks gearbox backlash, excites structural modes, and drives motor current toward the inverter's fault limits. The minimum-time trajectory may have four or seven jerk phases, so an unconditional additive offset to the trapezoidal time is invalid. Solve the constrained profile for the stated start/end velocity and acceleration, then include the stopping suffix and response delay when sizing a lease.

The idealized profiles still serve admission. Each added limit (jerk, torque, or thermal derating) can only shrink the **dynamic reachable set** $\mathcal{R}(T_{\text{rem}})$, the states reachable from the measured state within the remaining time $T_{\text{rem}} = t_{\text{intent_exp}} - t_{\text{now}}$. The transit times of the idealized profiles are therefore necessary lower bounds, and a proposal whose idealized time already exceeds T_{rem} can be rejected before a full path, torque, and stopping check. Section 10.6 applies this rejection to the arm's reach against the tracked horizon.

B.6.3 Hamilton-Jacobi reachability and worst-case differential games

While kinematic reachability examines static geometry and idealized transit bounds, dynamic reachability under external disturbances and modeling errors requires analyzing system evolution as a continuous differential game (Mitchell et al. 2005). Consider a nonlinear dynamical system governed by:

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), \mathbf{d}(t))$$

where $\mathbf{x} \in \mathbb{R}^n$ is the system state, $\mathbf{u} \in \mathcal{U}_{\text{adm}} \subset \mathbb{R}^m$ is the control input (seeking to maintain safety), and $\mathbf{d} \in \mathcal{W} \subset \mathbb{R}^p$ is an adversarial disturbance (representing unmodeled friction, wind gusts, dynamic obstacles, or worst-case model discrepancies).

Let the failure or collision region be represented by the open zero-sublevel set of a Lipschitz continuous surface function $l(\mathbf{x})$:

$$\mathcal{F}_{\text{fail}} = \{\mathbf{x} \in \mathbb{R}^n \mid l(\mathbf{x}) < 0\}$$

The safe set is the superlevel set $\{\mathbf{x} \mid l(\mathbf{x}) \ge 0\}$. The **Backward Reachable Tube (BRT)** $\mathcal{R}(t)$ is defined as the set of states from which the disturbance can force the system into collision at any time $t' \in [t, T]$, even if the control executes optimal evasive action:

$$\mathcal{R}(t) = \{\mathbf{x} \in \mathbb{R}^n \mid \forall \mathbf{u}(\cdot) \in \mathcal{U}_{\text{adm}},\ \exists \mathbf{d}(\cdot) \in \mathcal{W},\ \exists t' \in [t, T] \text{ s.t. } \mathbf{x}(t') \in \mathcal{F}_{\text{fail}}\}$$

Formulating safety verification as a continuous two-player zero-sum differential game, the value function $V(\mathbf{x}, t)$ represents the outcome of **continuous-state minimax Bellman dynamic programming** over trajectory time:

$$V(\mathbf{x}, t) = \sup_{\mathbf{u} \in \mathcal{U}_{\text{adm}}} \inf_{\mathbf{d} \in \mathcal{W}} \min_{t' \in [t, T]} l(\mathbf{x}(t'))$$

The system is guaranteed safe over $[t, T]$ if and only if $V(\mathbf{x}, t) \ge 0$. The zero-sublevel set of $V(\mathbf{x}, t)$ corresponds exactly to the Backward Reachable Tube: $\mathcal{R}(t) = \{\mathbf{x} \mid V(\mathbf{x}, t) < 0\}$.

Applying Bellman's principle of dynamic programming in continuous state space yields the **Hamilton-Jacobi-Isaacs (HJI)** variational inequality:

$$\min\left\{\frac{\partial V}{\partial t} + \mathcal{H}(\mathbf{x}, \nabla V(\mathbf{x}, t)),\ l(\mathbf{x}) - V(\mathbf{x}, t)\right\} = 0, \quad V(\mathbf{x}, T) = l(\mathbf{x})$$

where the Hamiltonian $\mathcal{H}(\mathbf{x}, \mathbf{p})$ evaluates the directional derivative of the value function along system dynamics under worst-case minimax competition:

$$\mathcal{H}(\mathbf{x}, \mathbf{p}) = \max_{\mathbf{u} \in \mathcal{U}_{\text{adm}}} \min_{\mathbf{d} \in \mathcal{W}} \mathbf{p}^\top \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{d})$$

DRAFT

The trajectory notation above is shorthand for a differential game with nonanticipating strategies: actions may depend on available state history, not future disturbances. The information pattern and regularity assumptions must match the Hamiltonian ordering; arbitrary open-loop input quantifiers alone do not establish a feedback safety guarantee. Here $\mathbf{p} = \nabla V(\mathbf{x}, t) \in \mathbb{R}^n$ is the costate vector, representing the spatial gradient (directional sensitivity vector) of the safety boundary.

Because the value function $V(\mathbf{x}, t)$ develops non-differentiable kinks and gradient discontinuities where characteristics collide or bifurcate, classical smooth solutions do not exist globally. The PDE is solved in the sense of **viscosity solutions** (Mitchell et al. 2005).[4]

[4] **Viscosity Solutions and Level Set Methods**: Introduced by Crandall and Lions, viscosity solutions provide the mathematically rigorous framework for continuous weak solutions to first-order Hamilton-Jacobi PDEs where spatial gradients ∇V are discontinuous. High-order numerical schemes (such as WENO spatial discretization and TVD Runge-Kutta time integration) evaluate the sub- and super-differentials of V on regular Eulerian grids, tracking the implicit zero-level set without explicit front parameterization.

A regular grid with N points per coordinate in state dimension n stores $\mathcal{O}(N^n)$ values, making direct reachability analysis expensive as dimension grows. If an infinite-horizon value converges under suitable game assumptions, its nonnegative set describes robust viability for that model. The limiting value need not be smooth and is not automatically a classical differentiable CBF.

At runtime, a gridded or learned approximation can support a safety filter only with controlled approximation error. Where a suitable smooth certificate is available, its directional derivatives supply barrier constraints; otherwise nonsmooth reachability methods are needed. Distilling a value function into a neural network does not preserve the offline guarantee without verification.

B.6.4 Spatial coordinate frames and lever-arm kinematics

When an IMU or camera is mounted at a fixed offset from a robot's center of rotation, angular velocity and angular acceleration induce apparent linear motion at the sensor that must be separated from true translation. Rigid-body pose in three-dimensional space is parameterized by the Special Euclidean group $SE(3)$, where a rigid transform from frame B to frame A is represented by the homogeneous transformation matrix $\mathbf{T}_{AB} \in SE(3)$:

$$\mathbf{T}_{AB} = \begin{bmatrix} \mathbf{R}_{AB} & \mathbf{t}_{AB} \\ \mathbf{0}^\top & 1 \end{bmatrix}, \quad \mathbf{R}_{AB} \in SO(3), \quad \mathbf{t}_{AB} \in \mathbb{R}^3$$

The rotation group $SO(3)$ consists of orthonormal rotation matrices with determinant one; $SE(3)$ combines one such rotation with a translation. Thus $\mathbf{p}_A = \mathbf{R}_{AB}\mathbf{p}_B + \mathbf{t}_{AB}$ maps coordinates of a point from B to A, and transforms along a chain compose as $\mathbf{T}_{AC} = \mathbf{T}_{AB}\mathbf{T}_{BC}$. When sensors such as IMUs or cameras are displaced from the body center of rotation by lever arm $\mathbf{r}_{P/O}$, rotational motion induces apparent velocities and accelerations at sensor location P. The linear velocity $\mathbf{v}_P$ and linear acceleration $\mathbf{a}_P$ satisfy:

$$\mathbf{v}_P = \mathbf{v}_O + \omega \times \mathbf{r}_{P/O}$$

$$\mathbf{a}_P = \mathbf{a}_O + \alpha \times \mathbf{r}_{P/O} + \omega \times (\omega \times \mathbf{r}_{P/O})$$

All vectors in these sums must be expressed in the same frame, and P must be fixed to the rigid body. Here ω is the body angular velocity, $\alpha = \dot{\omega}$ is the angular acceleration, $\alpha \times \mathbf{r}_{P/O}$ is the tangential acceleration, and $\omega \times (\omega \times \mathbf{r}_{P/O})$ is the centripetal acceleration. State estimation and perception pipelines must compensate for these kinematic lever-arm terms when synchronizing multi-camera extrinsics and fusing IMU data.

B.6.5 Watchdog validity leases and teleoperation latency bounds

When an application processor stalls mid-aisle while the mobile base is cruising at 1.5 m/s, the base continues advancing 1.5 mm per millisecond until the safety microcontroller's lease expires and the brakes engage. In distributed autonomous systems and supervisory teleoperation architectures, actuation authority is governed by bounded-duration validity leases and communications latency constraints.

B.6.5.1 Kinematic derivation of watchdog validity leases

Consider an autonomous mobile platform or manipulator moving at speed v toward an obstacle with measured physical clearance D_{clear}. If the host processor or neural network fails to refresh the control setpoint, a hardware or firmware watchdog must intervene to prevent boundary violation. For a stop triggered by lease expiry, measure clearance at the supporting observation's capture epoch.

DRAFT

The elapsed time from that epoch until physical braking initiates is $\tau_{\text{delay,sub}} + \Delta_{\text{da}}$. The pre-brake subtotal $\tau_{\text{delay,sub}}$ comprises five nonoverlapping intervals, a lease-expiry form of the stopping-budget delay whose hazard-detection form appears in section C.13:

$$\tau_{\text{delay,sub}} = T_{\text{lease}} + t_{\text{detect}} + T_{\text{hold}} + t_{\text{age}} + T_{\text{act}}$$

and the dispatch-to-admission interval Δ_{da} is charged beside it, never inside it. Here:

- T_{lease} runs from successful admission to lease expiry; receipt or publication alone does not renew it.
- t_{detect} covers the post-expiry permission check and stop-command transport to the drive. It excludes the lease countdown already charged above and any separately charged hold.
- T_{hold} is an optional additional hold or fault-confirmation interval before the stop command reaches the drive; it is zero when the selected path has no such interval.
- t_{age} runs from evidence capture to perception's dispatch of the observation, including sensing and perception inference. Clock-conversion uncertainty must enter the age bound or a justified spatial allowance once.
- Δ_{da} runs from that dispatch through successful admission, including remaining proposer inference, transport, deserialization, validation, activation, and the wait for the next permission tick. Capture to admission is therefore $t_{\text{age}} + \Delta_{\text{da}}$, and a stored dispatch age covers only its first term.
- T_{act} runs from delivery of the stop command until the actuator establishes the braking deceleration assumed below.

The event boundaries follow the stalled-proposer timeline in section 4.4. A heartbeat timeout is an alternative trigger with its own response path, not an extra countdown appended to an expired chunk lease. If clearance is instead referenced to a hazard's appearance, the bound must also include any time until the supporting observation captures it.

Under constant cruising speed v before brake onset, a verified lower bound on mechanical braking deceleration $a_{\text{brake}} > 0$, a localization bound δ_{loc}, and a fixed protective clearance δ_{margin}, the total stopping distance bounded by available clearance D_{clear} satisfies:

$$v\,(\tau_{\text{delay,sub}} + \Delta_{\text{da}}) + \frac{v^2}{2a_{\text{brake}}} + \delta_{\text{loc}} + \delta_{\text{margin}} \le D_{\text{clear}}$$

Solving directly for the maximum admissible validity lease T_{lease} yields:

$$T_{\text{lease}} \le \frac{D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - \frac{v^2}{2a_{\text{brake}}}}{v} - \left(t_{\text{detect}} + T_{\text{hold}} + t_{\text{age}} + \Delta_{\text{da}} + T_{\text{act}}\right)$$

This constant-deceleration model is a reference calculation, not the complete stopping budget of the running machine. A shaped stop must substitute its qualified stopping distance for $v^2/(2a_{\text{brake}})$ and reserve tracking error and every other justified allowance, and the same substitution applies to the teleoperation bound below. If the right-hand side is nonpositive, this budget permits no positive execution lease. The enforcer must select the available fallback immediately, because a negative bound means that even an immediate response lacks the stated stopping reservation.

B.6.5.2 Teleoperation network round-trip time bounds

When a human supervisor remotely teleoperates the robot across an external wireless link, the control loop includes human perceptual reaction latency and network packet transport delays, decomposed into five terms:

- T_{video} represent video camera exposure, encoding, and operator display processing, excluding network transport, which is charged in T_{RTT}.
- T_{human} denote human neuromuscular reaction time ($T_{\text{human}} \approx 150$–$250$ ms).
- $T_{\text{RTT}} = T_{\text{downlink}} + T_{\text{uplink}}$ represent network round-trip transport latency.
- T_{act} denote actuator braking engagement lag.

DRAFT

- $d_{\text{brake}} = \frac{v^2}{2a_{\text{brake}}}$ represent the purely mechanical braking distance.

Total available time before available clearance D_{clear} is exhausted is bounded by $T_{\text{total}} = (D_{\text{clear}} - d_{\text{brake}})/v$. The allowable round-trip network latency ceiling is:

$$T_{\text{RTT}} \leq \frac{D_{\text{clear}} - d_{\text{brake}}}{v} - (T_{\text{video}} + T_{\text{human}} + T_{\text{act}})$$

If network jitter pushes T_{RTT} beyond this bound, the human operator cannot perceive an obstacle and deliver a corrective command before the vehicle exhausts its stopping distance. Consequently, the local enforcer must evaluate physical invariants at a rate justified by its response budget, revoking operator command authority and executing autonomous braking before physical clearance is lost. Section 14.2 uses this bound to size a handover, where the operator's round trip spends the same pre-brake budget.

B.6.5.3 Kinodynamic bounds vs. wave-variable passivity

Transport delay in teleoperation creates two distinct failure modes: spatial boundary breach (kinematic collision) and high-frequency dynamic chatter (loss of closed-loop passivity). Wave variables (section B.10) preserve the communication channel's passivity under their delay assumptions. The coupled teleoperator still requires a valid energy argument for its other components. Passivity does not bound physical displacement. Safety requires satisfying both invariants simultaneously. Wave variables bound interactive contact energy, while the kinodynamic latency inequality reserves spatial clearance under its constant-speed, fixed-obstacle, and braking assumptions.

B.7 Rigid Body Contact Mechanics

In free space, a small change in joint torque produces a smooth change in link acceleration. When a gripper finger or foot touches a rigid surface, the gap closes to zero and a normal reaction force appears abruptly to prevent interpenetration. Simulating and controlling physical interaction (locomotion, dexterous manipulation, tool assembly) requires modeling this boundary transition. The ideal unilateral, nonadhesive rigid-contact model uses complementarity: interaction forces arise strictly when bodies establish physical contact.

Let $\mathbf{q} \in \mathbb{R}^n$ denote generalized configuration coordinates. Let $\phi(\mathbf{q})$ be the signed distance (or gap function) between contact geometries:

- $\phi(\mathbf{q}) > 0$: Bodies are separated.
- $\phi(\mathbf{q}) = 0$: Bodies are touching (contact established).
- $\phi(\mathbf{q}) < 0$: Bodies are penetrating (a geometric interpenetration that rigid mechanics strictly forbids).

Let λ_n (or f_n) denote the normal contact force pushing the bodies apart. In constrained mathematical optimization, the non-penetration condition corresponds to the inequality constraint $g(\mathbf{q}) = \phi(\mathbf{q}) \geq 0$. The governing physical law of unilateral rigid contact is precisely the **Karush-Kuhn-Tucker (KKT) complementary slackness condition**:

1. Non-penetration (primal feasibility): $\phi(\mathbf{q}) \geq 0$
2. Repulsive unilateral force (dual feasibility): $\lambda_n \geq 0$
3. Complementary slackness: $\phi(\mathbf{q})\lambda_n = 0$

These non-smooth physical contact laws map onto familiar mathematical concepts of constrained optimization:

Physical Entity	Mechanical Role in Physical Plant	Optimization Duality in ML Systems
Gap Function $\phi(\mathbf{q}) \geq 0$	Spatial clearance preventing interpenetration	Primal inequality constraint $g(\mathbf{x}) \geq 0$ defining the feasible region
Normal Force $\lambda_n \geq 0$	Repulsive contact force pushing bodies apart	Dual Lagrange multiplier $\lambda \geq 0$ associated with the active constraint

DRAFT

Physical Entity	Mechanical Role in Physical Plant	Optimization Duality in ML Systems
Complementary Slackness $\phi(\mathbf{q})\lambda_n = 0$	Contact force exists only when touching ($\phi = 0$)	KKT condition: multiplier is nonzero only when constraint is active
Delassus Operator $\mathbf{A}_{\text{Delassus}}$	Apparent inverse inertia reflected at contact point	Schur complement of the constraint Jacobian in the KKT system
Impact Impulse $P_n = m_{\text{eff}}\Delta v_n$	Instantaneous momentum transfer across zero duration	Non-differentiable jump in state trajectory; Dirac delta distribution
Restitution Law $v_n^+ = -ev_n^-$	Discontinuous velocity jump across collision boundary	Step discontinuity that breaks smooth reverse-mode automatic differentiation

Just as Lagrange multipliers in constrained optimization become nonzero ($\lambda > 0$) only when constraints are active and tight ($g = 0$), normal contact forces materialize exclusively upon contact closure:

- If bodies are separated ($\phi(\mathbf{q}) > 0$), the constraint is inactive, enforcing $\lambda_n = 0$.
- If bodies are touching ($\phi(\mathbf{q}) = 0$), the constraint is active, permitting repulsive normal forces $\lambda_n \geq 0$ to prevent interpenetration.
- This nonadhesive contact model excludes tensile normal forces ($\lambda_n < 0$); adhesion, grasping, and attached fixtures need other models.

B.7.1 The Delassus operator and acceleration-level LCP

At the velocity level, kinematic normal velocity is $v_n = \dot{\phi}(\mathbf{q}) = \mathbf{J}_n(\mathbf{q})\dot{\mathbf{q}}$, where $\mathbf{J}_n(\mathbf{q}) = \nabla\phi(\mathbf{q})^\top \in \mathbb{R}^{1\times n}$ is the contact normal Jacobian. Differentiating with respect to continuous time yields normal acceleration:

$$\ddot{\phi}(\mathbf{q}) = \mathbf{J}_n(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{J}}_n(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}}$$

Substituting the multi-body equations of motion $\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \tau + \mathbf{J}_n(\mathbf{q})^\top\lambda_n$ isolates configuration acceleration:

$$\ddot{\mathbf{q}} = \mathbf{M}(\mathbf{q})^{-1}\left(\tau - \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} - \mathbf{g}(\mathbf{q}) + \mathbf{J}_n(\mathbf{q})^\top\lambda_n\right)$$

Substituting $\ddot{\mathbf{q}}$ back into the normal acceleration expression yields:

$$\ddot{\phi} = \mathbf{A}_{\text{Delassus}}(\mathbf{q})\lambda_n + a_{\text{drift}}$$

where the scalar $\mathbf{A}_{\text{Delassus}}(\mathbf{q}) = \mathbf{J}_n(\mathbf{q})\mathbf{M}(\mathbf{q})^{-1}\mathbf{J}_n(\mathbf{q})^\top \geq 0$ is the **Delassus operational space compliance operator** (the apparent inverse inertia reflected at the contact point), and $a_{\text{drift}} = \mathbf{J}_n(\mathbf{q})\mathbf{M}(\mathbf{q})^{-1}(\tau - \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} - \mathbf{g}(\mathbf{q})) + \dot{\mathbf{J}}_n(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}}$ collects unforced kinematic and dynamic drift accelerations.

When contact is maintained ($\phi = 0, \dot{\phi} = 0$), non-penetration requires $\ddot{\phi} \geq 0$. The contact mechanics form a canonical **Linear Complementarity Problem (LCP)**:

$$\ddot{\phi} \geq 0, \quad \lambda_n \geq 0, \quad \ddot{\phi}\cdot\lambda_n = 0$$

Under polyhedral friction cone approximations, this generalizes to a vector LCP solvable via Lemke's pivoting algorithm or quadratic programming. This is a rigid-contact idealization. Real interfaces deform, and the numerical contact solution must still be checked against the motion and force quantities the application needs.

B.7.2 Non-smooth collision manifolds and velocity jumps

When rigid bodies collide, the impact occurs over an infinitesimal duration $\Delta t \to 0$. For frictionless normal impact against a stationary rigid plane, let $v_n^- < 0$ be the pre-impact normal velocity and $e \in [0,1]$ the coefficient of restitution. The Newton restitution model imposes the velocity jump:

$$v_n^+ = -ev_n^- \implies \Delta v_n = v_n^+ - v_n^- = -(1+e)v_n^-$$

5 **Moreau Time-Stepping and Non-Smooth Mechanics**: Measure-differential models represent ideal impulses without resolving microscopic contact duration. Numerical contact solvers still require a validated geometry, friction law, and step-size study for the plant; a smooth optimizer that omits impact can miss a relevant force transient.

DRAFT

With effective normal mass m_{eff}, the normal impulse is $P_n = m_{\text{eff}}\Delta v_n$. In an idealized rigid impact, velocity changes discontinuously, meaning the acceleration is a Dirac delta distribution $\delta(t - t_{\text{impact}})$ rather than an ordinary finite derivative:[5]

$$\lim_{\epsilon \to 0^+} \frac{\|\dot{\mathbf{q}}(t_{\text{impact}} + \epsilon) - \dot{\mathbf{q}}(t_{\text{impact}} - \epsilon)\|}{2\epsilon} = \infty$$

B.7.2.1 Failure modes for automatic differentiation and BPTT

For a differentiable discrete simulator $\mathbf{x}_{k+1} = \mathbf{F}_k(\mathbf{x}_k, \theta)$, define state sensitivity $\mathbf{S}_k = \partial \mathbf{x}_k / \partial \theta$. The chain rule propagates it as:

$$\mathbf{S}_{k+1} = \frac{\partial \mathbf{F}_k}{\partial \mathbf{x}_k}\mathbf{S}_k + \frac{\partial \mathbf{F}_k}{\partial \theta}.$$

For a rollout loss $\mathcal{L} = \sum_{k=0}^{N} \ell_k(\mathbf{x}_k, \theta)$, the parameter gradient is:

$$\nabla_\theta \mathcal{L} = \sum_{k=0}^{N} \left[\mathbf{S}_k^\top \nabla_{\mathbf{x}_k} \ell_k + \nabla_\theta \ell_k\right].$$

Reverse-mode differentiation evaluates the same chain rule without storing every forward sensitivity. Contact complicates the derivatives of $\mathbf{F}_k$, not the chain rule itself. Within a fixed contact mode, a transition can have a finite derivative; at a mode change it can be nonsmooth, and the derivative must account for how the impact time changes with the initial state. An acceleration impulse alone does not imply that every state-transition Jacobian diverges.

A solver that differentiates only its currently active branch can miss the sensitivity of contact timing. Likewise, the contact force is zero while bodies are separated, but a distance-based loss can still supply a gradient toward contact. Whether a rollout has flat regions or abrupt changes depends on its dynamics, contact discretization, and objective.

Compliant contact replaces ideal impulses with deformation and finite-duration forces. This can improve differentiability, but the selected force law must remain repulsive and its stiffness can require smaller time steps. Implicit differentiation of converged contact constraints avoids differentiating every solver iteration, provided the active set and regularity conditions support a derivative. Stochastic policy gradients offer another route because they do not require differentiating through the contact transition; their variance and sampling cost remain separate concerns.

B.7.3 Elastodynamic impact force and compliance deformation

When an effective moving mass m_{eff} strikes an obstacle or human tissue, rigid-body approximations break down because real materials deform elastically over a nonzero compression stroke $\delta(t)$. Let k_{eff} denote the effective contact stiffness across the interface. In series compliance between the manipulator structural chain (k_{robot}) and human tissue or obstacle (k_H):

$$\frac{1}{k_{\text{eff}}} = \frac{1}{k_{\text{robot}}} + \frac{1}{k_H}$$

B.7.3.1 Unmitigated elastic impact force

For an unmitigated collision at impact velocity v_{max}, initial kinetic energy $E_k = \frac{1}{2} m_{\text{eff}} v_{\text{max}}^2$ converts entirely into elastic strain energy $U_{\text{elastic}} = \frac{1}{2} k_{\text{eff}} \delta_{\text{max}}^2$ at the point of maximum compression ($\dot{\delta} = 0$). Energy conservation yields the peak structural deflection:

$$\frac{1}{2} m_{\text{eff}} v_{\text{max}}^2 = \frac{1}{2} k_{\text{eff}} \delta_{\text{max}}^2 \implies \delta_{\text{max}} = v_{\text{max}} \sqrt{\frac{m_{\text{eff}}}{k_{\text{eff}}}}$$

The resulting peak transient contact force $F_{\text{unbraked}} = k_{\text{eff}} \delta_{\text{max}}$ evaluates to:

$$F_{\text{unbraked}} = v_{\text{max}} \sqrt{k_{\text{eff}} m_{\text{eff}}}$$

This relation applies to a lossless linear spring with fixed effective mass and no additional energy input during compression. It identifies how speed, mass, and stiffness affect the modeled peak; a human-contact limit additionally depends on contact location, area, duration, and the applicable test conditions. The scalar spring calculation alone does not establish compliance with a safety standard.

DRAFT

B.7.3.2 Coupled contact indentation with mechanical braking

When active mechanical brakes engage with constant opposing force $m_{\text{eff}}a_{\text{brake}}$ throughout compression, the braking system performs mechanical work $W_{\text{brake}} = m_{\text{eff}}a_{\text{brake}}\delta$ across the indentation depth δ. The coupled energy balance becomes:

$$\frac{1}{2}m_{\text{eff}}v_{\text{impact}}^2 = \frac{1}{2}k_{\text{eff}}\delta_{\text{max}}^2 + m_{\text{eff}}a_{\text{brake}}\delta_{\text{max}}$$

Rearranging into quadratic form:

$$\delta_{\text{max}}^2 + \frac{2m_{\text{eff}}a_{\text{brake}}}{k_{\text{eff}}}\delta_{\text{max}} - \frac{m_{\text{eff}}v_{\text{impact}}^2}{k_{\text{eff}}} = 0$$

Solving for the physically admissible positive deformation root:

$$\delta_{\text{max}} = \sqrt{\left(\frac{m_{\text{eff}}a_{\text{brake}}}{k_{\text{eff}}}\right)^2 + \frac{m_{\text{eff}}v_{\text{impact}}^2}{k_{\text{eff}}}} - \frac{m_{\text{eff}}a_{\text{brake}}}{k_{\text{eff}}}$$

When $a_{\text{brake}} = 0$, this expression smoothly recovers the unmitigated deformation $\delta_{\text{max}} = v_{\text{impact}}\sqrt{m_{\text{eff}}/k_{\text{eff}}}$. For the unbraked spring model, the quarter-cycle compression duration is $t_{\text{peak}} = \frac{\pi}{2}\sqrt{m_{\text{eff}}/k_{\text{eff}}}$. This is not the peak time of the actively braked model. Reactive braking triggered only *after* physical contact cannot attenuate the unbraked initial force peak if sensor detection and brake engagement latency exceed this t_{peak}. Consequently, safety cases cannot substitute reactive post-impact braking for verified pre-impact separation clearance envelopes ($d_{\text{sep}} \geq d_{\text{stop}}$).

B.7.4 Wheel slip ratio and friction boundaries

For wheeled mobile robots and terrestrial platforms, tractive force transmission between the wheel contact patch and the ground plane is governed by non-linear slip dynamics. The longitudinal slip ratio λ quantifies the kinematic velocity mismatch between the wheel circumferential speed $r\omega$ (wheel radius r, angular rate ω) and the vehicle forward longitudinal speed v_x:

$$\lambda = \begin{cases} \frac{r\omega - v_x}{r\omega}, & \text{under acceleration } (r\omega > v_x \geq 0) \\ \frac{r\omega - v_x}{v_x}, & \text{under braking } (v_x > r\omega \geq 0) \end{cases}$$

For forward motion with nonnegative wheel speed, the same convention can be regularized near standstill:

$$\lambda = \frac{r\omega - v_x}{\max(|v_x|, |r\omega|, \epsilon_{\text{reg}})} \in [-1, 1]$$

The bound $[-1, 1]$ assumes v_x and $r\omega$ have the same sign; reverse motion needs a declared direction convention. The endpoint values below also assume the nonzero speed exceeds ϵ_{reg}. Here $\lambda = 0$ corresponds to pure rolling without slip, $\lambda = 1$ denotes complete drive-wheel spin-out ($v_x = 0, \omega > 0$), and $\lambda = -1$ corresponds to complete wheel lock-up ($r\omega = 0, v_x > 0$).

Tractive force F_x scales with the normal contact load F_z through the longitudinal friction coefficient $\mu_x(\lambda)$:

$$F_x(\lambda) = \mu_x(\lambda)F_z$$

At low slip ratios ($|\lambda| < \lambda_{\text{peak}}$), where the peak depends on tire and surface conditions, tire or tread rubber shears elastically. Tractive force is approximately linear in slip: $F_x \approx C_x\lambda$, with longitudinal traction stiffness C_x. Beyond λ_{peak}, adhesion collapses into gross sliding friction. The slope $d\mu_x/d\lambda$ turns negative, which can destabilize a torque-controlled wheel-speed equilibrium. If an ungrounded policy commands drive motor torque exceeding peak traction ($F_{\text{cmd}} > \mu_{\text{peak}}F_z$), the wheel rapidly accelerates into the unstable slip regime ($d\omega/dt = (\tau - rF_x)/J_{\text{wheel}} > 0$). The resulting slip can reduce lateral authority or disturb yaw, a cyber-physical disconnect that cannot be detected by directional agreement or cosine similarity metrics that evaluate only vector angles while ignoring control magnitude.

DRAFT

B.7.5 Grasp mechanics: Friction cones and force closure

The nonadhesive contact model above lets a contact push but never pull. In the parallel-jaw hold considered here, friction supports the object against downward motion. Coulomb's law bounds the tangential force $\mathbf{f}_t$ a contact can carry by the normal force f_n pressing it, $\|\mathbf{f}_t\| \le \mu f_n$, where μ is the friction coefficient between finger and object. Every admissible contact force therefore lies inside a **friction cone** about the contact normal, with half-angle $\arctan\mu$.

A parallel-jaw hold shows the consequence with nothing beyond Newton's second law. Two fingers squeeze an object of mass m on opposite vertical faces, each with normal force f_n. Friction at the two contacts must carry the weight and any upward acceleration a_z the arm imposes while it moves:

$$2\mu f_n \ge m(g + a_z) \quad \Longrightarrow \quad f_n \ge \frac{m(g+a_z)}{2\mu} \tag{B.1}$$

The required squeeze grows with the arm's acceleration and inversely with friction: halving μ doubles it. The object sets the other bound: a thin-walled cup or a ripe fruit deforms or breaks above some normal force. A grasp is feasible only when the interval between the two bounds is nonempty, and that interval is the band a guarded-contact check $f_{\min} \le f_n \le f_{\max}$ enforces (section 10.1). In this two-finger model, the contact-force magnitude in that check denotes the normal squeeze at each finger, measured or conservatively inferred under qualified contact geometry. A generic force-vector norm or the net object wrench cannot substitute for that squeeze. Each term is a measurement the grasp needs: the object's mass, the friction coefficient of this finger material on this surface, the planned peak acceleration, and the crush force. Horizontal acceleration and the moment of an off-center load add terms of the same form.

The general statement collects every contact into one linear map. A force $\mathbf{f}_i$ applied at contact i, located at $\mathbf{r}_i$ from the object's reference point, exerts on the object the wrench formed by the force and its moment $\mathbf{r}_i \times \mathbf{f}_i$. Stacking all contact forces into $\mathbf{f}_c$ gives the **grasp map** $\mathbf{G}$, with object wrench $\mathbf{w}_{obj} = \mathbf{G}\mathbf{f}_c$ (the same bold letter as the Kalman gain, but a different matrix). A grasp has **force closure** when every external wrench $\mathbf{w}_{ext}$ on the object can be balanced, $\mathbf{G}\mathbf{f}_c = -\mathbf{w}_{ext}$, by contact forces that all lie inside their friction cones (Lynch and Park 2017). Approximating each cone by a few edge vectors makes the test finite: force closure holds when the origin lies strictly inside the convex hull of the primitive wrenches those edges generate. For two fingers in a plane, Nguyen's condition is its geometric form: the segment joining the contact points must lie inside both friction cones (Nguyen 1988). In three dimensions, two point contacts cannot resist a torque about the line joining them; real fingertips resist it through torsional friction over a finite contact patch, the soft-finger contact model. Ferrari and Canny's quality measure, the radius of the largest origin-centered ball inside the hull, turns the yes-or-no test into the smallest disturbance the grasp is guaranteed to resist per unit of contact force (Ferrari and Canny 1992).

Force closure is qualitative. It says a balancing set of forces exists, not that the gripper can produce them within its force limit or without crushing the object. The magnitude check of equation B.1 therefore remains necessary for every grasp the machine admits.

B.8 Continuous Covariance Propagation and Observability

When sensors suffer line-of-sight dropouts or environmental occlusion, internal state estimators must project the physical state forward in time. Quantifying how rapidly estimation uncertainty grows across that blind interval requires continuous error-covariance dynamics and observability analysis. The discrete Kalman filter and its extended form, which the machine runs on dated measurements, are developed in section 9.2. The consistency tests that decide whether a filter's reported covariance can be trusted are in section 9.2.1. This section treats the continuous-time limit that governs uncertainty growth between measurements.

B.8.1 Continuous Lyapunov and Riccati covariance dynamics

To track how state-estimation uncertainty grows from process noise and contracts under sensor updates, consider a continuous-time linear dynamic system governed by:

$$\dot{\mathbf{x}}(t) = \mathbf{A}_{sys}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{w}(t)$$

$$\mathbf{y}(t) = \mathbf{H}\mathbf{x}(t) + \mathbf{v}_{\text{meas}}(t)$$

For the continuous white-noise model, $\mathbf{Q}$ and $\mathbf{R}_{\text{cont}}$ are process and measurement noise *intensities*, with covariance kernels $\mathbb{E}[\mathbf{w}(t)\mathbf{w}(s)^\top] = \mathbf{Q}\delta(t-s)$ and $\mathbb{E}[\mathbf{v}_{\text{meas}}(t)\mathbf{v}_{\text{meas}}(s)^\top] = \mathbf{R}_{\text{cont}}\delta(t-s)$. The model assumes suitable independence and $\mathbf{R}_{\text{cont}} \succ 0$. Measurement-noise intensity carries products of measurement-component units times seconds; per-sample measurement covariance carries products of measurement-component units.

Under an optimal continuous-time estimator (the Kalman-Bucy filter (Rudolph Emil Kalman 1960)), the error covariance matrix $\mathbf{P}(t) = \mathbb{E}[(\mathbf{x}-\hat{\mathbf{x}})(\mathbf{x}-\hat{\mathbf{x}})^\top]$ evolves according to the continuous matrix differential Riccati equation:[6]

$$\dot{\mathbf{P}}(t) = \mathbf{A}_{\text{sys}}\mathbf{P}(t) + \mathbf{P}(t)\mathbf{A}_{\text{sys}}^\top + \mathbf{Q} - \mathbf{P}(t)\mathbf{H}^\top\mathbf{R}_{\text{cont}}^{-1}\mathbf{H}\mathbf{P}(t)$$

[6] **Continuous Matrix Riccati Equation**: The measurement term reduces modeled covariance when valid measurements arrive. During occlusion, propagation follows the plant and process-noise model. Its growth may be bounded, linear, polynomial, or exponential depending on the dynamics and noise; the estimator must compare the resulting bound with the task tolerance.

When direct sensing is occluded or dropped ($\mathbf{H} = \mathbf{0}$), the measurement correction term vanishes. The covariance growth collapses to the open-loop **continuous Lyapunov differential equation**:

$$\dot{\mathbf{P}}(t) = \mathbf{A}_{\text{sys}}\mathbf{P}(t) + \mathbf{P}(t)\mathbf{A}_{\text{sys}}^\top + \mathbf{Q}$$

The solution propagates initial uncertainty and accumulated $\mathbf{Q}$ through $e^{\mathbf{A}_{\text{sys}}t}$. Unstable modes can grow exponentially; a random walk with $\mathbf{A}_{\text{sys}} = 0$ grows linearly in covariance. A state-memory record should carry the calibrated growth model and expire tracking permission before its declared error bound crosses the physical tolerance. Covariance alone is not a hard error envelope unless its tail and model assumptions are justified.

B.8.2 Closed-form double-integrator covariance expansion

Consider a one-dimensional double-integrator kinematic system modeling position $p(t)$ and velocity $v(t)$ under unmeasured stochastic acceleration noise $w(t)$:

$$\begin{bmatrix}\dot{p}(t)\\ \dot{v}(t)\end{bmatrix} = \begin{bmatrix}0 & 1\\ 0 & 0\end{bmatrix}\begin{bmatrix}p(t)\\ v(t)\end{bmatrix} + \begin{bmatrix}0\\ 1\end{bmatrix} w(t)$$

where $w(t)$ is zero-mean continuous white process noise with continuous spectral power intensity $q_c > 0$, such that $\mathbb{E}[w(t)w(s)] = q_c\delta(t-s)$. Here, $\mathbf{A}_{\text{sys}} = \begin{bmatrix}0 & 1\\ 0 & 0\end{bmatrix}$ and the continuous process noise matrix is $\mathbf{Q} = \begin{bmatrix}0 & 0\\ 0 & q_c\end{bmatrix}$. This intensity is not a per-sample acceleration variance. For position in meters and time in seconds, its units are square meters per cubic second, so multiplying it by elapsed time cubed gives positional variance in square meters.

Because $\mathbf{A}_{\text{sys}}^2 = \mathbf{0}$, the matrix exponential terminates after its linear term. The state transition is:

$$\Phi(t) = \mathbf{I} + \mathbf{A}_{\text{sys}}t = \begin{bmatrix}1 & t\\ 0 & 1\end{bmatrix}$$

During a blind occlusion window $t \in [0, \Delta t]$ with no measurement updates ($\mathbf{H} = \mathbf{0}$), the total state covariance $\mathbf{P}(t)$ evolves as the sum of unforced homogeneous propagation and accumulated process diffusion:

$$\mathbf{P}(t) = \Phi(t)\mathbf{P}_0\Phi(t)^\top + \int_0^t \Phi(t-t')\mathbf{Q}\Phi(t-t')^\top dt'$$

Let the initial state covariance at the instant of sensor loss ($t = 0$) be:

$$\mathbf{P}_0 = \begin{bmatrix}\sigma_{p,0}^2 & \sigma_{pv,0}\\ \sigma_{pv,0} & \sigma_{v,0}^2\end{bmatrix}$$

DRAFT

The homogeneous propagation term evaluates to:

$$\Phi(t)\mathbf{P}_0\Phi(t)^\top = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \sigma_{p,0}^2 & \sigma_{pv,0} \\ \sigma_{pv,0} & \sigma_{v,0}^2 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ t & 1 \end{bmatrix} = \begin{bmatrix} \sigma_{p,0}^2 + 2\sigma_{pv,0}t + \sigma_{v,0}^2 t^2 & \sigma_{pv,0} + \sigma_{v,0}^2 t \\ \sigma_{pv,0} + \sigma_{v,0}^2 t & \sigma_{v,0}^2 \end{bmatrix}$$

The accumulated stochastic diffusion term integrates across elapsed time:

$$\mathbf{Q}_d(t) = \int_0^t \begin{bmatrix} 1 & t-t' \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & q_c \end{bmatrix} \begin{bmatrix} 1 & 0 \\ t-t' & 1 \end{bmatrix} dt' = \int_0^t \begin{bmatrix} q_c(t-t')^2 & q_c(t-t') \\ q_c(t-t') & q_c \end{bmatrix} dt' = \begin{bmatrix} \frac{1}{3}q_c t^3 & \frac{1}{2}q_c t^2 \\ \frac{1}{2}q_c t^2 & q_c t \end{bmatrix}$$

Summing the homogeneous and stochastic contributions yields the closed-form positional variance $\sigma_p^2(t) = \mathbf{P}_{11}(t)$:

$$\sigma_p^2(t) = \sigma_{p,0}^2 + 2\sigma_{pv,0}t + \sigma_{v,0}^2 t^2 + \frac{1}{3}q_c t^3$$

This derivation explains the distinct physical error regimes during sensor occlusion. Initial velocity uncertainty $\sigma_{v,0}^2$ induces quadratic variance growth in time (t^2), while continuous stochastic disturbances q_c (such as air currents or unmodeled drivetrain chatter) inject cubic uncertainty growth ($\frac{1}{3}q_c t^3$). In long blind intervals, the cubic term dominates, rapidly exhausting safety margins unless motion is derated or halted.

B.8.3 Observability rank and Lie derivative extensions

Measuring only a mobile base's wheel speeds tells an estimator how fast the base is moving, but not where it started in the aisle: two trajectories shifted by 0.5 m produce identical wheel-speed traces. In state estimation and machine learning, observability is the mathematical dual of reachability: whereas reachability asks whether latent internal states can be steered by control inputs, observability asks whether latent states can be reconstructed from external sensor observations $\mathbf{y}(t)$.

In modern deep learning (such as world models, state-space models, and latent representation learning), neural encoders $\hat{\mathbf{z}} = q_\phi(\mathbf{y})$ attempt to reconstruct underlying states from sensory observations. Observability establishes the information-theoretic limit of this reconstruction: if a dynamical system is unobservable, the mapping from physical state trajectories to sensor observations is strictly non-injective. In that case, distinct physical states can produce mathematically indistinguishable observation sequences. No neural network, regardless of parameter count or training data, can reconstruct an unobservable state without additional information. Active excitation can help some nonlinear systems, but a known input cannot repair the unobservable subspace of a fixed LTI model.

A linear time-invariant system $(\mathbf{A}_{\text{sys}}, \mathbf{H})$ is observable on $[0, T]$ if and only if the **Kalman observability matrix** has full column rank n:

$$\mathbf{O}_{\text{obs}} = \begin{bmatrix} \mathbf{H} \\ \mathbf{H}\mathbf{A}_{\text{sys}} \\ \vdots \\ \mathbf{H}\mathbf{A}_{\text{sys}}^{n-1} \end{bmatrix}, \quad \text{rank}(\mathbf{O}_{\text{obs}}) = n$$

If $\text{rank}(\mathbf{O}_{\text{obs}}) < n$, the unobservable subspace $\ker(\mathbf{O}_{\text{obs}})$ contains initial state trajectories that produce identical output measurements. No linear or nonlinear estimator can distinguish between initial states that differ along $\ker(\mathbf{O}_{\text{obs}})$.

For a smooth autonomous nonlinear system $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$, $\mathbf{y} = \mathbf{h}(\mathbf{x})$ where $\mathbf{h} = [h_1(\mathbf{x}), \dots, h_p(\mathbf{x})]^\top$, the Hermann-Krener observability criterion (Hermann and Krener 1977) generalizes the Kalman rank test via successive directional derivatives along system dynamics. Differentiating the measurement output equation $\mathbf{y}(t) = \mathbf{h}(\mathbf{x}(t))$ with respect to continuous time yields:

$$\dot{\mathbf{y}}(t) = \frac{\partial \mathbf{h}}{\partial \mathbf{x}}\dot{\mathbf{x}} = \frac{\partial \mathbf{h}}{\partial \mathbf{x}}\mathbf{f}(\mathbf{x}) = L_{\mathbf{f}}\mathbf{h}(\mathbf{x})$$

Differentiating repeatedly produces the sequence of Lie derivatives, which are directional derivatives of the measurement channels along the unforced drift vector field $\mathbf{f}$:

$$\mathbf{y}^{(k)}(t) = L_{\mathbf{f}}^{k}\mathbf{h}(\mathbf{x}), \quad \text{where } L_{\mathbf{f}}^{k}h_\ell(\mathbf{x}) = \nabla(L_{\mathbf{f}}^{k-1}h_\ell(\mathbf{x}))\cdot\mathbf{f}(\mathbf{x})$$

These successive directional derivatives reveal how temporal variations in output channels encode higher-order kinematic and dynamic states (such as recovering joint velocities and accelerations from encoder or camera position sequences) without requiring real-time numerical differentiation of noisy signals.

The **Hermann-Krener observation space** $\mathbf{O}_{\mathrm{NL}}$ is the real vector space of all repeated Lie derivatives $\{L_{\mathbf{f}}^{k}h_\ell\}_{k\geq 0, 1\leq \ell\leq p}$. Its gradient differentials span the **observability codistribution**:

$$\mathrm{d}\mathbf{O}_{\mathrm{NL}}(\mathbf{x}) = \operatorname{span}\left\{\mathrm{d}L_{\mathbf{f}}^{k}h_\ell(\mathbf{x}) \;\middle|\; k\geq 0,\ 1\leq \ell\leq p\right\}$$

where $\mathrm{d}\phi(\mathbf{x}) = \frac{\partial\phi}{\partial\mathbf{x}}$. The system satisfies the **nonlinear observability rank condition** at $\mathbf{x}_0$ if:[7]

$$\dim(\mathrm{d}\mathbf{O}_{\mathrm{NL}}(\mathbf{x}_0)) = n$$

When full rank n is achieved, the directional gradients span the cotangent space $T_{\mathbf{x}}^{*}\mathcal{X}$, guaranteeing local weak observability: any infinitesimal deviation in latent state produces a distinguishable signature in the measurement sequence or its temporal derivatives.

[7] **Hermann-Krener Nonlinear Observability**: Full rank of the observation codistribution is a local structural test, not a sensor-noise or finite-horizon accuracy bound. A missing state direction may require another sensor, an active maneuver with its own permission, or a restricted operating envelope.

B.9 Centroidal Dynamics and Floating-Base Control

Legged robots have an unactuated floating base as well as motorized joints. Internal joint motion can change the base pose, but only external forces change total linear momentum, and only external moments change total angular momentum. Ground contacts therefore determine which center-of-mass and momentum trajectories the robot can sustain against gravity.

B.9.1 Floating-base equations of motion

Let $\mathbf{q} = [\mathbf{q}_b^\top, \mathbf{q}_j^\top]^\top \in SE(3)\times\mathbb{R}^n$ represent the generalized coordinates, where $\mathbf{q}_b \in SE(3)$ is the floating-base pose (position and orientation, 6 DoF) and $\mathbf{q}_j \in \mathbb{R}^n$ are the actuated joint angles. The total system possesses $n+6$ degrees of freedom. The displayed $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ use a local coordinate convention; a global implementation must distinguish configuration coordinates from generalized velocities, particularly with quaternion orientation. The equations of motion are (Siciliano et al. 2009):

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{S}^\top\tau + \sum_{k=1}^{N_c}\mathbf{J}_{\mathrm{c}_k}(\mathbf{q})^\top\mathbf{f}_k$$

The right-hand terms separate internal joint actuation from external contact support:

- $\mathbf{S} = [\mathbf{0}_{n\times 6}, \mathbf{I}_{n\times n}] \in \mathbb{R}^{n\times(n+6)}$ is the actuation selection matrix separating the 6 unactuated floating-base coordinates from the n actuated joints.
- $\tau \in \mathbb{R}^n$ is the commanded motor torque vector.
- $\mathbf{J}_{\mathrm{c}_k}(\mathbf{q}) = \partial\mathbf{p}_k/\partial\mathbf{q} \in \mathbb{R}^{3\times(n+6)}$ is the contact point Jacobian for point-contact force $\mathbf{f}_k \in \mathbb{R}^3$.

Partitioning the equations of motion into floating-base (b) and actuated joint (j) coordinates highlights the underactuation of legged machines:

$$\begin{bmatrix}\mathbf{M}_{bb}(\mathbf{q}) & \mathbf{M}_{bj}(\mathbf{q})\\ \mathbf{M}_{jb}(\mathbf{q}) & \mathbf{M}_{jj}(\mathbf{q})\end{bmatrix}\begin{bmatrix}\ddot{\mathbf{q}}_b\\ \ddot{\mathbf{q}}_j\end{bmatrix} + \begin{bmatrix}\mathbf{h}_b(\mathbf{q},\dot{\mathbf{q}})\\ \mathbf{h}_j(\mathbf{q},\dot{\mathbf{q}})\end{bmatrix} = \begin{bmatrix}\mathbf{0}\\ \tau\end{bmatrix} + \sum_{k=1}^{N_c}\begin{bmatrix}\mathbf{J}_{k,b}^\top\\ \mathbf{J}_{k,j}^\top\end{bmatrix}\mathbf{f}_k$$

where $\mathbf{h}(\mathbf{q},\dot{\mathbf{q}}) = \mathbf{C}(\mathbf{q},\dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})$. The top 6 rows have identically zero direct motor authority ($\mathbf{S}_b^\top\tau = \mathbf{0}$). The base equation still contains gravity and coupling to joint acceleration, so the base can accelerate even in flight:

$$\mathbf{M}_{bb}(\mathbf{q})\ddot{\mathbf{q}}_b + \mathbf{M}_{bj}(\mathbf{q})\ddot{\mathbf{q}}_j + \mathbf{h}_b(\mathbf{q},\dot{\mathbf{q}}) = \sum_{k=1}^{N_c}\mathbf{J}_{k,b}(\mathbf{q})^\top\mathbf{f}_k$$

DRAFT

B.9.2 Centroidal momentum dynamics

Projecting the multi-body floating-base dynamics onto the robot's center of mass $\mathbf{c} \in \mathbb{R}^3$ yields the Newton-Euler **centroidal momentum equations** (Lynch and Park 2017):

$$\dot{\mathbf{h}}_{\text{lin}} = m\ddot{\mathbf{c}} = \sum_{k=1}^{N_c} \mathbf{f}_k + m\mathbf{g}_0$$

$$\dot{\mathbf{h}}_{\text{ang}} = \sum_{k=1}^{N_c} [(\mathbf{p}_k - \mathbf{c}) \times \mathbf{f}_k + \tau_k]$$

where $\mathbf{h}_{\text{lin}}$ is linear momentum, $\mathbf{h}_{\text{ang}}$ is angular momentum about the CoM, m is the total robot mass, $\mathbf{g}_0$ is the gravitational acceleration vector, and $(\mathbf{p}_k, \mathbf{f}_k, \tau_k)$ are the position, force, and moment at each active contact patch.[8]

[8] **Centroidal Momentum Matrix**: Centroidal dynamics summarize the external wrench needed for a proposed CoM and angular-momentum change. A controller still needs feasible contacts and actuator torque; omitting angular momentum can mispredict the required contact moments.

The total centroidal momentum $\mathbf{h}_G = [\mathbf{h}_{\text{lin}}^\top, \mathbf{h}_{\text{ang}}^\top]^\top \in \mathbb{R}^6$ linearly maps from generalized velocities through the **Centroidal Momentum Matrix (CMM)** $\mathbf{A}_G(\mathbf{q}) \in \mathbb{R}^{6\times(n+6)}$ (Lynch and Park 2017):

$$\mathbf{h}_G = \mathbf{A}_G(\mathbf{q})\dot{\mathbf{q}}$$

Differentiating with respect to time relates generalized accelerations to external contact wrenches:

$$\dot{\mathbf{h}}_G = \mathbf{A}_G(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{A}}_G(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} = \sum_{k=1}^{N_c} \mathbf{X}_k^* \mathbf{w}_k + \begin{bmatrix} m\mathbf{g}_0 \\ \mathbf{0} \end{bmatrix}$$

where $\mathbf{X}_k^*$ transforms contact wrench $\mathbf{w}_k = [\mathbf{f}_k^\top, \tau_k^\top]^\top$ to the center of mass frame.

B.9.3 Physical contact feasibility constraints

For nonadhesive support contacts with finite friction, admissible contact wrenches must satisfy three physical invariants:

1. **Unilateral Normal Force:** Feet can only push against the ground:

$$f_{k,\perp} = \mathbf{f}_k^\top \hat{\mathbf{n}}_k \geq 0$$

2. **Coulomb Friction Cone:** Tangential shear forces cannot exceed normal traction:

$$\|\mathbf{f}_{k,\parallel}\| = \|\mathbf{f}_k - f_{k,\perp}\hat{\mathbf{n}}_k\| \leq \mu f_{k,\perp}$$

3. **Support condition for coplanar contacts:** Under flat-ground assumptions, the Zero Moment Point (ZMP) should remain inside the effective support polygon with a case-specific inset:[9]

$$\mathbf{p}_{\text{ZMP}} \in \mathcal{P}_{\text{support}}, \qquad \mathcal{P}_{\text{support}} = \text{Conv}\left(\bigcup_k \mathcal{A}_k\right),$$

where $\mathcal{A}_k$ is each active contact patch projected onto that plane.

[9] **Zero Moment Point (ZMP)**: ZMP is useful for a specified coplanar support model. Edge contact, friction loss, and multi-height supports require more general wrench feasibility checks; crossing a modeled polygon edge does not by itself predict a particular fall.

B.9.4 Hierarchical whole-body control quadratic program

In floating-base humanoid and legged systems, high-level policies (such as learned vision-language-action models or action chunking policies) propose desired kinematic behaviors: end-effector manipulation paths, torso orientation, gaze directions, or swing-foot trajectories. However, because the 6-DoF floating base is unactuated, these kinematic proposals cannot be executed directly by joint motors. The **Hierarchical Whole-Body Control (WBC) Quadratic Program** acts as a real-time multi-task constrained optimization projection layer. It projects competing operational-space task accelerations $\ddot{\mathbf{x}}_i^{\text{des}}$ through a prioritized optimization hierarchy while strictly enforcing rigid-body Newton-Euler dynamics, friction cones, and actuator limits. In optimization and machine learning terms, Whole-Body Control solves the physical counterpart of multi-task learning with conflicting gradients:

DRAFT

Concept	Multi-Task Deep Learning (PCGrad / MGDA)	Hierarchical Whole-Body Control (WBC)
Task Specifications	Loss functions $\mathcal{L}_1(\theta), \dots, \mathcal{L}_K(\theta)$	Operational-space tasks $\mathbf{x}_1 = f_1(\mathbf{q}), \dots, \mathbf{x}_K = f_K(\mathbf{q})$
Shared Resource	Parameter weight vector $\theta \in \mathbb{R}^P$	Generalized joint accelerations $\ddot{\mathbf{q}} \in \mathbb{R}^{n+6}$ and torques τ
Task Conflict	Negative gradient inner product $\nabla \mathcal{L}_i^\top \nabla \mathcal{L}_j < 0$	Task accelerations that cannot be achieved simultaneously
Decoupling Rule	Projecting gradients onto tangent hyperplanes (PCGrad)	Null-space projection operator $\mathbf{N}_i = \mathbf{I} - \mathbf{J}_i^\dagger \mathbf{J}_i$
Priority Hierarchy	Heuristic loss weighting or GradNorm tuning	Cascaded optimization preserving higher-priority optima
Feasibility Enforcer	Parameter norm clipping / weight decay	Hard KKT constraints: dynamics, friction cones, torque saturation

B.9.4.1 Operational-space tasks and analytical null-space projection

Let task i be defined by a kinematics mapping $\mathbf{x}_i = f_i(\mathbf{q}) \in \mathbb{R}^{m_i}$ (e.g., end-effector Cartesian pose, center of mass position, or torso orientation). Differentiating twice yields the task acceleration:

$$\ddot{\mathbf{x}}_i = \mathbf{J}_i(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{J}}_i(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}$$

A tracking controller generates desired task acceleration via proportional-derivative feedback:

$$\ddot{\mathbf{x}}_i^{\text{des}} = \ddot{\mathbf{x}}_i^{\text{ref}} + \mathbf{K}_{p,i}(\mathbf{x}_i^{\text{ref}} - \mathbf{x}_i) + \mathbf{K}_{d,i}(\dot{\mathbf{x}}_i^{\text{ref}} - \dot{\mathbf{x}}_i)$$

In complex humanoids, multiple tasks compete for limited degrees of freedom. Consider two prioritized tasks: Task 1 (highest priority, e.g., CoM balance and stance-foot ground contact) and Task 2 (secondary priority, e.g., end-effector trajectory tracking).

To ensure Task 2 never compromises Task 1, analytical Whole-Body Control projects Task 2 into the **kinematic null space** of Task 1. The unconstrained acceleration for Task 1 is:

$$\ddot{\mathbf{q}}_1^* = \mathbf{J}_1^\dagger \left(\ddot{\mathbf{x}}_1^{\text{des}} - \dot{\mathbf{J}}_1 \dot{\mathbf{q}} \right)$$

Assuming $\mathbf{J}_1$ has full row rank, $\mathbf{J}_1^\dagger = \mathbf{J}_1^\top (\mathbf{J}_1 \mathbf{J}_1^\top)^{-1}$ is the Moore-Penrose pseudo-inverse. The null-space projection matrix of Task 1 is:

$$\mathbf{N}_1 = \mathbf{I} - \mathbf{J}_1^\dagger \mathbf{J}_1$$

The projector satisfies the algebraic property:

$$\mathbf{J}_1 \mathbf{N}_1 = \mathbf{J}_1 \left(\mathbf{I} - \mathbf{J}_1^\dagger \mathbf{J}_1 \right) = \mathbf{J}_1 - \mathbf{J}_1 \mathbf{J}_1^\dagger \mathbf{J}_1 = \mathbf{0}$$

Projecting the secondary task command $\ddot{\mathbf{q}}_2$ through $\mathbf{N}_1$:

$$\ddot{\mathbf{q}}^* = \ddot{\mathbf{q}}_1^* + \mathbf{N}_1 \ddot{\mathbf{q}}_2^*$$

guarantees that Task 2 produces strictly zero acceleration in the direction of Task 1:

$$\mathbf{J}_1 \ddot{\mathbf{q}}^* = \mathbf{J}_1 \ddot{\mathbf{q}}_1^* + \mathbf{J}_1 \mathbf{N}_1 \ddot{\mathbf{q}}_2^* = \mathbf{J}_1 \ddot{\mathbf{q}}_1^* + \mathbf{0} = \ddot{\mathbf{x}}_1^{\text{des}} - \dot{\mathbf{J}}_1 \dot{\mathbf{q}}$$

Task 2 operates exclusively within the redundant internal degrees of freedom left unconstrained by Task 1.

DRAFT

B.9.4.2 Embedded whole-body control quadratic program

While analytical pseudo-inverse projections provide elegant decoupling, they cannot enforce inequality constraints such as unilateral contact forces, friction cones, and motor torque limits. Real-time controller firmware resolves this by formulating Whole-Body Control as a convex Quadratic Program whose execution deadline is part of the controller design.

Collect the decision variables $\mathbf{z} = [\ddot{\mathbf{q}}^\top, \mathbf{f}_c^\top, \tau^\top]^\top$, where $\ddot{\mathbf{q}} \in \mathbb{R}^{n+6}$ is generalized acceleration, $\mathbf{f}_c \in \mathbb{R}^{3N_c}$ collects contact forces, and $\tau \in \mathbb{R}^n$ is motor torque. A weighted task QP for a fixed set of sticking contacts then solves:

$$
\begin{aligned}
\min_{\ddot{\mathbf{q}}, \mathbf{f}_c, \tau} \quad & \sum_{i=1}^{K} w_i \|\mathbf{J}_i(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{J}}_i(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} - \ddot{\mathbf{x}}_i^{\text{des}}\|^2 + w_\tau \|\tau\|^2 + w_f \|\mathbf{f}_c - \mathbf{f}_{\text{nom}}\|^2 \\
\text{subject to:} \quad & \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \mathbf{S}^\top \tau + \sum_{k=1}^{N_c} \mathbf{J}_{c_k}(\mathbf{q})^\top \mathbf{f}_k \\
& \mathbf{J}_{c_k}(\mathbf{q})\ddot{\mathbf{q}} + \dot{\mathbf{J}}_{c_k}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} = \mathbf{0} \quad \forall k \in \{1, \dots, N_c\} \quad \text{(stationary sticking contacts)} \\
& \mathbf{F}_k \mathbf{f}_k \le \mathbf{0}, \quad f_{k,\perp} \ge 0 \quad \forall k \in \{1, \dots, N_c\} \quad \text{(friction pyramid)} \\
& -\tau_{\max} \le \tau \le \tau_{\max} \\
& \ddot{\mathbf{q}}_{\min}(\mathbf{q}, \dot{\mathbf{q}}) \le \ddot{\mathbf{q}} \le \ddot{\mathbf{q}}_{\max}(\mathbf{q}, \dot{\mathbf{q}})
\end{aligned}
$$

In this multi-task optimization architecture:

- **Dynamic Feasibility:** The equality constraint enforces the coupled multi-body floating-base equations of motion, including joint coupling, gravity, and the modeled external contact forces. The stance-contact equality prevents assigning a supporting force to a point that is simultaneously commanded to move away from the support.
- **Multi-Task Null-Space Hierarchy:** Finite objective weights w_i express a preference ($w_1 \gg w_2 \gg \cdots \gg w_K$). High-priority tasks (maintaining center-of-mass balance, stance-foot grounding, and trunk stability) dominate lower-priority goals (arm trajectory tracking or joint posture regularization toward nominal rest configurations). In strict hierarchical QP formulations, tasks are solved lexicographically in cascaded QPs, fixing the optimal residual of higher-priority tasks as hard constraints for subsequent stages.
- **Physical Contact and Torque Protection:** The linear inequalities enforce contact friction pyramids ($\mathbf{F}_k \mathbf{f}_k \le \mathbf{0}$) and motor saturation limits ($|\tau| \le \tau_{\max}$), restricting the solution to the chosen friction and torque model. Actual slip, electrical current, and joint-limit containment also depend on model error, sampling, and actuator response.
- **The Physical AI Synthesis:** Whole-Body Control serves as the real-time deterministic gatekeeper (section 12.1). High-level learned policies (such as Vision-Language-Action foundation models or diffusion trajectory planners) propose uncertified task goals $\mathbf{x}_i^{\text{ref}}$, while the WBC QP checks modeled task, contact, and torque feasibility before admission.

Here $\mathbf{F}_k$ describes the chosen inner approximation to the measured friction cone. The joint-acceleration bounds $\ddot{\mathbf{q}}_{\min}, \ddot{\mathbf{q}}_{\max}$ must be derived to preserve velocity and position limits over the integration step, with reserves for uncertainty. Finite task weights do not implement a strict hierarchy; cascaded QPs must preserve each higher-priority optimum as a constraint. The solve deadline must be validated with the selected contact count, solver, processor, friction estimate, and fallback. A feasible numerical solution does not itself prove that a foothold will support the load.

B.10 Passivity and Energy-Bounded Interaction

During teleoperation or stiff contact, transport delay can reduce feedback damping. **Passivity** evaluates a different property from tracking accuracy: whether a component can supply more energy through its ports than it has received or initially stored. This energy accounting is useful when connecting controllers to uncertain mechanical environments.

DRAFT

B.10.1 Energy storage and the passivity definition

At a mechanical interaction port, the inner product of effort and flow measures instantaneous power entering the plant. For a continuous-time dynamical system with state $\mathbf{x}(t)$, control input $\mathbf{u}(t)$ (an effort variable, such as force or torque **F**), and measured output $\mathbf{y}(t)$ (a flow variable, such as velocity **v**), the system is **passive** if there exists a continuously differentiable, non-negative storage function $V(\mathbf{x}) \geq 0$ (representing the total internal physical energy stored in mass momentum and structural compliance) such that:

$$\dot{V}(\mathbf{x}) \leq \mathbf{u}(t)^\top \mathbf{y}(t) - g(\mathbf{x}) \tag{B.2}$$

where $\mathbf{u}(t)^\top \mathbf{y}(t)$ represents instantaneous power injected into the system through the physical port, and $g(\mathbf{x}) \geq 0$ denotes internal energy dissipation (such as mechanical damping, viscous friction, or electrical resistance). Integrating equation B.2 over any operational duration $[0, T]$ yields the passivity energy inequality:

$$\int_0^T \mathbf{u}(t)^\top \mathbf{y}(t)\, dt \geq V(\mathbf{x}(T)) - V(\mathbf{x}(0)) + \int_0^T g(\mathbf{x}(t))\, dt \geq -V(\mathbf{x}(0)) \tag{B.3}$$

Under equation B.3 and the declared port orientation, the net physical energy extractable from this modeled component is strictly bounded by its initial stored energy $V(\mathbf{x}(0))$. A loaded mechanism can still release enough stored energy to injure or damage; passivity is an energy-bounding certificate, not an instantaneous contact-force limit.

Under a well-posed, power-conserving feedback interconnection, passive components admit a combined storage inequality. Stability conclusions additionally depend on the storage bounds and on strictness or detectability conditions; passivity alone does not guarantee every internal state converges. A human operator, powered tool, or active environment also cannot be assumed passive merely because it is connected to the robot.

B.10.2 The transport delay destabilization hazard

An untreated effort/flow communication channel need not remain passive when delayed. A fixed pure delay T_d contributes a frequency-dependent phase lag $\Delta\phi = -\omega T_d$ at angular frequency ω. In teleoperation or compliant interaction across wireless networks, late force feedback can arrive out of phase with the operator's current hand motion.

A negative instantaneous input power means the component is returning energy through its port. That is compatible with passivity when the energy was previously stored. The delayed link violates passivity only if its net delivered energy exceeds its incoming and initially stored energy under the declared port signs. Such excess can reduce damping or destabilize the coupled loop; the outcome depends on the controllers and mechanical environment.

B.10.3 Passivity preservation via wave variables

To prevent delay from injecting artificial energy into the teleoperation loop, Anderson and Spong (1989) introduced the **wave variable transformation**. Inspired by microwave transmission lines and scattering theory, wave variables map physical effort **F** and flow $\dot{\mathbf{x}}$ into incoming and outgoing wave channels with characteristic wave impedance $b > 0$:

$$\mathbf{u}_m(t) = \frac{\mathbf{F}_m(t) + b\dot{\mathbf{x}}_m(t)}{\sqrt{2b}}, \quad \mathbf{w}_m(t) = \frac{\mathbf{F}_m(t) - b\dot{\mathbf{x}}_m(t)}{\sqrt{2b}} \tag{B.4}$$

Computing instantaneous power from the wave transformation in equation B.4 reveals:

$$P_m(t) = \mathbf{F}_m(t)^\top \dot{\mathbf{x}}_m(t) = \frac{1}{2}\|\mathbf{u}_m(t)\|^2 - \frac{1}{2}\|\mathbf{w}_m(t)\|^2$$

In wave coordinates, power transmitted across the network port is the difference between incoming wave power $\frac{1}{2}\|\mathbf{u}_m\|^2$ and reflected wave power $\frac{1}{2}\|\mathbf{w}_m\|^2$. For an ideal transmission channel with communication delay T_d, transmitted waves are delayed: $\mathbf{u}_s(t) = \mathbf{u}_m(t - T_d)$ and $\mathbf{w}_m(t) = \mathbf{w}_s(t - T_d)$. The total energy stored in the communication channel in flight satisfies:

$$E_{\text{channel}}(t) = \frac{1}{2}\int_{t-T_d}^{t} \|\mathbf{u}_m(\sigma)\|^2 d\sigma + \frac{1}{2}\int_{t-T_d}^{t} \|\mathbf{w}_s(\sigma)\|^2 d\sigma \geq 0$$

DRAFT

Because the channel stores transmitted energy without amplifying wave amplitudes, the scattered communication link is passive and lossless under the stated constant-delay model; the delay line itself supplies no strict dissipation. Variable delay, packet loss, sampling, and saturation require additional analysis. Even the ideal passive channel does not bound spatial tracking errors; kinodynamic watchdog leases (section B.6.5) must be evaluated concurrently to guarantee spatial obstacle clearance.

B.11 Further Reading

For a deeper theoretical foundation in control theory, robotics, and dynamical systems, consult the following references:

- **Modern Robotics: Mechanics, Planning, and Control** (Lynch and Park 2017) provides a rigorous treatment of kinematics and dynamics using screw theory and Lie groups.
- **Robotics: Modelling, Planning and Control** (Siciliano et al. 2009) serves as a reference for multi-body robot dynamics, trajectory generation, and operational space control.
- **Feedback Systems: An Introduction for Scientists and Engineers** (Åström and Murray 2021) establishes classical and state-space control theory, frequency-domain stability margins, and state estimation from first principles.
- **Applied Nonlinear Control** (Slotine and Li 1991) provides a foundational treatment of nonlinear dynamical systems, Lyapunov stability certificates, and sliding mode control.
- **Control Barrier Functions: Theory and Applications** (Ames et al. 2019) sets out the formulation of control barrier functions, safety-critical quadratic programming filters, and forward invariance.
- **A Time-Dependent Hamilton-Jacobi Formulation of Reachable Sets for Continuous Dynamic Games** (Mitchell et al. 2005) establishes the level set method and viscosity solutions for continuous-state differential games and safety verification.
- **A Predictive Safety Filter for Learning-Based Control of Constrained Nonlinear Dynamical Systems** (Wabersich and Zeilinger 2021) develops predictive safety filters and constrained MPC methods for safe learning on physical systems.

DRAFT

C

Systems and Hardware

This appendix supplies reference models for the timing, memory, communication, and electrical limits that connect learned proposals to physical actuators. Its derivations and worked estimates help readers calculate response budgets, interpret hardware measurements, and implement the record formats used by the permission path. Each model states assumptions that must hold before its result can support a physical operating limit.

C.1 How to Use This Appendix

CONSULT this appendix when diagnosing physical systems bottlenecks, timing jitter, electrical rail instability, or hardware interface boundaries across chapters in this book.

C.2 Numbers to Know in Physical AI

Physical AI requires quantitative intuition across computation, motion, and heat. The latency hierarchy popularized by Jeff Dean[1] provides a useful starting point, but a delayed physical command also consumes clearance. The tables below separate representative rates and scenario calculations from bounds that require qualification on the actual machine.

[1] **Jeff Dean**: Google Senior Fellow and systems architect. His latency numbers originally presented with Peter Norvig around 2010 established the canonical latency hierarchy across storage, memory, and network tiers (Scott 2012). Physical AI extends this hierarchy down into electromechanical actuators, stopping kinematics, and thermal time constants.

The fastest events are transistor switching and local memory access. Operating-system dispatch and communication add scheduling and queueing delays. Actuator current then changes over an electrical time constant, while braking and heat accumulation unfold over longer intervals. These scales overlap; a task's assigned deadline comes from its physical consequence, not from its location in this hierarchy.

> **Systems Perspective C.1: Three physical numbers that matter most**
>
> - **Kinetic equivalence: 1 ms $= 1$ mm (at 1 m/s)**: At a nominal robotic speed of 1 m/s, every millisecond of perception, inference, or fieldbus latency translates into exactly 1 mm of blind travel before retarding torque can be applied. At highway velocity (30 m/s), each millisecond is 3 cm. In physical systems, software latency is not waiting time; it is physical displacement.
> - **Thermal divergence: $\tau_{\text{th,silicon}} \sim 1$ ms vs. $\tau_{\text{th}} \sim 100$ s**: Semiconductor junctions heat adiabatically within milliseconds during deep neural network bursts, potentially triggering thermal throttling before heat spreaders react. Electrical rail droop is a separate response to changing current demand. In contrast, electromagnetic stator windings heat over tens to hundreds of seconds, tolerating transient overcurrent for aggressive maneuvers but accumulating thermal energy that eventually limits sustained torque.
> - **The exposure wall: $T = 3/\lambda$**: Under a stationary Poisson model, zero observed failures gives an approximate one-sided 95 percent upper rate bound of $3/T$ after T operational hours (Hanley and Lippman-Hand 1983). Very small target rates demand correspondingly large exposure. Runtime barriers can support a broader assurance argument, but neither a barrier nor a finite test proves the absence of failure.

C.2.1 Rate and latency hierarchy across machine levels

Control rates in physical AI rise steeply from the deliberative brain down to the physical body (table C.1). Deliberative multimodal models (VLAs) operate at human reaction scales (1–5 Hz). Action chunking models emit future trajectory waypoints at 10–50 Hz. Beneath the proposal boundary, the permission path enforces safety barriers at 1 kHz. At the lowest levels, power electronic current loops and PWM switching operate at tens to hundreds of kilohertz to maintain electromagnetic flux and drive torque. For real-time timer schedulability and response-time analysis, see section C.3; for inverter gate switching and dead-time modeling, see section C.4.

Table C.1: Rate and Latency Hierarchy Across the Five Machine Levels: Representative rates from inverter switching to foundation-model deliberation. The reciprocal period and travel during that period at nominal speed (1 m/s) are scale comparisons, not independently established deadlines or evidence-age bounds.

Machine Level	Frequency Band	Cycle Period	Blind Travel at 1 m/s	Architectural Mechanism & Bound
Brain (Deliberation)	1–5 Hz	200–1,000 ms	200–1,000 mm	Multimodal VLA reasoning; memory- and compute-bound
Brain (Action Chunking)	10–50 Hz	20–100 ms	20–100 mm	Action chunk diffusion/transformer decoding; amortized
Nervous System (Permission)	1 kHz	1 ms	1 mm	Control barrier certificates, stopping envelopes, lease watchdog
Body (Current Loop)	10–25 kHz	40–100 µs	40–100 µm	Field-oriented current control (FOC), torque tracking, stator flux
Body (Inverter Switching)	50–200 kHz	5–20 µs	5–20 µm	Power MOSFET gate drive, dead-time insertion (t_{dead}), inductive droop

C.2.2 Kinetic translation and safe stopping envelopes

Total stopping distance $d_{\text{stop}} = v \cdot \tau_{\text{delay}} + v^2/(2a_{\text{brake}})$ combines the linear blind travel accrued during computational delay and the quadratic mechanical braking distance (table C.2). As platform speed increases, absolute blind travel expands rapidly, consuming entire clearance margins before deceleration can begin. Section C.13 derives the information-age and braking terms; section C.9.3 relates joint jerk to electrical limits.

Table C.2: Kinetic Translation Across Platform Archetypes: Pre-brake delay converts into unrecoverable physical travel before braking force begins. These illustrative archetypes assume constant speed during delay and constant braking afterward; they are not the running machine's qualified profiles. Parenthesized percentages give blind travel as a share of the modeled total.

Platform Archetype	Nominal Velocity v	Braking Decel a_{brake}	Blind Travel ($\tau_{\text{delay}} = 50$ ms)	Blind Travel ($\tau_{\text{delay}} = 200$ ms)	Total Stop ($\tau_{\text{delay}} = 200$ ms)
Humanoid / Quadruped	1 m/s (3.6 km/h)	4 m/s² (0.41 g)	50 mm	200 mm	325 mm (61.5%)
Warehouse Mobile Manipulator	1.5 m/s (5.4 km/h)	2 m/s² (0.20 g)	75 mm	300 mm	863 mm (34.8%)
Urban Delivery Robot	6 m/s (21.6 km/h)	4.5 m/s² (0.46 g)	300 mm	1.2 m	5.2 m (23.1%)
Autonomous Vehicle (Highway)	30 m/s (108 km/h)	7 m/s² (0.71 g)	1.5 m	6 m	70.3 m (8.5%)

C.2.3 Edge memory bandwidth and action chunk amortization

For O operations and D_{vol} bytes transferred from memory, an idealized execution-time lower bound is $\max(O/R_{\text{peak}}, D_{\text{vol}}/\text{BW})$, where R_{peak} is peak arithmetic throughput and BW is available memory bandwidth. The equivalent roofline throughput bound is $\min(R_{\text{peak}}, (O/D_{\text{vol}})\text{BW})$. The ratio O/D_{vol} is arithmetic intensity. This model identifies whether compute or memory transfer binds; synchronization, contention, and incomplete overlap increase actual time.

At small batch sizes, autoregressive generation can be limited by memory bandwidth. Table C.3 divides weight storage by the assumed sustained bandwidth to obtain a streaming-only lower bound on execution time. A chunk decoder that produces all H waypoints in one weight pass can amortize that transfer; one that makes multiple denoising or token-generation passes cannot claim the same amortization. The resulting waypoint rate is an output-throughput ceiling, not a fresh-observation feedback rate. Section C.6 explains how competing traffic reduces the bandwidth available to the decoder.

DRAFT

Table C.3: Edge Memory Bandwidth and Action Chunk Amortization: Weight-only streaming estimates under the stated bandwidth and precision assumptions. The chunk column assumes one weight pass produces the whole chunk; activations, decoder passes, and contention add work. More waypoints do not imply more frequent observation or replanning.

Model & Precision	Parameters	Memory Footprint	DRAM Read Time (140 GB/s)	Single-Step Max Rate	Chunk Rate ($H = 16$)
VLA-7B (FP16)	7.0B	14 GB	100 ms	10 Hz	160 Hz equivalent
VLA-7B (INT8)	7.0B	7 GB	50 ms	20 Hz	320 Hz equivalent
VLA-7B (INT4)	7.0B	3.5 GB	25 ms	40 Hz	640 Hz equivalent
VLA-14B (INT8)	14.0B	14 GB	100 ms	10 Hz	160 Hz equivalent

C.2.4 Thermal time constants across compute and electromechanics

For a constant heat input and a single thermal node initially at ambient, the temperature rise above T_{amb} follows $\Delta T(t) = \Delta T_{\max}(1 - e^{-t/\tau_{\text{th}}})$ with steady-state rise $\Delta T_{\max}$ and time constant τ_{th} (table C.4). Local silicon temperature can change rapidly during a computational burst, requiring thermal qualification of the workload and cooling path. Electrical droop has a separate current-transient timescale. In contrast, electromagnetic stator windings heat over minutes, allowing transient torque overdrive if bounded by an $I^2_{\text{phase}}t$ thermal watchdog. For first-order thermal differential equations and stator winding degradation limits, see section C.9; for regenerative energy absorption on DC power buses, see section C.10.

Table C.4: Thermal Time Constants Across Compute and Electromechanical Subsystems: Thermal response spans several orders of magnitude. The listed ranges are representative scales, not universal device limits. Heating rates, thermal trips, and sustained torque require the actual thermal network and initial temperature.

Subsystem Component	Physical Mechanism	Thermal Time Constant τ_{th}	Critical Failure Mode	Safety Mitigation
Silicon Junction (Die)	Transistor channel self-heating	1–10 ms	Gate delay change, leakage rise, thermal trip	Thermal monitoring and frequency throttling
SoC Heat Sink / Package	Convective heat spreader dissipation	10–60 s	Package thermal saturation, sustained throttling	Active fan modulation, workload migration
Motor Stator Windings	Copper resistive Joule heating ($I^2_{\text{phase}}R_{\text{phase}}$)	30–180 s	Insulation breakdown (Class H 180°C), short	$I^2_{\text{phase}}t$ thermal protection, current derating
Motor Frame / Housing	Bulk metallic casing heat conduction	10–30 min	Structural deformation, bearing grease loss	Natural convection, passive cooling fins
Traction Battery Pack	Electrochemical cell internal resistance	5–20 min	Chemistry-dependent overheating and thermal runaway	Liquid cooling loop, charge/discharge cutoff

C.2.5 Statistical safety bounds and exposure walls

For zero observed failures in stationary Poisson exposure, the one-sided 95 percent upper rate bound is approximately $3/T$, where T is total operating time (Hanley and Lippman-Hand 1983). Table C.5 shows the exposure needed to put that bound at three illustrative target rates. These are statistical calculations, not a mapping from a whole-system accident rate to a safety integrity level. In particular, ISO 26262 random-hardware-failure metrics do not describe every cause of a learned system's failure (International Organization for Standardization 2018). Correlated trials, changing operating conditions, and unobserved failures invalidate a naive accumulation of hours.

DRAFT

Table C.5: Statistical Testing Exposure: Approximate exposure for a one-sided 95 percent upper rate bound after zero observed failures. A system assurance argument also needs evidence about failure mechanisms and operating conditions.

Illustrative target rate λ	Required failure-free exposure $T \approx 3/\lambda$	Interpretation
10^{-8}/hour	300,000,000 hours	Upper rate bound under the declared Poisson model
10^{-7}/hour	30,000,000 hours	Same confidence level and observation assumptions
10^{-6}/hour	3,000,000 hours	A rate alone does not establish a safety classification

C.2.6 Fieldbus latencies, jitter, and determinism

Communication buses differ sharply in latency and jitter (table C.6). Whereas distributed cluster fabrics (such as RoCEv2 or InfiniBand) prioritize aggregate bandwidth using credit-based flow control and statistical multiplexing, onboard physical AI buses must guarantee bounded delivery times. Industrial fieldbuses such as EtherCAT combine hardware forwarding with scheduled exchange and clock synchronization. A specific jitter claim requires the configured system's evidence. Classical serial buses like Controller Area Network (CAN) 2.0B provide low-overhead bitwise arbitration for up to 8 bytes, but saturate rapidly under multi-joint control traffic. The Flexible Data-Rate variant, CAN FD, expands payloads to 64 bytes with accelerated data bit rates. Meanwhile, switched IEEE Time-Sensitive Networking (TSN) uses scheduled transmission gates to multiplex gigabit vision streams with hard real-time actuator commands. In contrast, non-deterministic best-effort Ethernet and shared wireless channels introduce tail latencies that exceed the reaction deadlines of high-speed electromechanical machines. For IEEE 1588 PTP hardware timestamping bounds, see section C.7; for CAN 2.0B vs. CAN FD priority arbitration and EtherCAT cycle budgets, see section C.11.

Table C.6: Communication Bus Latencies, Jitter, and Real-Time Determinism: Representative scales for configured networks, not protocol-level worst-case guarantees. Required jitter follows the plant and deadline; bounded control does not universally require sub-microsecond jitter. Delivery guarantees require a traffic model, topology, arbitration analysis, and measured implementation behavior.

Bus / Network Technology	Nominal Transit Latency	Illustrative Jitter	Determinism Mechanism	Primary Machine Role
EtherCAT (ETG.1000)	100 µs–1 ms	< 1 µs	Hardware cut-through on-the-fly frame processing	Synchronous joint servo drive & sensor feedback (Body/Nervous)
CAN FD (ISO 11898-1)	100–500 µs	50–200 µs	Bitwise non-destructive priority arbitration (64 B)	Distributed sensors, multi-axis actuator controllers (Nervous/Body)
CAN 2.0B (ISO 11898-1)	200 µs–1 ms	100–400 µs	Bitwise non-destructive priority arbitration (8 B)	Legacy sensors, low-rate auxiliary controllers (Nervous/Body)
TSN Ethernet (802.1Qbv)	10–100 µs	< 5 µs	Time-aware shaper with scheduled transmission gates	High-bandwidth sensor ingress (lidar/cameras) to SoC (Boundary)
Standard IP / UDP Ethernet	0.5–5 ms	1–20 ms	Switched full-duplex links; best-effort queueing	Asynchronous logging, inter-node telemetry (Brain)
Shared Wi-Fi telemetry	5–20 ms	10–500 ms (RF fade)	Wireless packet retransmission, contention window	High-level fleet dispatch, cloud mission updates (World/Governance)

C.3 Real-Time Timers, Watchdogs, and Schedulability

A real-time task is correct only if it computes the required result before its deadline. Average inference latency and throughput do not establish that property. A permission task needs a bound that includes its own execution, blocking on shared resources, and interference from other work.

DRAFT

The following single-core scheduling models separate those contributions. Their guarantees apply only under their stated task assumptions; operating-system configuration and loaded measurements must establish whether the implementation satisfies them.

C.3.1 Real-time task schedulability under rate-monotonic and earliest-deadline-first scheduling

In contrast to general-purpose Linux time-sharing, real-time operating systems schedule tasks based on deterministic timing contracts rather than dynamic heuristics. A periodic real-time task i is characterized by its worst-case execution time (WCET) C_i, relative deadline D_i, and period T_i. When multiple real-time tasks share a single core, schedulability depends on the priority assignment discipline:

Under **Rate-Monotonic Scheduling (RMS)**, fixed-priority preemptive scheduling assigns priority inversely proportional to task period ($T_i < T_j \implies \text{priority}(i) > \text{priority}(j)$) (Liu and Layland 1973). For a set of n independent periodic tasks, with negligible scheduling overhead, no blocking or release jitter, and implicit deadlines ($D_i = T_i$), a sufficient condition for schedulability is the Liu and Layland utilization bound:

$$U = \sum_{i=1}^{n} \frac{C_i}{T_i} \leq n\left(2^{1/n} - 1\right)$$

As $n \to \infty$, the bound converges monotonically to $\lim_{n\to\infty} n(2^{1/n} - 1) = \ln 2 \approx 0.693$ (69.3 percent). If total processor utilization does not exceed 69.3 percent, the task set is guaranteed to meet all deadlines under RMS. Task periods may instead form a harmonic set, in which every period is an exact integer multiple of every shorter period ($T_j = m \cdot T_i$ for integer $m \geq 1$, such as 1 ms, 5 ms, 10 ms, and 100 ms). For a harmonic set, the utilization bound rises to 100 percent. In physical AI architectures, rate hierarchies are purposefully engineered with harmonic cadences to maximize processor utilization without sacrificing determinism.

When processor utilization exceeds the conservative Liu and Layland bound ($U > \ln 2$), or when relative deadlines are constrained ($D_i \leq T_i$), **Response Time Analysis (RTA)** evaluates exact schedulability from the worst-case **response time** R_i (Liu and Layland 1973; Kopetz 2011):

$$R_i = C_i + B_i + I_i \leq D_i$$

where B_i is the maximum blocking duration induced by lower-priority tasks holding shared resources, and I_i is the interference from higher-priority tasks. The response time is computed via the fixed-point recurrence. The sum runs over the higher-priority task set. The ceiling counts how many releases of each such task can interfere during the current response-time estimate. An enlarged estimate may expose another release and therefore require another iteration:

$$R_i^{(\ell+1)} = C_i + B_i + \sum_{j \in hp(i)} \left\lceil \frac{R_i^{(\ell)}}{T_j} \right\rceil C_j$$

For fixed priorities, bounded blocking, no self-suspension, and zero release jitter, start with $R_i^{(0)} = C_i + B_i$ and iterate until $R_i^{(\ell+1)} = R_i^{(\ell)} \leq D_i$ (establishing schedulability) or $R_i^{(\ell+1)} > D_i$ (signaling deadline violation). See section 4.5.3 and section 4.5.1 for the role of response time variance in the nervous system.

In dynamic-priority systems, **Earliest Deadline First (EDF)** assigns highest priority to the active task with the closest absolute deadline $d_{i,k} = r_{i,k} + D_i$. For independent jobs on a single-core preemptive processor with no blocking and negligible scheduling overhead, EDF is optimal: if a task set is schedulable by any scheduling algorithm, it is schedulable by EDF (Liu and Layland 1973). For periodic tasks with $D_i = T_i$, EDF guarantees schedulability if and only if:

$$\sum_{i=1}^{n} \frac{C_i}{T_i} \leq 1$$

achieving 100 percent theoretical utilization without requiring harmonic periods. When relative deadlines are strictly less than periods ($D_i < T_i$), schedulability requires the processor demand criterion over the Demand Bound Function (DBF):

$$\text{dbf}(t) = \sum_{i=1}^{n} \max\left(0, \left\lfloor \frac{t - D_i}{T_i} \right\rfloor + 1\right) C_i \leq t, \quad \forall t \geq 0$$

evaluating whether cumulative execution demand exceeds available physical time across all time intervals t. Under Linux, EDF is exposed via the `SCHED_DEADLINE` policy implementing the Constant Bandwidth Server (CBS) algorithm. A CBS task declares its runtime Q_i, deadline D_i, and period T_i via `sched_setattr()`. If a task attempts to execute beyond its declared runtime Q_i within period T_i, the kernel dynamically throttles the task until its next period, protecting co-located real-time threads from execution overruns.

In standard multi-threaded Linux, mutual exclusion primitives (such as futex-backed mutexes) assume threads will eventually yield the processor. When real-time tasks share data structures (such as seqlock mailboxes or actuator command queues) protected by naive mutual exclusion, they suffer from **unbounded priority inversion** (Sha et al. 1990; Reeves 1997). A low-priority task L acquires a lock; a high-priority task H becomes ready and blocks waiting for the lock; intermediate-priority tasks M that do not need the lock preempt task L, delaying task H for an arbitrary duration. To bound blocking time B_i in the RTA recurrence, real-time operating systems use formal synchronization protocols:

1. **Priority Inheritance Protocol (PIP)**: When task H blocks on a lock held by task L, the operating system temporarily elevates task L's active priority to task H's priority, preventing preemption by task M. Under `PREEMPT_RT` Linux, standard in-kernel spinlocks are converted to sleeping `rt_mutex` locks that enforce PIP automatically, while user-space threads configure `PTHREAD_PRIO_INHERIT`. While PIP eliminates unbounded inversion, it permits transitive blocking chains ($B_i \leq \sum_k C_k$) and potential deadlock.
2. **Priority Ceiling Protocol (PCP)**: Each lock is assigned a static priority ceiling equal to the highest priority of any task that may lock it. A task i can lock a resource only if its priority is strictly higher than the priority ceilings of all locks currently held by other tasks. PCP prevents mutual-exclusion deadlocks and guarantees that a task is blocked at most once by at most one lower-priority critical section (Sha et al. 1990):

   $$B_i = \max_{k \in lp(i), s \in cs(k)} {C^{\text{cs}}}_{k,s}$$

   where $lp(i)$ is the set of tasks with priority lower than task i, and $cs(k)$ is the set of critical sections executed by task k with a priority ceiling at or above the priority of task i.

C.3.2 Worst-case execution time analysis for physical ML pipelines

In classical embedded systems, the worst-case execution time C_i is determined via Static Timing Analysis (STA) (Hennessy and Patterson 2019). STA parses binary machine instructions, constructs a Control Flow Graph (CFG), and solves an Integer Linear Program via the Implicit Path Enumeration Technique (IPET) using cycle-accurate microarchitectural models of processor pipelines, branch predictors, and cache sets. In physical AI systems, evaluating C_i for learned vision-language-action (VLA) and diffusion policies presents three distinct architectural challenges:

1. **Microarchitectural opacity**: Modern neural accelerators (GPUs, NPUs, Tensor Processing Unit (TPU) hardware) feature multi-level shared caches, dynamic frequency scaling (DVFS), out-of-order warp schedulers, and memory crossbar contention that make a sound static bound difficult without detailed timing and interference models.
2. **Algorithmic execution variance**: Learned pipelines follow dynamic execution paths, including adaptive denoising loops in diffusion models, variable sequence lengths in autoregressive decoders, and data-dependent sparse attention kernels.
3. **Software runtime overhead**: Deep learning runtimes (e.g., PyTorch, TensorRT, Open Neural Network Exchange (ONNX) Runtime) introduce non-deterministic host-to-device kernel launch queueing, unified memory migration, and internal memory allocation locks. Launch

DRAFT

overhead and jitter depend on the runtime, driver, submission path, and load; a per-kernel constant is not portable across systems.

To constrain execution variability for neural policies that cross the proposal boundary, physical AI systems enforce deterministic execution contracts and hybrid measurement bounds:

- **Static shape contracts**: Action chunk horizons (H), token context lengths, and sensor input tensors are locked to fixed maximum dimensions. Dynamic input padding replaces variable-length tensors, ensuring constant compute graph geometry and eliminating dynamic kernel recompilation.
- **Zero runtime allocation**: All execution buffers, KV caches, scratchpad memory, and direct memory access (DMA) descriptors are preallocated during initialization. Dynamic memory calls (`malloc`, `cudaMalloc`, `free`) are strictly forbidden on cyclic control paths.
- **Reduced host dispatch overhead via CUDA Graphs**: Fixing denoising iterations bounds one source of algorithmic work. Capturing and instantiating a reusable graph reduces repeated per-kernel host setup, as the CUDA Graphs documentation explains. Graph launch still uses the runtime and driver, and device scheduling, frequency changes, and shared-resource contention remain. A graph does not by itself provide deterministic execution.
- **Extreme Value Theory (EVT) tail bounds**: Because finite empirical profiling cannot expose the true maximum execution time under worst-case hardware interference, engineers apply Extreme Value Theory (Coles 2001). Under the Pickands–Balkema–de Haan theorem, execution time exceedances over a high operational threshold u converge asymptotically to a Generalized Pareto Distribution (GPD):

$$F_{\text{GPD}}(y) = 1 - \left(1 + \frac{\xi y}{\tilde{\sigma}}\right)^{-1/\xi}$$

on the support $1+\xi y/\tilde{\sigma} > 0$, with the exponential limit at $\xi = 0$. Here $y = x - u > 0$, $\tilde{\sigma} > 0$ is the scale parameter, and ξ is the shape parameter (tail index). The shape parameter characterizes the tail behavior:

  - $\xi < 0$ (Weibull domain): Bounded upper tail with a finite model endpoint $x_F = u - \tilde{\sigma}/\xi$, under the fitted model; an estimated finite endpoint is not proof of a hardware ceiling.
  - $\xi = 0$ (Gumbel domain): Light, exponential tail.
  - $\xi > 0$ (Fréchet domain): Heavy, polynomial tail. The fitted sign alone neither identifies a hardware failure mechanism nor determines whether a deadline can be defended.

For an acceptable target exceedance probability ϵ (such as 10^{-6} or 10^{-8} per invocation), a model-based execution-time quantile $z_\epsilon(\epsilon)$ is computed as:

$$z_\epsilon(\epsilon) = u + \frac{\tilde{\sigma}}{\xi}\left[\left(\frac{N}{N_u}\epsilon\right)^{-\xi} - 1\right]$$

where N is total sample count and N_u is the count of observations exceeding threshold u. For $\xi = 0$, the continuous limit is $u - \tilde{\sigma}\ln(N\epsilon/N_u)$. These are fitted quantiles, conditional on the sampling regime, threshold choice, tail model, and parameter uncertainty. They do not certify a deterministic WCET. A placement record must distinguish measured maxima, probabilistic estimates, and justified execution bounds; the permission path must remain schedulable when the proposer exceeds its estimate.

C.3.3 Operating-system determinism through interrupt handling, memory locking, and cache locality

On a heterogeneous robotics system on chip (SoC), the nervous system and safety monitors execute under real-time operating systems (RTOS) or real-time Linux kernels (such as Linux patched with `PREEMPT_RT`). Interrupts and non-preemptible kernel critical sections can delay user-space tasks. A hard response bound requires bounding those intervals on the chosen kernel and hardware. In physical AI pipelines where control loops govern physical momentum, operating-system determinism requires eliminating non-preemptible kernel sections, bounding interrupt preemption latency, isolating execution cores, locking virtual memory, and enforcing cache locality.

Linux fair scheduling balances CPU service among runnable tasks. Its historical CFS implementation accounts for weighted execution time; newer kernels use EEVDF, which also considers eligibility and virtual deadlines. Neither policy establishes the physical deadline guarantee needed by the permission task. In physical AI systems, real-time control threads must instead be configured with POSIX static priority scheduling policies (`SCHED_FIFO` or `SCHED_RR`) across priority levels 1 to 99 (or `SCHED_DEADLINE` implementing Earliest Deadline First). Under `SCHED_FIFO`, the highest-priority runnable thread executes immediately and runs until it blocks on I/O, yields voluntarily, or is preempted by a strictly higher-priority real-time thread.

In mainline Linux kernels, disabling preemption during spinlock acquisition (`preempt_disable()`), executing non-preemptible softirqs, and servicing asynchronous workqueues can delay user-space execution by tens of milliseconds. When an unprivileged machine learning process or device driver holds an in-kernel spinlock, a high-priority 1 kHz real-time safety task cannot preempt the CPU, even if its timer has expired. A kernel configured with `PREEMPT_RT` reduces non-preemptible execution through four mechanisms, while hardware, drivers, and remaining critical sections still require timing qualification:

1. *Sleeping Spinlocks (`rt_mutex`)*: Standard in-kernel spinlocks (`spinlock_t` and `rwlock_t`) are replaced by sleeping mutexes backed by `rt_mutex` with Priority Inheritance Protocol (PIP) support. When a high-priority thread waits for an `rt_mutex`, the waiter sleeps and the lock owner inherits its priority until it can release the lock. Raw spinlocks remain non-preemptible; interrupt masking depends on the primitive used. Their maximum hold times must be included in the platform timing analysis.
2. *Preemptible Read-Copy Update (`CONFIG_PREEMPT_RCU`)*: RCU read-side critical sections (`rcu_read_lock()` / `rcu_read_unlock()`) become preemptible, preventing deferred memory reclamation from stalling real-time threads.
3. *Forced Interrupt Threading*: Hardware interrupt service routines (ISRs) are split into minimal top-half handlers and prioritized kernel threads (`irq/<irq>-<name>`) scheduled under `SCHED_FIFO`.
4. *High-Resolution Timers (`hrtimers`)*: Traditional Linux timer ticks execute at coarse periodic jiffies (1 ms or 4 ms granularity), introducing substantial quantization error and timer slack. `PREEMPT_RT` binds the timer subsystem to hardware per-CPU clock event devices (such as the ARM Generic Timer or x86 Local APIC), enabling sub-microsecond timer resolution. Real-time cyclic threads invoke `clock_nanosleep(CLOCK_MONOTONIC, TIMER_ABSTIME, &next_period, NULL)` using absolute monotonic deadlines, avoiding cumulative drift from relative sleeps. Wake-up jitter remains part of the response-time bound.

When an external hardware peripheral (such as an IMU, joint encoder counter, or fieldbus controller) asserts an interrupt request (IRQ), the processor halts user execution and saves register context. It then vectors to the hardware ISR via the interrupt controller (such as an ARM Generic Interrupt Controller GICv3 or x86 APIC). The worst-case interrupt latency $t_{\text{irq,lat}}$ to enter the hardware interrupt handler can be budgeted as:

$$t_{\text{irq,lat}} = t_{\text{irq_disabled,max}} + t_{\text{hw_pipe}} + t_{\text{context_save}} + \sum_{j \in hp(\text{irq})} t_{\text{ISR}_j}$$

This expression does not include threaded-handler work or the subsequent scheduling delay before a user-space task runs. Here $t_{\text{irq_disabled,max}}$ is the longest duration during which CPU interrupts were disabled across the kernel, $t_{\text{hw_pipe}}$ is the processor pipeline flush delay, $t_{\text{context_save}}$ is the hardware register preservation time, and $\sum t_{\text{ISR}_j}$ represents the execution duration of higher-priority ISRs.

To prevent high-bandwidth sensor streams (such as GigE Vision cameras or 3D lidars streaming gigabits of packet traffic) from generating an *interrupt storm* that starves the 1 kHz permission path, real-time architectures strictly enforce top-half and bottom-half partitioning:

- **Top-half (Hardware ISR)**: Executes in hard-interrupt context with CPU interrupts masked. It executes the absolute minimum hardware operations: reading the peripheral interrupt status register, clearing the physical interrupt line, latching high-resolution hardware counter timestamps, and waking the associated threaded IRQ. The handler's maximum execution time must be bounded on the target.

DRAFT

- **Bottom-half (Threaded IRQ)**: In `PREEMPT_RT` and RTOS environments, complex packet deserialization, frame CRC verification, and data copies are deferred to dedicated kernel threads (`irq/<irq>-<name>`). By configuring these threaded IRQs under `SCHED_FIFO` with priorities lower than the 1 kHz safety monitor (e.g., setting camera IRQ threads to priority 50 and the motor permission thread to priority 90), the scheduler prevents those lower-priority threads from preempting the control task. Hard-interrupt top halves and shared-memory traffic still contribute interference.

Heterogeneous multi-core robotics SoCs must also isolate deterministic control threads from background operating-system disturbances. Kernel boot parameters and memory layout rules establish strict CPU shielding and cache locality:

- `isolcpus=2,3`: Removes cores 2 and 3 from the general kernel scheduler balancing domain, reducing automatic load balancing onto those cores; explicit affinity, cpusets, and kernel work still require configuration.
- `nohz_full=2,3`: Enables full dynamic tickless operation. When an isolated core runs a single real-time thread, the kernel can suppress the periodic scheduling timer tick (100–1000 Hz), removing that source of periodic interruption while other interrupts and scheduling delays remain.
- `rcu_nocbs=2,3`: Offloads RCU callback processing from isolated cores to housekeeping cores (cores 0 and 1).
- *IRQ Affinity Partitioning*: Peripheral hardware interrupts are directed away from real-time cores by writing CPU bitmasks to `/proc/irq/<id>/smp_affinity`. High-rate camera MSI-X vectors and Ethernet controller interrupts are pinned exclusively to housekeeping cores, reducing controllable interrupt interference. Nonmaskable events, local timers, and platform firmware disturbances still require accounting.
- *Cache Line Alignment and False Sharing Elimination*: Cache-line size is architecture dependent; the examples here assume 64-byte lines. When multiple CPU cores access independent variables that reside within the same 64-byte line, hardware cache coherency protocols (MESI/MOESI) repeatedly invalidate the line across core private caches upon every store, a phenomenon known as **false sharing** or *cache line bouncing*. A single false sharing interaction can stall a real-time core for 50 to 100 clock cycles. Separating independently written state into aligned, padded cache-line slots avoids false sharing; merely aligning the beginning of a larger structure does not isolate every member. The target's remaining cache misses and contention still need timing bounds. Furthermore, real-time control paths pre-warm L1 instruction and data caches during initialization by executing a dummy pass over critical control tables before arming actuators.

Virtual memory subsystems rely on demand paging, so deterministic execution also requires locking virtual memory and eliminating page faults. When a process accesses an unmapped virtual address, the CPU raises an architectural page fault exception (`#PF`) and suspends execution. The kernel page-table handler then allocates a physical page frame, updates translation lookaside buffer (TLB) entries, and zeroes the memory (a *minor page fault*, requiring 10–50 µs). If the requested page was swapped to secondary flash storage, the thread blocks on disk I/O (a *major page fault*, requiring 10–50 ms). Furthermore, Transparent Huge Pages (THP) memory compaction (`khugepaged`) can asynchronously stall threads for tens of milliseconds while defragmenting physical memory pages. A page fault can consume the remaining response-time margin; its mere occurrence does not imply that every deadline is missed.

The following Linux/glibc sketch illustrates initialization and absolute-period sleeping. It assumes the shown page and cache-line sizes. Production code must also validate limits and privileges, measure completion against the deadline, and enter the assessed fallback on an overrun. A late absolute sleep can return immediately; it must not trigger an uncontrolled series of catch-up actuator writes.

        g_telemetry.sequence_id++;
    }
}
```

Beyond address space locking and stack prefaulting, the cyclic 1 kHz control loop operates under a strict **zero dynamic allocation invariant**. In general-purpose systems programming, developers routinely rely on dynamic memory managers (`malloc`, `free`, C++ `new`, `delete`) or standard container expansions (`std::vector::push_back`). In a real-time control loop, however, dynamic allocation introduces three catastrophic failure modes:

1. *Arena Mutex Contention*: Modern allocators (such as `ptmalloc` in `glibc`) partition memory into multiple heap arenas protected by mutual-exclusion mutexes. If another thread in the same process acquires an arena lock, a high-priority 1 kHz real-time control thread calling `malloc` blocks on that mutex, suffering from priority inversion and waiting milliseconds.
2. *Kernel Syscall Invocations*: When an allocator exhausts its active arena chunk, it issues `brk()` or anonymous `mmap()` system calls. These kernel entries acquire the process's `mmap_lock` (or `mmap_sem`), which is shared with background kernel threads such as `khugepaged` performing transparent huge page compaction or memory defragmentation, stalling user-space execution for tens of milliseconds.
3. *Heap Fragmentation*: Repeated cyclic allocations and deallocations fragment the heap, degrading allocation search times across segregated free lists into non-deterministic search loops.

Consequently, all message structures, matrix workspace buffers, trajectory buffers, and seqlock mailbox slots must be statically allocated at startup or drawn from fixed-size, lock-free memory pools (such as slab allocators). Furthermore, `mlockall(MCL_FUTURE)` must be paired with explicit memory pre-allocation and page prefaulting. Linux uses optimistic memory allocation (overcommit), so virtual address ranges returned by `malloc()` are not backed by physical page frames until the thread actually writes to each 4 KB page. Touching an uninitialized buffer for the first time inside the

control loop triggers a minor page fault exception (`#PF`). The kernel page-fault handler must then allocate physical memory, zero the page, and update the MMU page table and TLB entries, a stall of 10–50 µs that jeopardizes sub-millisecond control deadlines. Prefaulting and successful memory locking establish page residency before arming actuators. TLB and cache entries can still be evicted, so their miss costs remain in the execution budget; copy-on-write faults and later mapping changes must also be excluded.

C.3.4 Hardware watchdogs and fault response

In distributed computing clusters, node liveness and consensus are managed via software heartbeats and distributed leases (such as Raft heartbeats, ZooKeeper leases, or Kubernetes node probes) operating over second-scale intervals. If a worker node crashes, the cluster orchestrator reschedules containers onto alternative nodes. In physical AI systems, however, an autonomous machine traveling through physical space cannot wait seconds for a software orchestrator. If the GPU driver deadlocks, memory bus crossbars stall, or a kernel panic freezes the operating system, physical momentum continues unchecked. To detect a missed execution checkpoint, an embedded design uses a **hardware watchdog timer**. Its clock and response path must be independent of the monitored processor. An independent crystal oscillator or low-speed internal oscillator (`LSI`) completely decoupled from the main system phase-locked loop (PLL) is required.

The hardware watchdog timer comprises an autonomous down-counter register $W(t)$ clocked at frequency f_{wdg} (typically 32 kHz from an independent on-chip RC oscillator). At system initialization, the register is loaded with a threshold value W_{init}. Software execution threads must periodically refresh (or "kick") the register before the count decrements to zero:

$$W(t) = W_{\text{init}} - \left\lfloor f_{\text{wdg}} \cdot t \right\rfloor$$

At expiry, the timer asserts its configured reset or fault output. A separately wired trip is required when processor reset alone is insufficient to de-energize the actuators.

In safety-critical systems, simple down-counters are vulnerable to runaway execution bugs: if a corrupted control loop enters an infinite spin-loop that happens to execute the watchdog refresh instruction, the watchdog is continually fed despite the control failure. To prevent this, robust physical AI architectures employ a **Windowed Watchdog Timer (WWDG)**. A windowed watchdog defines both an upper counter threshold W_{upper} and a lower counter threshold W_{lower}. The software refresh is valid only while the counter lies between them:

$$W_{\text{lower}} \leq W(t_k) \leq W_{\text{upper}}$$

Because the counter falls at the fixed rate f_{wdg}, the two counter thresholds convert to the time bounds T_{lower} and T_{upper} that section 13.5 uses for the service window, measured from the last reload:

$$T_{\text{lower}} = \frac{W_{\text{init}} - W_{\text{upper}}}{f_{\text{wdg}}}, \quad T_{\text{upper}} = \frac{W_{\text{init}} - W_{\text{lower}}}{f_{\text{wdg}}}$$

If software attempts to refresh the watchdog too early ($t_k < T_{\text{lower}}$, equivalently $W(t_k) > W_{\text{upper}}$), the early write indicates an abnormal loop short-circuit or clock glitch. Refreshing too early or failing to refresh before T_{upper} trips the hardware watchdog controller immediately.

Feeding the watchdog directly from a periodic timer interrupt is an unsafe anti-pattern, because the timer interrupt may continue firing even if the primary motion planning and safety monitor threads are deadlocked. To check completion of the expected software checkpoints, control software can implement **multi-stage token-passing checkpointing** using rolling polynomial accumulators:

$$T_{k+1} = \text{CRC32}\left(T_k \oplus \text{Signature}_k\right)$$

1. At the beginning of the 1 kHz tick, a watchdog token T_0 is generated from the hardware monotonic cycle counter.
2. Stage 1 (Sensor Ingress): Validates camera, IMU, and joint telemetry timestamps, updating the token: $T_1 = \text{CRC32}(T_0 \oplus \text{sensor_valid_signature})$.

3. Stage 2 (State Estimation & Tracking): Computes joint tracking errors, updating $T_2 = \text{CRC32}(T_1 \oplus \text{tracking_valid_signature})$.
4. Stage 3 (Permission Enforcer): Validates Control Barrier Functions and stopping distance envelopes, computing $T_3 = \text{CRC32}(T_2 \oplus \text{enforce_valid_signature})$.
5. Stage 4 (Actuator Dispatch): Transmits admitted setpoints across the fieldbus, computing $T_{\text{final}} = \text{CRC32}(T_3 \oplus \text{dispatch_valid_signature})$.

Only if T_{final} matches the expected value for this tick may the watchdog refresh routine service the timer. The token detects omitted or misordered checkpoints under its fault model; a CRC is neither authentication nor proof that the computed state or command is physically correct.

A watchdog timeout must reach a validated hardware fail-safe response path independently of the processor it monitors. A CPU reset or non-maskable interrupt alone does not establish that connection. When the assessed response includes **safe torque off (STO)**, a separately wired output disables the gate drive that generates motor torque; the wiring, response time, and diagnostic coverage require device-specific qualification. Gate disable does not establish an instantaneous mechanical stop. Winding current takes time to decay, moving axes may coast, and a gravity-loaded axis may require a holding brake or a powered stop before torque removal. The complete watchdog-to-plant response belongs in the stopping budget.[2]

[2] **Hardware Watchdog Down-Counters**: A configured watchdog expires when its expected service does not occur. Its oscillator, timeout, output wiring, and plant response differ by device. Feeding it merely from an unrelated interrupt does not prove that the monitored control computation progressed; a firmware-fed reset also need not signal a drive. See the Linux watchdog API for reset behavior and section 12.9 for stop selection.

C.4 Inverter Timers and Power Electronics Gate Drive

In machine learning control frameworks (such as reinforcement learning policies, imitation learning, or model predictive control pipelines), actuator actions are formulated as continuous numerical setpoints, such as commanded joint torques τ^* or angular velocities $\dot{\mathbf{q}}^*$. In physical realization, however, torque is generated by synthesizing rotating electromagnetic stator flux through high-frequency switching of power semiconductor bridges (typically at 20 kHz to 100 kHz). Actuator motor drives employ three-phase half-bridge inverters to convert DC bus voltage into alternating stator currents.

C.4.1 Microcontroller timer dead-time insertion

Bridging the digital software domain with physical power silicon requires strict microarchitectural timing interlocks. Each inverter phase comprises a half-bridge with a high-side power MOSFET (or GaN FET / IGBT) and a low-side power MOSFET connected across the DC supply rail V_{bus}. Microcontroller timer peripherals generate complementary pulse-width-modulated (PWM) drive signals with hardware-enforced **dead-time insertion** t_{dead}:

$$t_{\text{dead}} \geq t_{\text{off, max}} + t_{\text{prop, skew}} - t_{\text{on, min}} + t_{\text{margin}}$$

where $t_{\text{off, max}}$ is the maximum turn-off delay of the power switch, $t_{\text{on, min}}$ is the minimum turn-on delay, $t_{\text{prop, skew}}$ is the propagation delay mismatch across isolated gate drivers, and t_{margin} is an engineering safety buffer.[3]

[3] **Inverter Dead-Time Insertion**: Timer dead time is selected from switch and driver timing over temperature and load, then verified with the actual gate waveforms. An overlap can create a damaging bus short; a numeric current or fuse outcome requires the circuit impedance and protection response.

Modern motor control microcontrollers (such as STM32 Advanced-control timers TIM1/TIM8 or TI C2000 ePWM modules) synthesize PWM waveforms using hardware up-down counting counters (`TIMx_CNT`). In **center-aligned mode**, the counter counts up from 0 to the auto-reload value (`TIMx_ARR`) and back down to 0, producing symmetrical PWM waveforms with period $T_{\text{pwm}} = 2 \cdot \text{ARR} \cdot T_{\text{timer_clk}}$. Center-aligned PWM provides symmetric switching and repeatable ADC trigger opportunities. Ripple reduction and valid sampling windows depend on duty cycle, modulation, current-sensing topology, and settling time. Synchronization alone does not remove switching noise.

The timer's hardware Dead-Time Generator (DTG) monitors the compare match outputs (`TIMx_CCRx`) and inserts dead-time delay cycles N_{dtg} using an autonomous digital delay line:

$$t_{\text{dead}} = N_{\text{dtg}} \cdot T_{\text{dtg}}$$

By latching the DTG configuration behind hardware register lock bits (`BDTR.LOCK`), the microcontroller guarantees that the dead-time delay cannot be altered by runaway firmware or memory corruption. Once locked at boot, the register ignores subsequent software writes until the next hardware reset.

DRAFT

A power MOSFET or GaN FET switch possesses input capacitance $C_{\text{iss}} = C_{\text{gs}} + C_{\text{gd}}$, where C_{gd} is the non-linear reverse transfer (Miller) capacitance. During gate turn-on and turn-off, charge transfer follows:

$$Q_g = \int_0^{t_{\text{sw}}} I_g(t)dt = Q_{\text{gs}} + Q_{\text{gd}}$$

During turn-off, the gate driver sinks current through gate resistance $R_{g,\text{off}}$. The gate-source voltage V_{gs} drops to the **Miller plateau voltage** V_{plateau}, where it dwells while the drain-to-source voltage V_{ds} traverses the entire DC rail:

$$t_{\text{plateau}} = \frac{Q_{\text{gd}}}{I_{g,\text{off}}} = \frac{Q_{\text{gd}} \cdot R_{g,\text{off}}}{V_{\text{plateau}} - V_{\text{ee}}}$$

Turn-on and turn-off times depend on gate resistance, driver strength, load, and device charge. Neither is universally longer; dead time must use the measured worst-case mismatch.

If dead time is insufficient, both high-side and low-side switches conduct simultaneously (**shoot-through**), creating a low-impedance short circuit directly bridging the DC rail to ground:

$$I_{\text{shoot-through}} = \frac{V_{\text{bus}}}{2R_{\text{ds(on)}} + R_{\text{trace}}}$$

This resistive expression gives a prospective current, not its instantaneous value. Loop inductance limits the initial rise, and the resulting device stress depends on switching overlap, protection delay, and the circuit safe operating area.

Even when dead time is configured correctly, half-bridge legs face **parasitic Miller cross-conduction**. When the high-side MOSFET turns on, the phase node voltage slews at high speed ($dV_{\text{ds}}/dt \sim 10$–$50$ V/ns in modern SiC and GaN bridges). This steep voltage transient forces displacement current through the low-side switch's Miller capacitance:

$$I_{\text{miller}} = C_{\text{gd}} \frac{dV_{\text{ds}}}{dt}$$

This current flows through the low-side gate resistor $R_{g,\text{off}}$ back to ground, inducing a parasitic gate voltage rise:

$$V_{\text{gs,induced}} = I_{\text{miller}} \cdot R_{g,\text{off}} = C_{\text{gd}} \frac{dV_{\text{ds}}}{dt} R_{g,\text{off}}$$

If $V_{\text{gs,induced}}$ exceeds the gate threshold voltage V_{th} (typically 1.5–3.0 V in GaN FETs), the low-side switch turns on spuriously while the high-side switch is conducting, inducing catastrophic shoot-through. Power electronics gate drivers counter this using **Active Miller Clamps (AMC)**, an internal low-impedance switch that clamps the gate directly to the negative rail whenever V_{gs} drops below 1.0 V, or split gate drives ($R_{g,\text{on}}/R_{g,\text{off}}$) with antiparallel Schottky diodes.

While necessary for silicon survival, dead time introduces non-linear voltage distortion into stator windings. During the dead-time interval t_{dead}, both active MOSFETs are commanded off, and signed instantaneous phase current i_{phase} (positive from the inverter node into the winding) is forced to freewheel through antiparallel body diodes. The sign of the phase current determines whether the inverter phase node clamps to V_{bus} or ground, producing an average phase voltage error:

$$\Delta V_{\text{phase}} = -\text{sgn}(i_{\text{phase}}) \cdot \frac{t_{\text{dead}}}{T_{\text{pwm}}} V_{\text{bus}}$$

In three-phase synchronous machines, this square-wave error injects 5th and 7th harmonic voltages into the stationary reference frame. When transformed into the rotor synchronous dq reference frame via Park's transformation, these odd harmonics combine into a **6th harmonic voltage disturbance**. The amplitudes and phases follow the harmonic coefficients of the phase-voltage error and the chosen transformation convention. They are not equal to the fundamental square-wave coefficient. The current loop filters these voltage harmonics before they become torque ripple, creating a corresponding **6th harmonic torque ripple**:

$$\tau_{\text{ripple}}(6\theta_e) = \frac{3}{2} N_{\text{poles}} \lambda_{\text{pm}} \cdot \Delta i_q(6\theta_e)$$

DRAFT

Left uncompensated, this hardware-induced torque ripple produces high-frequency torque chatter that excites mechanical drivetrain resonances. Modern motor drives implement dead-time compensation algorithms in low-level firmware that inject feedforward voltage vectors opposite to $\Delta V_{d,q}$, linearizing the actuator response for high-level ML policies.

C.5 Inductive Voltage Droop and Gate Delay Stretch

In data center machine learning clusters, power delivery networks (PDNs) are supported by large rack-level voltage regulator modules (VRMs) and extensive decoupling capacitor planes. On embedded physical AI compute platforms, deep learning accelerators (such as tensor cores and systolic array matrix engines) share tightly constrained power rails with CPU cores and real-time safety microcontrollers. When a deep neural network transitions from idle to full execution, current draw increases by tens of amperes within nanoseconds.

C.5.1 Power delivery network impedance and rail droop

A power delivery network (PDN) has parasitic resistance and inductance in each source path. For a lumped branch with resistance R_{PDN}, inductance $L_{\text{parasitic}}$, and branch current I_{branch}, its voltage drop is:

$$V_{\text{source}} - V_{\text{rail}} = L_{\text{parasitic}} \frac{dI_{\text{branch}}}{dt} + I_{\text{branch}} R_{\text{PDN}}$$

The accelerator's load current need not equal this branch current during a transient: local decoupling supplies their difference. The rail response follows the coupled source-path and capacitor equations of section C.10. Substituting the full load-current slew into every upstream inductance would ignore that buffering.

To prevent rail excursions from exceeding allowable voltage tolerances $\pm\Delta V_{\text{max}} = V_{\text{nom}} \times \delta_{\text{tol}}$ (typically ± 5 percent, or 45 mV on a 0.9 V digital core rail), the power delivery network must maintain an impedance profile strictly below the **target impedance** Z_{target} across the entire operational frequency band:

$$Z_{\text{target}} = \frac{V_{\text{nom}} \cdot \delta_{\text{tol}}}{\Delta I_{\text{max}}}$$

For a 0.9 V accelerator drawing a 50 A step transient with 5 percent allowable ripple, $Z_{\text{target}} = 45\ \text{mV}/50\ \text{A} = 0.90\ \text{m}\Omega$ from DC up to gigahertz frequencies. Exceeding this impedance at any excitation frequency permits transient load steps to pull the supply rail outside its timing-qualified window.

Switched-mode power supplies (VRMs) have limited feedback control loop bandwidth (100 kHz to 1 MHz) and cannot supply charge during nanosecond current transitions. Energy must be buffered across a **multi-tier decoupling capacitor hierarchy** structured by frequency response:

1. *On-Die Decoupling (>100 MHz)*: Deep trench and metal-insulator-metal (MIM) capacitors fabricated directly on the silicon die ($C_{\text{die}} \sim$ 10–100 nF, parasitic loop inductance < 10 pH, response time < 0.5 ns) supply charge during the initial clock cycles.
2. *Package Decoupling (10–100 MHz)*: Land-side capacitors (LSC) mounted under the BGA package ($C_{\text{pkg}} \sim$ 1–10 µF, loop inductance $\sim$ 50–200 pH, response time 1–5 ns).
3. *Board-Level High-Frequency MLCCs (100 kHz–10 MHz)*: Low-ESL surface-mount multi-layer ceramic capacitors (0201/0402 case sizes, $C \sim 0.1$–10 µF, loop inductance ~ 0.5–2 nH, response time 10–100 ns).
4. *Bulk Decoupling (DC–100 kHz)*: Polymer tantalum or aluminum electrolytic capacitors ($C_{\text{bulk}} \sim$ 100–1000 µF, response time 1–10 µs) sustain the rail until the active VRM regulation loop stabilizes.

Parasitic inductance and parallel capacitor branches can also create **anti-resonance** impedance peaks between their resonances. A simple LC frequency scale is $f_0 = 1/(2\pi\sqrt{L_{\text{parasitic}}C})$, but the peak magnitude requires the complete network, including capacitor equivalent series resistance and inductance. Excitation near a poorly damped peak can amplify supply excursions. A target-impedance check therefore needs the measured or modeled impedance spectrum, not capacitance alone.

DRAFT

C.5.2 Digital logic gate delay and the alpha-power law

When a 0.90 V core rail sags by 60 mV during an accelerator burst, transistor drive current drops and every logic gate along a critical path switches more slowly, eating into register setup slack. In sub-micron CMOS silicon, logic gate propagation delay t_{prop} is governed by the Sakurai-Newton **alpha-power law**:[4]

$$t_{\text{prop}}(V) \propto \frac{C \cdot V}{(V - V_{\text{th}})^{\alpha}}$$

where C is the gate load capacitance, V_{th} is the transistor threshold voltage, and $\alpha \in [1.2, 1.5]$ is the velocity saturation index (contrasting with $\alpha = 2.0$ in long-channel theory).

When rail voltage droops from V_{nom} to V_{droop}, propagation delay stretches according to:

$$\frac{t_{\text{prop}}(V_{\text{droop}})}{t_{\text{prop}}(V_{\text{nom}})} = \frac{V_{\text{droop}}}{V_{\text{nom}}} \left(\frac{V_{\text{nom}} - V_{\text{th}}}{V_{\text{droop}} - V_{\text{th}}} \right)^{\alpha}$$

In a synchronous digital pipeline with clock period T_{clk}, setup time t_{setup}, and clock skew t_{skew}, timing closure requires:

$$t_{\text{prop}} + t_{\text{setup}} + t_{\text{skew}} \leq T_{\text{clk}}$$

The following illustrative calculation evaluates the delay ratio and remaining path slack with the same voltage-dependent model. A droop consumes setup margin; whether it causes a timing violation depends on the original slack, clock response, and characterized process corner.

For a drop from 0.90 V to 0.81 V, with threshold 0.35 V and exponent 1.3, delay rises by 13.5 percent to 908.3 ps. Starting with 150 ps of slack leaves 41.7 ps. These assumptions therefore do not predict a setup violation. Some processors respond to droop with active clock stretching, increasing the clock period while the rail recovers. The supported response, detection delay, and resulting execution-time stretch require device-specific characterization. Section 13.4 connects rail disturbance to the permission task's timing budget.

[4] **Sakurai-Newton Delay Modeling**: The alpha-power law models voltage-dependent gate delay; its parameters are technology dependent. The model predicts reduced setup slack during droop, while a missed deadline, register error, or reset must be established against measured path slack and device thresholds.

C.6 DRAM Contention and Interconnect Arbitration

In cloud machine learning clusters, GPUs use high-bandwidth memory (HBM) physically separated from host CPU memory. This separates some accelerator traffic from host DRAM, although accelerator clients still contend for those channels. In embedded robotics SoCs, however, system architectures rely on Unified Memory Architecture (UMA) to satisfy size, weight, and power (SWaP) constraints. Application CPU cores, neural accelerators, GPU cores, and high-rate PCIe or CSI camera DMA engines all share a single physical DRAM interface. In these shared-memory multi-core platforms, DMA transfers and vision prefetching compete directly with the permission path for memory controller command queues and physical DRAM banks.

C.6.1 DRAM bank organization and conflict latency

DRAM organizes storage into channels, ranks, **bank groups**, and banks; their counts and timing depend on the memory standard and device organization. Each individual bank possesses an independent row buffer consisting of sense amplifiers. A read that changes the open row can require the following sequence:

1. **Row precharge** (t_{RP}): Closes the active row and equalizes the bitlines for the next activation (18.75 ns per bank at LPDDR5-6400).
2. **Row activate** (t_{RCD}): Reads an entire page of storage cells (e.g., 2 KB to 8 KB) across wordlines into the bank's open row buffer (18.75 ns at LPDDR5-6400).
3. **Column access** (read latency, t_{CL}): Reads or writes data beats from the open row buffer onto the memory data bus. LPDDR5 specifies this latency in clock cycles that depend on the data rate, so a row hit pays only this step.

To sustain high data rates, modern DRAM organizes banks into bank groups. An LPDDR5 channel offers three bank organizations: 16 banks divided into 4 bank groups for the higher data rates, 16 independent banks, or 8 larger banks formed by merging pairs (Steiner et al. 2022). In bank-group

DRAFT

mode, consecutive column commands to the same bank group must wait a longer column-to-column delay $t_{\text{CCD_L}}$ than commands to different groups, which need only $t_{\text{CCD_S}}$, because banks in one group share internal data paths. An address mapping that interleaves consecutive bursts across bank groups hides the longer spacing; one that keeps a stream inside a single group exposes it.

When consecutive memory operations target different rows within the same physical bank (a **bank conflict**), the memory controller cannot immediately access the column. It must execute a precharge followed by an activate before issuing the column command, introducing a compulsory stall:

$$\Delta t_{\text{conflict}} \approx t_{\text{RP}} + t_{\text{RCD}}$$

At LPDDR5-6400 that stall is 37.5 ns. The minimum time between consecutive row activations to the same bank is also governed by the row cycle time $t_{\text{RC}} = t_{\text{RAS}} + t_{\text{RP}}$, where t_{RAS} is the minimum time a row must stay open. Repeated conflicts in one bank are therefore spaced at least t_{RC} apart.

Memory controllers select between an *open-page* or *closed-page* policy to balance row-buffer locality against thrashing. Under an open-page policy, row buffers remain active after access in anticipation of spatial locality. While this maximizes bandwidth for sequential streaming (such as dense general matrix multiplication (GEMM) weight fetching or linear camera DMA writes), sporadic random accesses (such as sensor fusion state lookups or 1 kHz safety monitor checks) frequently hit different rows in active banks. When a continuous camera DMA stream writes video frames to the same DRAM bank that holds real-time safety buffers, repeated row-buffer conflicts transform low-latency reads into multi-hundred-nanosecond stalls.[5]

[5] **DRAM Bank-Conflict Penalties**: A row change in one bank can add precharge and activate time. Video DMA can also queue transactions ahead of a safety read. The resulting delay must be bounded for the specific address mapping, arbitration policy, and workload; a fixed penalty per request is generally unjustified.

Modern DRAM controllers employ **First-Ready First-Come-First-Served (FR-FCFS)** command scheduling. FR-FCFS prioritizes column read/write requests that hit currently open row buffers over older requests that require row precharge and activation, maximizing overall DRAM bus throughput. However, under high cognitive load, a continuous flood of vision DMA requests or matrix multiplication memory bursts will repeatedly hit open rows. FR-FCFS schedulers then systematically postpone isolated, latency-critical read requests issued by real-time safety threads, potentially starving those requests unless the controller enforces age or service bounds.

C.6.2 Interconnect crossbars and burst contention

On-chip interconnect fabrics (such as ARM CoreLink AXI4 crossbars or Network-on-Chip (NoC) meshes) split high-bandwidth accelerator and camera DMA transactions into bounded bursts of up to $A_{\text{len}} = 256$ beats. In a shared crossbar without real-time prioritization, transactions enter a FIFO or weighted round-robin queue. For K competing accelerator transactions admitted ahead of a safety-critical permission request, the queuing transfer latency is:

$$t_{\text{queue,ideal}} = \frac{\sum_{k=1}^{K} D_{\text{vol}_k}}{\text{BW}_{\text{bus}}}$$

Adding physical bank-switch penalties $\sum \Delta t_{\text{conflict}}$, device-specific refresh overhead, and bus turnaround penalties increases the safety read latency. Refresh mode, temperature, address mapping, and controller policy determine the bound. To protect real-time control paths against memory contention, embedded systems implement three structural defenses:

1. *AXI Quality of Service (QoS) Priority Elevation*: The `AxQOS` field communicates a requested priority. The interconnect and memory controller must implement a documented service policy; the field alone does not guarantee preemption or bounded latency. Already issued transactions and refresh can still block a safety read.
2. *DRAM Bank Partitioning and Page Coloring*: The operating system memory allocator allocates physical memory pages such that real-time safety code and high-rate camera DMA buffers map to strictly disjoint physical DRAM banks, removing those bank conflicts when the physical address mapping is known and enforced. Shared channels, refresh, and controller queues remain.
3. *On-Chip SRAM Isolation*: Critical safety states, barrier function parameters, and active trajectory splines bypass external DRAM entirely, executing exclusively out of static on-chip SRAM or Data Tightly Coupled Memory (DTCM).

C.7 Clock Synchronization and Network Timestamps

In distributed machine learning clusters, nodes synchronize system clocks via Network Time Protocol (NTP) primarily for coarse event logging and telemetry, while parallel training algorithms synchronize execution through communication barriers (such as NCCL AllReduce). In physical AI systems, however, time directly maps to physical space: when a robot moves at 30 m/s, a 1 ms synchronization error produces 3 cm of spatial displacement, warping sensor fusion point clouds and invalidating safety clearance buffers. Distributed perception pipelines must convert sensor timestamps into a common clock domain with a measured conversion-error bound.

C.7.1 Precision time protocol message exchange

The following end-to-end delay exchange illustrates IEEE 1588 Precision Time Protocol (PTP), synchronizing a follower clock (S) to a leader clock (M). IEEE 802.1AS uses a related timing architecture with peer-delay measurement; its exchange is not identical:

1. t_1: Master transmits a *Sync* frame, recording its local transmission timestamp.
2. t_2: Slave receives the *Sync* frame, recording its local arrival timestamp.
3. t_3: Slave transmits a *Delay_Req* frame, recording its local transmission timestamp.
4. t_4: Master receives the *Delay_Req* frame, recording its local arrival timestamp.

Under the assumption of clock stability and symmetric forward and reverse propagation delay ($T_{\text{prop},M\to S} = T_{\text{prop},S\to M} = T_{\text{prop}}$), the time relationships satisfy:

$$t_2 = t_1 + \theta_{\text{offset}} + T_{\text{prop}}$$

$$t_4 = t_3 - \theta_{\text{offset}} + T_{\text{prop}}$$

where θ_{offset} is the slave-minus-master clock offset. The estimated clock offset is:

$$\theta_{\text{offset}} = \frac{(t_2 - t_1) - (t_4 - t_3)}{2}$$

The one-way network propagation delay is:

$$T_{\text{prop}} = \frac{(t_2 - t_1) + (t_4 - t_3)}{2}$$

Slave clocks adjust their local time base using a closed-loop digital **proportional-integral (PI) clock servo** filter. At synchronization step k, the measured offset $\theta_{\text{offset}}[k]$ drives frequency correction $\Delta f[k]$ applied to the hardware accumulator register:

$$\Delta f[k] = -K_p \theta_{\text{offset}}[k] - K_i \sum_{j=0}^{k} \theta_{\text{offset}}[j]$$

Here Δf is added to the follower frequency, $K_p, K_i > 0$, and the sampling interval is absorbed into K_i. A positive follower-minus-leader offset therefore slows the follower; using the opposite hardware correction convention reverses the sign.

If forward and reverse path delays are asymmetric ($\Delta t_{\text{asym}} = T_{\text{prop},M\to S} - T_{\text{prop},S\to M} \neq 0$), the calculated offset incurs an unobservable systematic bias of $\Delta t_{\text{asym}}/2$. Residual clock uncertainty ϵ_{sync}, combining asymmetric propagation, oscillator frequency drift between sync intervals, and hardware timestamp quantization, is explicitly bounded:

$$\epsilon_{\text{sync}} \leq \frac{|\Delta t_{\text{asym}}|}{2} + \Delta t_{\text{interval}} \cdot \left| \frac{\Delta f_{\text{res}}}{f_{\text{nom}}} \right| + 2T_{\text{quant}}$$

Here Δf_{res} bounds residual frequency error after servo correction, rather than the applied correction itself; T_{quant} bounds timestamp quantization. Additional timestamp-reference and servo errors must be included if they are not covered by these terms. This conversion bound is stored directly in the proposal header's `sync_error_ns` field (table C.10) and added to every evidence-age calculation in the 1 kHz permission path:

$$t_{\text{age}} = (t_{\text{current}} - t_0) + \epsilon_{\text{sync}}$$

DRAFT

C.7.2 Physical layer hardware timestamping

Software-based timestamping captures timestamps inside the OS network socket layer or interrupt service routine. It suffers from variable kernel queueing, driver interrupt latency, and thread scheduling jitter, which inject $50\,\mu s$ to 5 ms of non-deterministic timing error. To eliminate host dispatch error, physical AI hardware uses **Physical Layer (PHY) Hardware Timestamping**.[6] Dedicated timestamping units in the Ethernet PHY or media access control (MAC) controller capture hardware counter values at the exact instant the physical Start of Frame Delimiter (SFD) crosses the Media Independent Interface (MII / RGMII). This removes software dispatch from the capture point. Timestamp resolution, reference-plane calibration, and residual error remain device-specific and must be measured.

[6] **Hardware Timestamping**: A compatible PHY or MAC timestamps frames closer to the wire than a software interrupt handler. Hardware timestamping removes one source of dispatch variation, while path asymmetry and clock conversion remain. Timestamp uncertainty belongs in the physical belief record and permission budget.

C.8 Heterogeneous SoC Mailboxes, Memory Barriers, and Zero-Copy IPC

Large sensor buffers can consume substantial shared-memory bandwidth when each pipeline stage makes another copy. A copy may generate both a read and a write of the payload, depending on cache residency and the transfer path. On a heterogeneous robotics SoC, that traffic can contend with a safety processor's memory accesses. Shared buffers reduce copying, but require explicit ownership and publication ordering. Small proposal records may instead use a bounded copy into protected memory. The mechanisms below distinguish four contexts. A discrete safety microcontroller receives proposals over a board-level link. Application and safety cores on one die exchange platform-specific mailboxes. Linux processes share coherent memory. Supported GPU processes share device allocations. Their ordering and lifetime contracts are not interchangeable.

C.8.1 Board-level links into a local mailbox

The machine in this book keeps its safety microcontroller on a separate chip with its own memory (section 13.6), so no memory is shared with the application processor and nothing in this subsection depends on the host's cache or interconnect.

1. The application processor serializes the proposal into a frame that carries a sequence number, the evidence and issue timestamps, and a CRC, and sends it over a board-level link such as SPI, a UART, or CAN FD.
2. The microcontroller's link peripheral writes the incoming bytes into a receive buffer in its own SRAM by DMA. A double buffer lets the DMA fill one half while firmware reads the other.
3. The DMA-complete interrupt checks the frame's length, CRC, and sequence number, then publishes the proposal into the seqlock mailbox of algorithm C.1. The writer and the reader, the permission tick, both run on the microcontroller.
4. The permission tick makes one bounded read of that mailbox and checks age, expiry, and permission before using the payload.

The link is a black channel in the sense of the functional-safety fieldbus profiles (International Electrotechnical Commission 2021). Corruption, repetition, loss, and delay are detected end to end by the frame's CRC, sequence number, and timestamps and by the lease, so the link's hardware and drivers need not be trusted for correctness. Its timing is another matter. Serialization at the link rate, DMA completion, and receive-interrupt latency age every newly admitted proposal and must be bounded and charged to the dispatch-to-admission interval.

C.8.2 Remote processor messaging over shared SRAM

When one system-on-chip hosts both domains, the shared-die placement of section 13.2, communication between Linux application cores and a real-time safety core relies on shared SRAM mailboxes signaled via hardware doorbells:

1. Core A (Application Processor) writes a message payload to a fixed buffer in shared SRAM.
2. Core A makes the payload visible to Core B using the platform's coherent mapping or explicit cache maintenance and ordering.
3. Core A triggers an inter-processor interrupt (IPI) by writing to Core B's hardware mailbox register.

DRAFT

4. Core B checks publication order, integrity, age, and permission before using the payload.

Linux RPMsg is a virtio-based messaging framework that may use shared memory and a platform-specific kick. It provides standard transport abstraction but does not prescribe this fixed-buffer protocol or a universal latency bound. It applies only to this shared-die case; a discrete microcontroller shares no memory to message through.

C.8.3 CPU pipeline reordering and memory fences

In weakly ordered memory architectures (such as ARMv8-A and ARMv9-A), processors do not guarantee that memory writes will be observed by other cores in program order. Out-of-order execution engines and asynchronous write buffers can reorder stores to non-dependent addresses:

```
// Core A (Application Processor); q_target and q_cmd are joint_target_t structs
shared_buffer->q_target = q_cmd; // Store 1: Payload (struct copy)
mailbox_doorbell = 1;            // Store 2: Interrupt trigger
```

If the CPU reorders Store 2 ahead of Store 1, Core B receives the interrupt before the new joint target is committed to physical memory. The consumer then reads stale or partially written struct fields across the mailbox boundary.

To enforce deterministic ordering across heterogeneous cores, developers must insert architectural **hardware memory barriers**:

```
shared_buffer->q_target = q_cmd; // Struct copy of the joint targets
__asm__ volatile("dmb oshst" ::: "memory"); // Outer-shareable store barrier
mailbox_doorbell = 1;            // Assert doorbell register
```

In ARM architectures, memory barriers and instructions are distinguished by scope and execution semantics:

- `DMB` (Data Memory Barrier): Ensures that memory accesses specified before the barrier appear in memory before memory accesses specified after the barrier. It does not block execution of non-memory instructions.
- `DSB` (Data Synchronization Barrier): Waits for completion of the memory accesses and maintenance operations covered by its type and scope before subsequent instructions execute.
- `ISB` (Instruction Synchronization Barrier): Flushes the CPU instruction prefetch pipeline, ensuring subsequent instructions are fetched anew from cache or memory.

Barriers operate across explicit architectural **shareability domains**:

- `DMB ISHST` (Inner Shareable Store): Orders stores across cores within the local application CPU cluster sharing a coherent L2/L3 cache.
- `DMB OSHST` / `DMB OSH` (Outer Shareable): Orders accesses in the configured outer-shareable domain; membership depends on the SoC, and ordering does not create coherence.
- `DMB SY` (System): Enforces ordering across all system masters and peripherals on the SoC.

Cache maintenance is necessary when the communicating agents do not share a coherent mapping. The producer cleans dirty payload lines, completes the required maintenance, and orders publication. The consumer invalidates stale lines before reading under the platform contract. A supported non-cacheable mapping can avoid those cache operations, but does not make barriers single-cycle or remove interconnect contention. Device memory has different access restrictions from Normal memory and is not an interchangeable choice for arbitrary structure copies. Alignment must match the actual cache-line size. Section 4.3.2 and section 13.2 connect these mechanisms to the proposal boundary.[7]

C.8.4 POSIX shared memory and lock-free SPSC ring buffers

Within user-space Linux runtimes, independent operating system processes (such as a vision preprocessing daemon, a multimodal VLA policy inference server, and a high-rate state estimator) exchange telemetry and sensor streams. They avoid kernel socket copies by using **POSIX Shared Memory** (`shm_open` and `mmap`):

7 | **Hardware Memory Barriers**: Barriers order accesses only within their specified shareability and memory-attribute contract. On a noncoherent route, cache clean/invalidate operations or coherent mappings are also required. Arm's memory-ordering guide distinguishes ordering from coherence.

1. A producer process creates a POSIX shared memory object using `shm_open("/robot_telemetry", O_CREAT | O_RDWR, 0660)` located in the RAM-backed `tmpfs` filesystem (`/dev/shm`), bypassing physical storage media entirely.
2. Sizing the segment via `ftruncate(fd, sizeof(telemetry_ring_buffer_t))` establishes its length; physical backing is generally allocated when pages are faulted in.
3. Both producer and consumer processes map the memory into their respective virtual address spaces via `mmap(NULL, sizeof(...), PROT_READ | PROT_WRITE, MAP_SHARED, fd, 0)`.
4. Each process prefaults and successfully locks its mapping with `mlock()` before cyclic execution. This prevents swapping of those pages; mapping changes and copy-on-write behavior still need explicit control.
5. *Position-Independent Memory Layout*: Because Address Space Layout Randomization (ASLR) and independent virtual memory spaces cause `mmap()` to return different base virtual addresses in each process, data structures placed in shared memory must never store absolute virtual pointers (`void*` or raw references). All references within shared buffers must be position-independent, structured as relative byte offsets, flat fixed-size arrays, or integer indices.

When streaming sequential sensor frames or trajectory waypoints across processes, mutual-exclusion mutexes introduce non-deterministic blocking and priority inversion. A **lock-free single-producer single-consumer (SPSC) ring buffer** coordinates one producer and one consumer using acquire-release atomic indices. The following C++ sketch assumes lock-free atomics, bounded nonthrowing copies of `T`, and coherent memory. Cross-process use additionally requires a platform-supported shared atomic representation and one-time construction before either process accesses it:

```
#include <atomic>
#include <cstdint>
#include <cstddef>
#include <new>

template <typename T, size_t Capacity>
class LockFreeSpscRingBuffer {
    static_assert(Capacity > 0 && (Capacity & (Capacity - 1)) == 0,
                  "Capacity must be a nonzero power of two");
    static_assert(std::atomic<uint64_t>::is_always_lock_free,
                  "Index atomics must be lock-free on this target");

private:
    // Align head and tail to distinct 64-byte cache lines to eliminate false sharing
    alignas(64) std::atomic<uint64_t> write_index_{0};
    alignas(64) std::atomic<uint64_t> read_index_{0};
    alignas(64) T storage_[Capacity];

public:
    bool Push(const T& item) {
        const uint64_t current_write = write_index_.load(std::memory_order_relaxed);
        const uint64_t current_read = read_index_.load(std::memory_order_acquire);

        if (current_write - current_read >= Capacity) {
            return false; // Buffer full: non-blocking drop or backpressure
        }

        // Fast bitwise masking replacing expensive modulo division
        storage_[current_write & (Capacity - 1)] = item;

        // Release order ensures item stores are committed before advancing pointer
        write_index_.store(current_write + 1, std::memory_order_release);
        return true;
    }

    bool Pop(T& item) {
        const uint64_t current_read = read_index_.load(std::memory_order_relaxed);
        const uint64_t current_write = write_index_.load(std::memory_order_acquire);
```

```
        if (current_read == current_write) {
            return false; // Buffer empty
        }

        item = storage_[current_read & (Capacity - 1)];

        // Release order publishes free slot back to producer
        read_index_.store(current_read + 1, std::memory_order_release);
        return true;
    }
};
```

Separating the indices onto different cache lines avoids false sharing between the two independently written counters on a target with the assumed line size. Each side still reads the other's counter, and payload ownership still moves between cores, so coherence traffic remains. Power-of-two capacity permits masking for wraparound. Neither alignment nor this indexing choice establishes a cycle-time bound without target measurements.

C.8.5 Multi-rate synchronization: Double-buffering versus triple-buffering

In cyber-physical machines, producer and consumer tasks rarely execute at the same frequency. A multimodal vision-language-action policy may produce candidate trajectory chunks at 20 Hz (50 ms period) with variable inference jitter ($\pm$15 ms). The downstream safety permission filter and motor tracking loop, by contrast, execute strictly at 1 kHz (1 ms period). Double-buffering separates a buffer being written from one being read, but it also needs an ownership protocol. If the producer finishes while the consumer still owns the old front buffer, the producer must wait, drop an update, or acquire another buffer. Rate mismatch alone does not make double-buffering incorrect. Allowing a writer to reuse a reader-owned buffer does.

Triple-buffering provides a private producer buffer, a private consumer buffer, and an intermediate buffer holding the latest completed update. Publication atomically exchanges the producer buffer with the intermediate buffer. At a tick boundary, the consumer may exchange its private buffer with the intermediate buffer, then read its new private buffer without concurrent writes. The exchanged state must include the new-data flag so that publication and ownership remain one atomic operation.

This is a latest-value channel: intermediate updates may be overwritten before the consumer acquires them. A queue is needed when every update must be retained. A compare-and-swap retry loop is lock-free only under its progress assumptions and is not automatically wait-free. The implementation must establish ordering, buffer lifetime, and a bounded reader attempt on the target. A failed attempt leaves the current record subject to its existing evidence and expiry checks.

C.8.6 CUDA inter-process communication for multi-accelerator pipelines

On high-throughput robotics platforms (such as autonomous mobile robots equipped with multiple GMSL2 camera clusters and lidar arrays), raw perception data streams into accelerator GPU memory for tensor processing. In modular physical AI software architectures, perception preprocessing (e.g., optical flow, spatial unprojection, and feature extraction) and foundation policy inference often execute in separate Linux processes for fault containment. Passing multi-gigabyte tensor buffers between processes via host system RAM consumes tens of gigabytes per second of shared DRAM bandwidth, precipitating memory bus contention.

To eliminate host DRAM staging entirely, **CUDA Inter-Process Communication (CUDA IPC)** enables direct peer-to-peer GPU memory access across distinct Linux process address spaces:

```
// Process A (Perception Producer): Export GPU device memory handle
float *d_camera_tensor;
cudaMalloc((void **)&d_camera_tensor, TENSOR_BYTES);

// Allocate and capture an opaque 64-byte IPC memory handle
cudaIpcMemHandle_t ipc_mem_handle;
cudaIpcGetMemHandle(&ipc_mem_handle, (void *)d_camera_tensor);
```

```
// Send the 64-byte handle to Process B via POSIX shm or UNIX domain socket
send_ipc_handle_to_consumer(&ipc_mem_handle);
```

In Process B (Policy Consumer), the exported handle is mapped directly into its local GPU virtual address space without copying:

```
// Process B (Policy Consumer): Map exported GPU memory directly
cudaIpcMemHandle_t received_handle;
receive_ipc_handle_from_producer(&received_handle);

float *d_mapped_tensor;
cudaIpcOpenMemHandle((void **)&d_mapped_tensor, received_handle,
                     cudaIpcMemLazyEnablePeerAccess);

// Wait on this publication's imported completion event before reading.
// Launch inference kernel directly referencing Process A's physical GPU memory
launch_vla_encoder_kernel<<<grid, block, 0, compute_stream>>>(d_mapped_tensor);

// At shutdown, finish outstanding work before releasing the mapping.
cudaStreamSynchronize(compute_stream);
cudaIpcCloseMemHandle((void *)d_mapped_tensor);
```

CUDA IPC requires compatible devices, drivers, and operating-system support. An imported allocation must remain alive until every importer finishes and closes its mapping. Publication requires explicit synchronization, not just handle transfer. CUDA IPC relies on strict memory allocation invariants: exported memory must be allocated as device memory via `cudaMalloc()` within the GPU's physical device memory. Managed memory (`cudaMallocManaged`) and host pinned memory are explicitly unsupported by the CUDA IPC subsystem. On supported same-host multi-accelerator topologies, an imported allocation may be accessed through peer-to-peer links. CUDA IPC is not a transport between arbitrary independent SoCs. Rather than copying tensor buffers through host DRAM, the GPU hardware memory management unit (MMU) routes memory transactions directly across high-speed interconnect links. This eliminates host CPU DRAM double-buffering and saves tens of gigabytes per second of shared bus bandwidth.

To synchronize GPU execution across processes without round-tripping to host CPU threads, CUDA IPC exports **cross-process CUDA event** synchronization primitives via `cudaIpcGetEventHandle()` and `cudaIpcOpenEventHandle()`. Process A creates an interprocess event with timing disabled, records it after producing the buffer, and publishes the corresponding completion generation. The consumer must wait on that generation before using the data, and the producer must not reuse the buffer before the consumer finishes. Process B imports the event handle and enqueues a hardware barrier on its local stream:

$$\text{cudaStreamWaitEvent}(\text{consumer_stream}, \text{imported_event}, 0)$$

Once the host has enqueued the dependency, later consumer-stream work waits for the recorded producer event without a host polling loop. Setup and submission still involve the CPU, and latency remains platform dependent. The CUDA IPC documentation specifies supported allocation and event types.

C.9 Actuator Electrical and Thermal Dynamics

In reinforcement learning and simulation environments (such as MuJoCo or Isaac Gym), policy actions are typically abstracted as instantaneous torque or position commands applied at discrete simulation steps. In physical systems, however, actuators convert electrical energy into mechanical work through electromagnetic Lorentz forces, subject to coupled electrical, thermal, and kinematic constraints.

C.9.1 Stator electrical rise time

A brushless permanent-magnet synchronous motor (PMSM / BLDC) phase winding has phase resistance R_{phase} and phase inductance L_{phase}. Applying terminal voltage V_{terminal} against back-electromotive force $e_{\text{bemf}} = K_e\omega_m$ yields the first-order stator current ODE:

$$L_{\text{phase}}\frac{di_{\text{phase}}(t)}{dt} + R_{\text{phase}}\, i_{\text{phase}}(t) = V_{\text{terminal}} - K_e\omega_m$$

In three-phase synchronous machines under Field-Oriented Control (FOC), the stator currents are transformed from the three-phase abc frame into the orthogonal rotor synchronous dq reference frame via the Clarke and Park transformations:

$$v_d = R_{\text{phase}} i_d + L_d\frac{di_d}{dt} - \omega_e L_q i_q$$

$$v_q = R_{\text{phase}} i_q + L_q\frac{di_q}{dt} + \omega_e L_d i_d + \omega_e \lambda_{\text{pm}}$$

The d axis rotates with the rotor magnet flux, and the q axis lies perpendicular to it. This separates flux and torque-producing current. Here $\omega_e = N_{\text{poles}}\omega_m$ is electrical angular velocity (N_{poles} pole pairs), λ_{pm} is the rotor permanent-magnet flux linkage, and L_d, L_q are direct and quadrature axis inductances. Under standard constant torque-angle control ($i_d = 0$), electromagnetic torque is directly proportional to quadrature current:

$$\tau_{\text{motor}} = \frac{3}{2}N_{\text{poles}}\,\lambda_{\text{pm}} i_q = K_t i_q$$

For a commanded voltage step with the rotor held at rest ($\omega_m = 0$) and zero initial current, quadrature current rises exponentially:

$$i_q(t) = \frac{V_{\text{terminal}}}{R_{\text{phase}}}\left(1 - e^{-t/\tau_e}\right), \quad \tau_e = \frac{L_q}{R_{\text{phase}}}$$

where τ_e is the electrical time constant. Current, and therefore delivered torque, reaches approximately 63 percent of its steady-state value after one time constant τ_e (section 2.4.2 computes it for the running machine's hub motors from their datasheet inductance and resistance). An unprivileged neural policy step command cannot produce an instantaneous step in physical torque.

Furthermore, achievable current is constrained by inverter voltage saturation:

$$\sqrt{v_d^2 + v_q^2} \le \frac{V_{\text{bus}}}{\sqrt{3}}$$

As rotor speed ω_m rises, back-EMF $\omega_e\lambda_{\text{pm}}$ increases, consuming available quadrature voltage v_q. At the actuator's base speed, voltage headroom vanishes, and torque collapses unless negative direct-axis current ($i_d < 0$, flux weakening) is commanded to oppose part of the magnet flux linkage, within current and magnet-demagnetization limits.

C.9.2 Lumped thermal networks and stator Joule heating

Current flowing through stator windings dissipates resistive Joule heat:

$$P_{\text{loss}}(t) = \frac{3}{2} i_q^2(t) R_{\text{phase}}(T_{\text{winding}})$$

where copper electrical resistance increases linearly with temperature:

$$R_{\text{phase}}(T_{\text{winding}}) = R_0\left[1 + \alpha_{\text{Cu}}(T_{\text{winding}} - T_0)\right]$$

with temperature coefficient $\alpha_{\text{Cu}} \approx 0.00393\ \text{K}^{-1}$ for copper. At an operating temperature of 150°C, stator copper resistance is approximately 50 percent higher than at room temperature (25°C). To sustain the same commanded torque $\tau_{\text{motor}} = K_t i_q$, the motor requires identical current i_q but generates 50 percent more thermal dissipation. This creates positive feedback between winding temperature and Joule heating that accelerates thermal degradation.

In a physical motor, **multi-node lumped thermal networks** span multiple physical interfaces with disparate thermal masses:

DRAFT

1. *Stator Winding Copper*: Low thermal capacitance C_{cu}, rapid heating from Joule dissipation ($\tau_{\text{th,cu}} \sim 10$–$30$ s).
2. *Stator Iron Laminations*: Moderate thermal capacitance C_{iron}, absorbing iron eddy-current and hysteresis losses P_{iron} and heat conducted across winding insulation $R_{\text{th,cu-iron}}$. The iron losses depend on flux, frequency, and material.
3. *Motor Frame and Aluminum Housing*: Large thermal capacitance C_{case}, conducting heat into the robotic link structure and convecting to ambient air through $R_{\text{th,case-amb}}$ ($\tau_{\text{th,case}} \sim 10$–$30$ min).

The temperature dynamics across these nodes satisfy the coupled differential system:

$$C_{\text{cu}} \frac{dT_{\text{winding}}}{dt} = P_{\text{loss}}(t) - \frac{T_{\text{winding}} - T_{\text{iron}}}{R_{\text{th,cu-iron}}}$$

$$C_{\text{iron}} \frac{dT_{\text{iron}}}{dt} = \frac{T_{\text{winding}} - T_{\text{iron}}}{R_{\text{th,cu-iron}}} + P_{\text{iron}} - \frac{T_{\text{iron}} - T_{\text{case}}}{R_{\text{th,iron-case}}}$$

$$C_{\text{case}} \frac{dT_{\text{case}}}{dt} = \frac{T_{\text{iron}} - T_{\text{case}}}{R_{\text{th,iron-case}}} - \frac{T_{\text{case}} - T_{\text{amb}}}{R_{\text{th,case-amb}}}$$

For initial temperature at ambient, a simplified single-node lumped thermal model uses effective thermal resistance to ambient R_{th} (in K/W) and thermal heat capacity C_{th} (in J/K). The temperature rise $\Delta T(t) = T_{\text{winding}}(t) - T_{\text{amb}}$ satisfies:[8]

$$C_{\text{th}} \frac{d\Delta T(t)}{dt} = P_{\text{loss}}(t) - \frac{\Delta T(t)}{R_{\text{th}}}$$

[8] **Stator Thermal Time Constants**: Resistive Joule heating elevates motor phase winding temperatures during continuous high-torque maneuvers. Because copper electrical resistivity increases linearly with temperature, hot windings have higher resistance, reducing torque output under terminal voltage saturation. Exceeding winding insulation temperature limits breaks down dielectric coatings, causing inter-turn short circuits and permanent winding damage.

Under constant power, temperature rises with thermal time constant $\tau_{\text{th}} = R_{\text{th}} C_{\text{th}}$:

$$\Delta T(t) = P_{\text{loss}} R_{\text{th}} \left(1 - e^{-t/\tau_{\text{th}}}\right)$$

Continuous torque capacity τ_{cont} is bounded by the maximum allowable winding temperature rise $\Delta T_{\max}$:

$$\tau_{\text{cont}} \leq K_t \sqrt{\frac{2\Delta T_{\max}}{3 R_{\text{th}} R_{\text{phase}}}}$$

The factor $2/3$ follows from the three-phase loss convention above; use the winding resistance at the limiting temperature. Other motor and inverter losses reduce the available thermal margin.

Transient torque peaks $\tau_{\text{peak}} \approx 2$–$4 \times \tau_{\text{cont}}$ are permitted during aggressive dynamic maneuvers only if an active digital ${I_{\text{phase}}}^2 t$ thermal protection observer running on the safety microcontroller bounds the thermal integral:

$$\Delta T[k+1] = \Delta T[k] e^{-\Delta t/\tau_{\text{th}}} + R_{\text{th}} P_{\text{loss}}[k] \left(1 - e^{-\Delta t/\tau_{\text{th}}}\right)$$

The thermal class is an insulation service rating, not a sharp instantaneous breakdown temperature. Current derating must begin with margin below the winding and rotor limits, accounting for model error, initial temperature, and response time.

C.9.3 Reflected rotor inertia and angular jerk limits

Geared electromagnetic actuators amplify delivered motor torque while multiplying rotor inertia at the joint output. For a transmission with gear reduction ratio $N_{\text{gear}} = \omega_m / \dot{q}$, kinetic energy conservation dictates the reflected inertia acting at the output link:

$$E_k = \frac{1}{2} J_{\text{rotor}} \omega_m^2 + \frac{1}{2} J_{\text{load}} \dot{q}^2 = \frac{1}{2} (J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}) \dot{q}^2$$

The effective rotational inertia seen at joint coordinate q is:

$$J_{\text{eff}} = J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}$$

DRAFT

The joint equation of motion under motor electromagnetic torque τ_{motor} is:

$$\ddot{q} = \frac{N_{\text{gear}}\tau_{\text{motor}} - \tau_{\text{ext}}}{J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}}$$

Differentiating $\ddot{q}$ with respect to gear ratio N_{gear} at zero external load yields:

$$\frac{\partial \ddot{q}}{\partial N_{\text{gear}}} = \frac{\tau_{\text{motor}}(J_{\text{load}} - N_{\text{gear}}^2 J_{\text{rotor}})}{(J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}})^2}$$

Setting $\frac{\partial \ddot{q}}{\partial N_{\text{gear}}} = 0$ yields the **inertia-matching ratio** $N^* = \sqrt{J_{\text{load}}/J_{\text{rotor}}}$. When $N_{\text{gear}} > N^*$, counter-intuitively, increasing the gear ratio decreases delivered joint acceleration because the motor spends the majority of its torque accelerating its own rotor rather than the link.

C.9.3.1 Dynamic angular jerk and torque slew limits

For constant effective inertia and constant external torque, angular jerk $j_{\text{joint}}(t) = \dddot{q}(t)$ measures the time rate of change of joint acceleration:

$$j_{\text{joint}}(t) = \frac{N_{\text{gear}}}{J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}} \frac{d\tau_{\text{motor}}(t)}{dt}$$

Electromagnetic torque relates to stator quadrature current via torque constant K_t: $\tau_{\text{motor}} = K_t i_q$. From the stator electrical dynamics in this section, current slew rate is bounded by winding inductance L_{phase}:

$$\frac{d\tau_{\text{motor}}}{dt} = K_t \frac{di_q}{dt} = \frac{K_t}{L_{\text{phase}}} \left(V_{\text{terminal}} - K_e \omega_m - R_{\text{phase}} i_q\right)$$

For a signed voltage constrained by $|V_{\text{terminal}}| \leq V_{\text{max}}$, a conservative magnitude bound in this scalar winding model is:

$$|j_{\text{joint}}| \leq \frac{N_{\text{gear}} K_t (V_{\text{max}} + |K_e \omega_m + R_{\text{phase}} i_q|)}{L_{\text{phase}}(J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}})}$$

Positive and negative current slew have different available voltage headroom. A tighter directional bound retains the signs in the preceding current equation. Changing external torque, coupled joint motion, and inverter limits require additional terms.

When a tracker requests a step torque discontinuity $\Delta\tau$ across discrete timesteps, the commanded derivative $\frac{d\tau}{dt} \to \infty$ cannot be delivered instantaneously by physical silicon. The inverter enters hard voltage saturation, causing steep current slew (dI/dt), intense thermal stress on power MOSFETs, and shock loads across gear-tooth contact flanks ($\sigma_b \propto W_t/(bmY)$). Synchronous pre-actuation invariant filters evaluate numerical torque derivatives $(\tau[k] - \tau[k-1])/\Delta t$ to ensure requested actions remain within allowable jerk envelopes before latching power stages.

C.10 DC Bus Power Distribution and Energy Absorption

In data center machine learning clusters, electrical power is managed by high-capacity facility uninterruptible power supplies (UPS) and dedicated substation transformers. On mobile autonomous platforms, computational accelerators and mechanical actuators draw from a shared, finite DC power distribution network. A robotic platform's electrical power distribution network must supply acceleration surges and absorb regenerative braking energy across finite bus capacitance and harness impedance.

C.10.1 Inductive droop and capacitive decoupling

When multiple high-torque actuators accelerate simultaneously (such as a humanoid jumping or an articulated arm bracing against an unexpected payload), total load current steps by $\Delta I_{\text{load}} = \sum_{k=1}^{N_{\text{axes}}} \Delta I_k$ with steep current slew rates $dI_{\text{load}}/dt \sim 10^5$–$10^6$ A/s. The electrical wiring harness connecting the main battery to distributed joint inverters possesses parasitic loop inductance L_{bus}

DRAFT

(typically 1–5 µH for a 1-meter harness) and harness resistance R_{bus}. These parasitics impede source current delivery, producing instantaneous inductive rail droop at the actuator inverter terminals:

$$V_{\text{source}}(t) - V_{\text{bus}}(t) = R_{\text{bus}} I_{\text{source}}(t) + L_{\text{bus}} \frac{dI_{\text{source}}}{dt}$$

The capacitor is connected across this same bus node; its voltage change is not another independent series drop. For an ideal capacitor, $\Delta V_C(t) = V_{\text{bus}}(0) - V_{\text{bus}}(t)$. Local inverter bus capacitance C_{bus} must supply the instantaneous charge deficit between load demand and battery source current:

$$\Delta V_C(t) = \frac{1}{C_{\text{bus}}} \int_0^t \left(I_{\text{load}}(s) - I_{\text{source}}(s)\right) ds$$

If the DC bus terminal voltage drops below the drive's configured **Under-Voltage Lockout (UVLO)** threshold V_{UVLO} (e.g., 18 V on a 24 V nominal bus, or 36 V on a 48 V bus), the gate driver IC enters UVLO fault protection. It disables gate bias within microseconds to prevent power MOSFETs from operating in their linear resistive region. The resulting loss of commanded torque can let a gravity-loaded joint descend. Current decay and the holding-brake response determine the plant motion.

If the current deficit starts at ΔI_{step} and decreases linearly to zero over Δt_{step}, integrating that triangular deficit gives:

$$C_{\text{bus}} \geq \frac{\Delta I_{\text{step}} \cdot \Delta t_{\text{step}}}{2\Delta V_{\text{droop, max}}}$$

A constant deficit over the same interval removes the factor of two in the denominator. The source dynamics and capacitor ESR must also satisfy the terminal-voltage limit. Local capacitor banks combine low-ESR multi-layer ceramic capacitors (MLCCs) for high-frequency ripple filtering (20–100 kHz inverter switching) with bulk electrolytic or polymer capacitors for transient step energy buffering. The bank must also carry the RMS ripple current of the actual switching waveform. Equivalent-series-resistance losses scale with that current squared.

C.10.2 Regenerative braking surges and chopper sizing

During controlled regenerative deceleration or emergency stopping, mechanical kinetic energy $E_k = \frac{1}{2}mv^2$ (linear platform motion) or $E_k = \frac{1}{2}J_{\text{eff}}\dot{q}^2$ (articulated joint rotation) is converted back into electrical energy by the motor acting as a generator. Current flows back through the inverter bridge into the DC bus via active synchronous rectification or freewheeling body diodes.

If the battery cannot accept this regenerative current (for example, when the battery pack reaches its chemistry-specific charge limit, when battery internal resistance rises at freezing temperatures, or when safety contactors open to isolate the pack), the returned electrical energy $\eta_{\text{regen}} E_k$ is forced into the local bus capacitor C_{bus}. The resulting terminal voltage surge follows the ideal capacitor relationship:

$$\Delta E_C = \frac{1}{2} C_{\text{bus}} \left(V_{\text{final}}^2 - V_{\text{initial}}^2\right) = \eta_{\text{regen}} E_k$$

$$V_{\text{final}} = \sqrt{V_{\text{initial}}^2 + \frac{2\eta_{\text{regen}} E_k}{C_{\text{bus}}}}$$

An overvoltage protection trip and semiconductor breakdown are different thresholds. Exceeding the configured trip requests the assessed protective response; exceeding device voltage ratings can cause avalanche stress or damage. Disabling gate commands does not by itself absorb returned energy.

To prevent overvoltage destruction, motor drives incorporate an active **dynamic brake chopper**. When DC bus voltage crosses a hardware clamp threshold $V_{\text{clamp,on}}$, a high-power semiconductor switch (MOSFET or IGBT) modulates an auxiliary low-inductance braking resistor R_{brake} with hysteresis:[9]

$$R_{\text{brake}} \leq \frac{V_{\text{clamp}}^2}{P_{\text{regen, peak}}}$$

[9] **Dynamic Braking Choppers**: A qualified chopper can dissipate returned energy when the battery is unavailable as a sink. Its threshold, switch and resistor ratings, pulse duration, and thermal recovery must be tested. Regeneration and chopper operation are not inherent to every emergency stop; safe torque off can instead leave a motor coasting.

DRAFT

$$P_{\text{regen, peak}} \approx \eta_{\text{regen}} \cdot \tau_{\text{brake}} \cdot \omega_{\max}$$

The chopper comparator switches the resistor on when $V_{\text{bus}} \geq V_{\text{clamp,on}}$ and turns off when $V_{\text{bus}} \leq V_{\text{clamp,off}}$, preventing rapid oscillation. In addition to peak power sizing, the braking resistor must be rated for single-pulse adiabatic energy absorption:

$$E_{\text{pulse}} \geq \eta_{\text{regen}} E_k$$

with a thermal cooldown time constant that prevents cumulative thermal failure during repeated stop-and-go duty cycles.

C.11 Real-Time Fieldbuses and Lock-Free Synchronization

In distributed machine learning clusters, networks are built on high-bandwidth fabrics (such as 100/400 Gbps RoCEv2 or InfiniBand) optimized for aggregate data-parallel throughput via credit-based flow control. In physical AI systems, however, the onboard communication fabric must simultaneously multiplex two diametrically opposed traffic classes:

1. *High-bandwidth best-effort perception streams*: Multi-gigabit video from high-resolution GMSL2/GigE Vision cameras (2–8 Gbps) and 3D lidar point clouds (100–1000 Mbps) streaming into the AI accelerator's unified memory for foundation model inference.
2. *Hard real-time periodic control traffic*: Deterministic 1 kHz joint setpoint commands and high-resolution torque/position feedback (100–500 kbps) exchanged with distributed motor inverters.

If these two traffic classes share a naive best-effort Ethernet fabric with first-in, first-out (FIFO) queueing, multi-megabyte perception bursts cause severe queue congestion and buffer bloat. A burst of video frames can delay a motor control packet by 5–20 ms, violating the 1 ms control deadline, starving the inverter current loop, and tripping hardware emergency stops. Coordinating distributed drives while ingesting perception streams requires an architectural separation of fabrics, deterministic bus schedules, and bounded lock-free publication protocols.

C.11.1 Fieldbus serialization and schedulability

On shared physical buses, N_{axes} actuator drives transmit telemetry and receive setpoints cyclically. To prevent perception traffic from corrupting motor timing, physical AI architectures use dedicated deterministic fieldbuses (CAN 2.0B, CAN FD, or EtherCAT) or time-scheduled switched Ethernet (IEEE TSN).

Classical **Controller Area Network (CAN 2.0B, ISO 11898-1)** uses differential signaling over a shielded twisted pair ($V_{\text{CANH}} - V_{\text{CANL}} \approx 2.0$ V for dominant logic 0, and 0 V for recessive logic 1):

- *Arbitration Mechanics*: Nodes access the physical medium using non-destructive bitwise arbitration. When two nodes transmit simultaneously, a dominant bit overrides a recessive bit. A node transmitting a recessive bit that samples a dominant bit on the physical bus immediately ceases transmission and yields the bus to the higher-priority frame without message corruption.
- *Framing and Payload Constraints*: Standard CAN 2.0B frames support either an 11-bit standard or 29-bit extended identifier, with payload length strictly capped at $B_{\text{payload}} \leq 8$ bytes via a 4-bit Data Length Code (DLC).
- *Bit-Stuffing and Latency*: Classical CAN inserts an opposite bit after a run of five identical bits in the stuffed region. Serialization time includes the identifier format, payload, CRC, stuffing, and interframe spacing. Let $B_{\text{wire},i}$ be that complete bit count for frame i; then $C_i = B_{\text{wire},i}/R_{\text{bit}}$. Extended identifiers consume more bits than standard identifiers.
- *The Scalability Bottleneck*: The necessary load condition is $\sum_i C_i/T_i \leq 1$, but meeting deadlines also requires priority and blocking analysis. There is no universal utilization threshold at which CAN queueing diverges. Axis capacity depends on command and feedback packing, periods, identifiers, and tolerated retransmissions; one frame per axis is a workload assumption.

DRAFT

Controller Area Network with Flexible Data-Rate (**CAN FD**, ISO 11898-1:2015) overcomes the payload and bandwidth limits of classical CAN through dual bit-rate switching and payload expansion up to 64 bytes:

- *Arbitration Phase*: Transmitted at the nominal bit rate R_{nom} (typically 500 kbps or 1 Mbps). The bit time $T_{\text{bit,nom}} = 1/R_{\text{nom}}$ must accommodate physical cable propagation delays across the robot chassis and transceiver delays ($2t_{\text{prop}} + t_{\text{transceiver}}$), allowing non-destructive bitwise priority arbitration. Nodes drive the bus using dominant or recessive states. If two nodes transmit simultaneously, the lower numerical message identifier (higher logical priority) overwrites recessive bits, winning the bus without collision or frame destruction.
- *Data Phase*: Once arbitration is established, the winning node asserts the Bit Rate Switch (BRS) bit, accelerating transmission to the data bit rate R_{data} (typically 2–8 Mbps). The data phase no longer needs round-trip arbitration within each bit. Signal integrity, receiver sampling, and transceiver delay compensation still constrain its rate.
- *Bit-Stuffing Overhead*: Dynamic stuff bits are inserted after 5 consecutive identical bits in arbitration, while the CRC field incorporates fixed stuff bits with an explicit stuff count. In the worst-case bit pattern, bit stuffing can inflate frame transmission duration by up to 20 percent.

The serialization duration for frame i is:

$$t_{\text{frame},i} \approx \frac{B_{\text{arb},i}}{R_{\text{nom}}} + \frac{B_{\text{data},i}}{R_{\text{data}}} + t_{\text{stuff},i} + t_{\text{interframe},i}$$

where $B_{\text{arb},i}$ is the arbitration field length (identifier, control bits), $B_{\text{data},i}$ is the payload and CRC length, $t_{\text{stuff},i}$ accounts for stuff bits, and $t_{\text{interframe},i}$ is the minimum 3-bit inter-frame spacing.

In a **CAN FD response-time budget**, a higher-priority release cannot preempt a frame already transmitting. For a simplified error-free fixed-priority message set with no prior instance of frame i pending, the following conservative recurrence charges higher-priority interference across the whole response window:

$$R_i = C_i + B_i + \sum_{j \in hp(i)} \left\lceil \frac{R_i + J_j + T_{\text{bit}}}{T_j} \right\rceil C_j$$

Here $C_i = t_{\text{frame},i}$, J_j is higher-priority release jitter, and T_{bit} accounts for arbitration at the boundary. Iterate from $C_i + B_i$ to convergence or a deadline overrun. Add the message's own release jitter if its deadline starts before it becomes ready. The lower-priority blocking term is:

$$B_i = \max_{k \in lp(i)} C_k$$

Set $B_i = 0$ when no lower-priority frame exists. This simplified test is not an exact general CAN schedulability test: queued prior instances, controller transmit-buffer behavior, errors, and retransmissions require a matching busy-period analysis. A long CAN FD payload improves packing efficiency but can also increase the non-preemptive blocking seen by a short urgent command.

For high-axis-count systems (such as humanoids with 30 to 50 degrees of freedom), **EtherCAT** (ETG.1000) achieves deterministic 1 kHz to 10 kHz cycle times over standard 100BASE-TX full-duplex Ethernet ($R_{\text{link}} = 100$ Mbps). Rather than transmitting individual frames per axis, EtherCAT structures communication as an active logical ring:

1. The real-time master (executing on the safety microcontroller or `PREEMPT_RT` Linux host) transmits a single standard Ethernet frame (EtherType `0x88A4`) traversing all slave drives in a physical daisy chain.
2. Each drive integrates an EtherCAT Slave Controller (ESC) application-specific integrated circuit (ASIC) (such as Beckhoff ET1100 or field-programmable gate array (FPGA) IP). As the frame's bits pass through the ESC's physical shift registers, the ESC **processes data on the fly**:
    - It reads commanded setpoints (joint target position, velocity, and feedforward torque) directly from its allocated byte offset in the datagram.

DRAFT

- It writes actual measured feedback (encoder position, phase current, and drive status flags) into the moving frame.

3. Each slave contributes a forwarding delay that depends on its controller and ports; the frame returns from the final slave along the return path. The example below assigns an illustrative delay per slave.

The cycle must accommodate the following round-trip budget for S slave drives, with B_{frame} measured in bits and each delay bounded for the topology:

$$T_{\text{cycle}} \geq \frac{B_{\text{frame}}}{R_{\text{link}}} + t_{\text{master}} + \sum_{s=1}^{S} t_{\text{slave},s} + t_{\text{prop}} + t_{\text{guard}}$$

For 30 axes, the assumed command and feedback sizes give 600 bytes of process data. An illustrative 750 bytes frame takes 60 µs to serialize at 100 Mb/s. Charging 1 µs per slave adds 30 µs, so the subtotal is already 90 µs. Master processing, propagation, omitted wire overhead, and guard time must still fit the cycle. This partial sum is not a measured round-trip bound. EtherCAT distributed clocks align local device timers through measured offsets and propagation compensation. The qualified synchronization error and arrival deadline determine when a drive may use the frame. Clock synchronization does not remove frame transit time.

C.11.2 Time-sensitive networking and scheduled ethernet gates

While EtherCAT processes frames on the fly through specialized slave controllers, modern multi-camera and lidar robotic systems require multi-gigabit Ethernet fabrics that transport high-bandwidth vision data alongside hard real-time actuator commands. IEEE **Time-Sensitive Networking (TSN)** provides deterministic Ethernet via standards that bound queuing jitter and reserve transmission windows:

The **IEEE 802.1Qbv Time-Aware Shaper (TAS)** coordinates traffic transmission using hardware-controlled transmission gates associated with each priority egress queue (traffic classes 0 to 7). A cyclic **Gate Control List (GCL)**, synchronized across all network bridges via IEEE 802.1AS (generalized Precision Time Protocol), switches gates open or closed at precise physical time epochs. By reserving dedicated time windows exclusively for high-priority Scheduled Traffic (ST), TAS eliminates queuing interference from lower-priority Best-Effort (BE) traffic.

Standard Ethernet frames are non-preemptive: once a transmission begins, it cannot be interrupted on physical copper or optical links. If a lower-priority best-effort packet begins transmission immediately before an ST time slice opens, the scheduled frame experiences transmission blocking of up to the maximum frame duration. To prevent this, TAS enforces a **guard band** before each scheduled traffic window:

$$t_{\text{guard}} \geq \frac{B_{\text{BE,wire}}}{R_{\text{link}}}$$

Here $B_{\text{BE,wire}}$ is the maximum non-preemptible wire occupancy in bits, including the applicable framing overhead. A payload MTU in bytes cannot be divided directly by a bit rate. The configured guard must also cover clock error and implementation timing uncertainty. During it, a best-effort frame may start only if it can finish before the reserved window.

IEEE 802.1Qbu and IEEE 802.3br frame preemption reduce blocking by interrupting eligible traffic at permitted fragment boundaries. The remaining bound includes the maximum non-preemptible fragment and its overhead, not merely a nominal minimum fragment size. Both the link partners and the schedule must support the mechanism. Preemption saves reserved idle time at the cost of fragmentation overhead and additional configuration obligations.

The four primary real-time communication protocols differ in framing, arbitration, clock synchronization, and axis-count scaling (table C.7).

DRAFT

Table C.7: Comprehensive Architectural Synthesis of Real-Time Fieldbus Protocols: Comparison of CAN 2.0B, CAN FD, EtherCAT, and IEEE TSN across physical layer, framing, arbitration, jitter, and multi-axis control capacity.

Attribute / Metric	CAN 2.0B (ISO 11898-1)	CAN FD (ISO 11898-1:2015)	EtherCAT (ETG.1000)	IEEE TSN (802.1Qbv / 802.1Qbu)
Physical Layer	Differential twisted pair	Differential twisted pair	100BASE-TX full-duplex Ethernet	1000BASE-T / 10GBASE-T switched Eth
Physical Topology	Linear multidrop bus	Linear multidrop bus	Daisy-chain / logical ring	Switched star / tree / mesh
Raw Line Bit Rate	1 Mbps max	1 Mbps arb / 2–8 Mbps data	100 Mbps full-duplex	1–10 Gbps full-duplex
Maximum Payload (MTU)	8 bytes	64 bytes	Up to 1486 bytes per datagram	1500 bytes (9000 B jumbo)
Arbitration Mechanism	Bitwise non-destructive priority	Bitwise non-destructive with bit-rate switch	Hardware on-the-fly ESC processing	Time-Aware Shaper (GCL) + frame preemption
Delay qualification	Frame priorities, load, blocking, errors	Nominal/data rates, packing, blocking, errors	Frame size, topology, slave and master delays	Gate schedule, path, clock error, preemption
Hardware Clock Sync	No network clock service in CAN framing	No network clock service in CAN FD framing	Distributed Clocks; qualified residual error	IEEE 802.1AS; qualified residual error
Axis-count scaling	Per-axis frame count and period	Payload packing and response deadlines	Process-data bytes and number of slaves	Reserved traffic windows and link capacity
Primary Robotic Domain	Auxiliary sensors, low-rate IO	Quadruped leg clusters, gripper drives	Multi-axis humanoids, surgical arms	Sensor fusion ingress + safety backbone

For either CAN variant, sum every command and feedback frame in the required cycle, then account for competing traffic, non-preemptive blocking, and the declared error model. EtherCAT avoids a separate frame for each axis, but its process-data size and forwarding delay still grow with the topology. TSN reserves service along a path. An end-to-end bound must include each hop's schedule, serialization, forwarding, and synchronization uncertainty. These distinct budgets, rather than a protocol name or a universal axis count, support the selection in section 4.5.

C.11.3 Lock-free seqlocks for multi-rate shared memory

When a producer updates multiword state read by a deadline-bound enforcer, waiting on a producer-held mutex can violate the reader's deadline. The single-slot mailbox in algorithm C.1 uses a **sequence counter**, which marks a single writer's publication in progress with an odd value and a completed publication with an even value:

1. **Writer Protocol**:
   - Publish an odd sequence value, write the payload, and make it visible through the platform's coherent or cache-maintained memory contract.
   - Publish the next even value with release ordering.
2. **Reader Protocol**:
   - Read S_1 with acquire ordering. If it is odd, reject this publication without waiting.
   - Make one bounded copy to scratch memory using the platform's required load ordering, then read S_2.
   - Stage the candidate only if $S_1 = S_2$ and both are even, and the copied frame passes integrity, timestamp, and requested-expiry checks. Full admission remains separate. Retain the active command only while its own state, evidence, lease, and stopping margin permit; otherwise enter the state-matched fallback.

The algorithm is platform pseudocode, not portable C++ with a non-atomic payload: racing ordinary C++ loads and stores would be undefined behavior even if the sequence check later rejects

DRAFT

the copy. The platform must define safe concurrent copying, cache maintenance, aligned counter atomicity, and wraparound behavior. On the machine's discrete microcontroller, the writer is the link-receive interrupt and the reader is the permission tick on the same core, so the counter protocol needs only compiler ordering between them. A data memory barrier matters where a DMA engine or a second master writes the same memory. Arm M-profile cores provide that barrier only as the full-system `DMB` (ARM Limited 2012), so the `OrderingFence` steps below stand for whatever the target requires rather than an A-profile shareability option. The reader's one-attempt execution time can be bounded on the target hardware; success probability depends on the writer's schedule and cannot be inferred from payload size alone. Conventional Linux seqlock readers may retry, as the kernel documentation shows, but a real-time permission gate cannot use an unbounded retry loop.

Algorithm C.1 Single-Slot Trajectory Seqlock Baseline

Require: proposal P (proposal header with sequence_id, t_evidence_ns, sync_error_ns, t_expire_ns; waypoints $\mathbf{w}_{1..H}$; crc32), scratch buffer B_{scratch} in static SRAM reserved for this staging attempt, mailbox $(c_{\text{seq}}, \text{Slot}_{\text{shared}})$ in the microcontroller's own SRAM, written by the link-receive interrupt after the frame's CRC and sequence checks and read by the permission tick, current time t_{now} and evidence-age budget $t_{\text{age,max}}$ (the configured upper-age ceiling for candidate staging), both on the safety microcontroller's clock

Ensure: candidate snapshot in B_{scratch} or rejection; the active spline remains unchanged

function PUBLISHRECEIVEDCHUNK(P) ▷ *runs in the link-receive interrupt*
  $c_{\text{curr}} \leftarrow \text{AtomicLoadExplicit}(c_{\text{seq}}, \text{memory_order_relaxed})$
  $\text{AtomicStoreExplicit}(c_{\text{seq}}, c_{\text{curr}} + 1, \text{memory_order_relaxed})$ ▷ *mark odd: write in progress*
  $\text{OrderingFence}()$ ▷ *odd counter ordered before payload stores*
  $\text{CopyMemory}(\text{Slot}_{\text{shared}}.\text{payload}, P, \text{sizeof}(P))$ ▷ *copy multi-word trajectory*
  $\text{OrderingFence}()$ ▷ *payload stores ordered before even counter*
  $\text{AtomicStoreExplicit}(c_{\text{seq}}, c_{\text{curr}} + 2, \text{memory_order_release})$ ▷ *mark even: publish committed*
end function
function STAGELATESTACTIONCHUNK($B_{\text{scratch}}, t_{\text{now}}$)
  $c_{\text{start}} \leftarrow \text{AtomicLoadExplicit}(c_{\text{seq}}, \text{memory_order_acquire})$ ▷ *load initial counter*
  if c_{start} is odd **then**
    return STATUS_WRITER_ACTIVE ▷ *writer active; retain prior spline*
  end if
  $\text{OrderingFence}()$ ▷ *prevent payload reads hoisting before counter*
  $\text{CopyMemory}(B_{\text{scratch}}, \text{Slot}_{\text{shared}}.\text{payload}, \text{sizeof}(\text{Payload}))$ ▷ *tentative copy; active spline unchanged*
  $\text{OrderingFence}()$ ▷ *payload reads complete before c_{end}*
  $c_{\text{end}} \leftarrow \text{AtomicLoadExplicit}(c_{\text{seq}}, \text{memory_order_acquire})$ ▷ *re-read sequence counter*

    return STATUS_TORN_READ ▷ *concurrent write detected*
  end if
  if $\text{ComputeCrc32}(B_{\text{scratch}}.\text{bytes_before_crc}) \neq B_{\text{scratch}}.\text{crc32}$ **then**
    return STATUS_CHECKSUM_INVALID
  end if
  if $t_{\text{now}} \geq B_{\text{scratch}}.\text{t_expire_ns}$ **then**
    return STATUS_REQUEST_EXPIRED ▷ *requested expiry is absolute*
  end if
  if $t_{\text{now}} - B_{\text{scratch}}.\text{t_evidence_ns} + B_{\text{scratch}}.\text{sync_error_ns} > t_{\text{age,max}}$ **then**
    return STATUS_EVIDENCE_STALE ▷ *conversion error is added to every age*
  end if
  return STATUS_CANDIDATE_STAGED ▷ *full admission must finish before activation*
end function

The proposal header and chunk payload of section 4.4.1 cross the proposal boundary through this mailbox (section 4.3). Section C.15.1 gives their byte layout. A successful read yields a candidate in

DRAFT

owned staging memory. Admission separately checks producer sequence and lineage, the complete trajectory and stop, and the current seam state before activation (section 11.8). Scheduling that work must preserve the permission tick; the scratch slot cannot be reused while admission still reads it. At activation the MCU rereads its clock, rechecks evidence and deadlines, and records the successful admission time. A mailbox read neither renews the active lease nor resets the evidence epoch.

C.12 Camera Projective Geometry and Covariance Propagation

In computer vision for machine learning, neural models typically process normalized pixel tensors to predict 2D bounding boxes or semantic segmentation masks. In physical AI systems, however, visual observations must be grounded as physical objects in continuous Euclidean 3D metric space to evaluate spatial clearance buffers D_{clear} and enforce collision-avoidance invariants. Perception pipelines map continuous Euclidean 3D scenes onto discrete 2D camera photosite grids, and unproject pixel detections back into metric space under quantified measurement uncertainty.

C.12.1 Intrinsic projection matrix and radial distortion

Under the standard pinhole camera model, a 3D point $\mathbf{p}_c = [X_c, Y_c, Z_c]^\top$ in camera coordinates projects onto pixel coordinates $[u, v]^\top$ via the intrinsic calibration matrix $\mathbf{K}$:[10]

$$\tilde{\mathbf{m}} = \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \frac{1}{Z_c}\mathbf{K}\mathbf{p}_c = \frac{1}{Z_c}\begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} X_c \\ Y_c \\ Z_c \end{bmatrix}$$

where (f_x, f_y) are focal lengths in pixel units and (c_x, c_y) is the principal point. Non-linear radial lens distortion is modeled by distortion coefficients (k_1, k_2):

$$r^2 = x_n^2 + y_n^2, \quad x_d = x_n(1 + k_1 r^2 + k_2 r^4), \quad y_d = y_n(1 + k_1 r^2 + k_2 r^4)$$

where $(x_n, y_n) = (X_c/Z_c, Y_c/Z_c)$ are normalized image coordinates.

[10] **Pinhole Intrinsic Projection**: The pinhole model projects 3D points onto a 2D sensor through calibrated intrinsics. Under fixed pixel noise, the lateral variance after depth unprojection grows with squared distance; depth-error and calibration terms follow their own models. Uncalibrated intrinsics can bias a clearance estimate and must be included in its error envelope.

C.12.2 Metric unprojection and spatial covariance propagation

When unprojecting a 2D pixel observation $[u, v]^\top$ with measured depth Z_c into 3D camera coordinates, photosite measurement noise $\Sigma_{\text{meas}} = \text{diag}(\sigma_u^2, \sigma_v^2, \sigma_z^2)$ propagates through the unprojection Jacobian $\mathbf{J}_{\text{unproj}}$:

$$\mathbf{p}_c = \begin{bmatrix} (u - c_x)Z_c/f_x \\ (v - c_y)Z_c/f_y \\ Z_c \end{bmatrix}, \quad \mathbf{J}_{\text{unproj}} = \frac{\partial \mathbf{p}_c}{\partial [u, v, Z_c]} = \begin{bmatrix} \frac{Z_c}{f_x} & 0 & \frac{u - c_x}{f_x} \\ 0 & \frac{Z_c}{f_y} & \frac{v - c_y}{f_y} \\ 0 & 0 & 1 \end{bmatrix}$$

The propagated camera-frame spatial covariance is:

$$\Sigma_c = \mathbf{J}_{\text{unproj}} \Sigma_{\text{meas}} \mathbf{J}_{\text{unproj}}^\top$$

Evaluating the diagonal terms shows that lateral positional variance along the camera X-axis scales with the square of depth:

$$\sigma_{x_c}^2 \approx \left(\frac{Z_c}{f_x}\right)^2 \sigma_u^2 + \left(\frac{u - c_x}{f_x}\right)^2 \sigma_z^2$$

For fixed pixel noise, the first variance contribution scales with Z_c^2, so its standard deviation grows linearly with distance. The depth-error contribution follows the depth sensor's own model. Transforming this 3D point into the robot body frame via rigid extrinsic transform $\mathbf{T}_{bc} = [\mathbf{R}_{bc}, \mathbf{p}_{bc}; \mathbf{0}^\top, 1]$ yields the spatial body covariance:

$$\Sigma_{\text{body}} = \mathbf{R}_{bc} \Sigma_c \mathbf{R}_{bc}^\top + \Sigma_{\text{ext}}$$

DRAFT

where Σ_{ext} models independent extrinsic uncertainty under this first-order approximation; correlations require the corresponding cross terms. A probabilistic clearance buffer may scale with $\sqrt{\lambda_{\max}(\Sigma_{\text{body}})}$ at a declared tail risk. A deterministic permission check instead needs a justified bounded-error envelope; covariance alone does not give a worst-case bound.

C.12.3 Zhang's planar homography and camera calibration

Zhang's calibration technique computes the camera intrinsic matrix $\mathbf{K}$ by observing a planar calibration rig (such as a checkerboard pattern) across $N \geq 3$ distinct orientations (Zhang 2000). Without loss of generality, assume the model plane lies on $Z = 0$ in world coordinates. A 3D model point $\mathbf{M} = [X, Y, 0, 1]^\top$ maps to a 2D image point $\tilde{\mathbf{m}} = [u, v, 1]^\top$ through a 3×3 planar homography matrix $\mathbf{H}$:

$$s \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \mathbf{K} \begin{bmatrix} \mathbf{r}_1 & \mathbf{r}_2 & \mathbf{r}_3 & \mathbf{t} \end{bmatrix} \begin{bmatrix} X \\ Y \\ 0 \\ 1 \end{bmatrix} = \mathbf{K} \begin{bmatrix} \mathbf{r}_1 & \mathbf{r}_2 & \mathbf{t} \end{bmatrix} \begin{bmatrix} X \\ Y \\ 1 \end{bmatrix} = \mathbf{H} \begin{bmatrix} X \\ Y \\ 1 \end{bmatrix}$$

where $\mathbf{H} = [\mathbf{h}_1\ \mathbf{h}_2\ \mathbf{h}_3] = \lambda \mathbf{K} [\mathbf{r}_1\ \mathbf{r}_2\ \mathbf{t}]$ with arbitrary nonzero scalar λ.

C.12.3.1 Orthogonality constraints on the absolute conic

Because the rotation vectors $\mathbf{r}_1$ and $\mathbf{r}_2$ are orthonormal columns of an $SO(3)$ matrix ($\mathbf{r}_1^\top \mathbf{r}_2 = 0$ and $\|\mathbf{r}_1\| = \|\mathbf{r}_2\| = 1$), inverting $\mathbf{K}$ yields:

$$\mathbf{r}_1 = \frac{1}{\lambda} \mathbf{K}^{-1} \mathbf{h}_1, \quad \mathbf{r}_2 = \frac{1}{\lambda} \mathbf{K}^{-1} \mathbf{h}_2$$

Imposing orthonormality on $\mathbf{r}_1$ and $\mathbf{r}_2$ defines two algebraic constraints per homography:

$$\mathbf{h}_1^\top \mathbf{K}^{-\top} \mathbf{K}^{-1} \mathbf{h}_2 = 0$$

$$\mathbf{h}_1^\top \mathbf{K}^{-\top} \mathbf{K}^{-1} \mathbf{h}_1 - \mathbf{h}_2^\top \mathbf{K}^{-\top} \mathbf{K}^{-1} \mathbf{h}_2 = 0$$

The symmetric matrix $\mathbf{B} = \mathbf{K}^{-\top} \mathbf{K}^{-1}$ represents the image of the absolute conic (IAC):

$$\mathbf{B} = \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ B_{12} & B_{22} & B_{23} \\ B_{13} & B_{23} & B_{33} \end{bmatrix}$$

Defining the 6-vector $\mathbf{b} = [B_{11}, B_{12}, B_{22}, B_{13}, B_{23}, B_{33}]^\top$, each quadratic term $\mathbf{h}_i^\top \mathbf{B} \mathbf{h}_j$ can be rewritten as the linear inner product $\mathbf{v}_{ij}^\top \mathbf{b}$, where:

$$\mathbf{v}_{ij} = \begin{bmatrix} h_{i1} h_{j1} \\ h_{i1} h_{j2} + h_{i2} h_{j1} \\ h_{i2} h_{j2} \\ h_{i3} h_{j1} + h_{i1} h_{j3} \\ h_{i3} h_{j2} + h_{i2} h_{j3} \\ h_{i3} h_{j3} \end{bmatrix}$$

The two constraints per observed orientation become the linear system:

$$\begin{bmatrix} \mathbf{v}_{12}^\top \\ (\mathbf{v}_{11} - \mathbf{v}_{22})^\top \end{bmatrix} \mathbf{b} = \mathbf{0}$$

DRAFT

Stacking $N \geq 3$ images forms the homogeneous system $\mathbf{Vb} = \mathbf{0}$, where $\mathbf{V} \in \mathbb{R}^{2N \times 6}$. The right singular vector of $\mathbf{V}$ corresponding to the smallest singular value provides $\mathbf{b}$ up to a scale factor. The intrinsic parameters (f_x, f_y, c_x, c_y) and skew γ are then extracted, after fixing the scale and sign, via a positive-definite factorization of $\mathbf{B}$. Degenerate views or measurement noise can make that factorization invalid. Distinct orientations alone do not guarantee a well-conditioned calibration. This closed-form linear solution initializes the non-linear Levenberg–Marquardt optimization minimizing reprojection residuals over all observed fiducial corners.

C.13 Kinematic Stopping Envelopes and Information Age Lag

In distributed systems, pipeline latency represents elapsed waiting time or queuing delay. In physical AI, end-to-end software latency converts directly into irreversible physical displacement, uninspected "blind travel," during which an embodied machine traverses space with undiminished momentum before actuators can begin retarding motion. Halting an embodied machine transporting mass m at velocity v requires balancing sensorimotor information freshness, neural compute budgets, and fieldbus dispatch against physical mechanical braking deceleration.

C.13.1 Sensorimotor information age and lag distance

For a stop triggered by a specified hazard detector and stop path, let τ_{delay} bound the time from the physical state represented by the evidence until validated braking deceleration begins (section B.6.5 gives the lease-expiry form, which charges the lease interval in place of recognition and compute):

$$\tau_{\text{delay}} = t_{\text{age}} + t_{\text{detect}} + T_{\text{compute}} + T_{\text{bus}} + T_{\text{act}}$$

The five intervals partition the pre-brake timeline without overlap:

- t_{age} is the upper evidence age at a declared decision-start epoch, including capture/readout, completed processing and transport, and clock-conversion uncertainty.
- t_{detect} bounds any remaining recognition or expiry-detection interval after that epoch; work already included in evidence age is not charged twice.
- T_{compute} bounds subsequent stop-decision work and any still-required input transfer.
- T_{bus} bounds command dispatch and network queuing.
- T_{act} ends when the measured actuator begins delivering the specified deceleration, not when a command register is written.

The intervals must be disjoint and ordered along the actual stop path. Clearance and motion must share a declared epoch: if the clearance is already propagated to current time, do not subtract historical travel a second time. Under the explicit simplifying assumption that speed cannot increase before brake onset, the blind travel is bounded by $d_{\text{blind}} = v\,\tau_{\text{delay}}$. If propulsion or a slope can increase speed, use its validated acceleration bound in this interval instead.

C.13.2 Braking dynamics and friction limits

Tire-floor friction and actuator torque place upper limits on achievable deceleration. The bound $a \leq \mu g$ does not establish what braking the machine will deliver. Let $a_{\text{brake}} > 0$ be a validated lower bound on *achieved* deceleration throughout the stop, for the declared load, temperature, slope, brake condition, and surface. A justified friction floor μ_{min} may support that bound, but does not replace brake tests. With constant or stronger braking after onset, a localization bound δ_{loc}, a fixed protective clearance δ_{margin}, and a tracking-error bound ϵ_{track},

$$d_{\text{stop}}(v) = v\,\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}}.$$

Motion is admitted only when $d_{\text{stop}}(v) \leq D_{\text{clear}}$, where D_{clear} is taken as a validated lower bound on available path clearance. This is a constant-deceleration reference model. The smooth stop in section 12.3 ramps acceleration from and back to zero, so it does not satisfy a strictly positive deceleration floor throughout braking. For that profile, replace $v^2/(2a_{\text{brake}})$ with the integral of its validated speed trajectory and use its full duration. The sampled controller must reserve intersample travel and a state-matched stop before the viable region is lost.

C.13.3 Kinetic energy derating and friction collapse

In an ideal friction-limited model, lowering μ from μ_{nom} to a positive μ_{fault} changes the braking-distance ratio to $\mu_{\text{nom}}/\mu_{\text{fault}}$. That ratio is illustrative; actual deceleration can also be limited by brake hardware or control. If surface friction is not sensed in time, derive a_{brake} from a controlled surface condition and inspection schedule, exclude degraded surfaces, or withhold motion. For the constant-speed pre-brake model above, solving the clearance inequality gives

$$v_{\text{clamp}} = -a_{\text{brake}}\tau_{\text{delay}} + \sqrt{(a_{\text{brake}}\tau_{\text{delay}})^2 + 2a_{\text{brake}}\left(D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - \epsilon_{\text{track}}\right)}.$$

This clamp is valid only when D_{clear} exceeds the three fixed allowances, the braking lower bound and timing upper bounds hold, and the speed bound is enforced before entering the hazard corridor. No positive clamp follows if the available deceleration floor is unknown or zero.

C.14 Machine Data Sheet and Record Register

Every calculation on the running machine draws its inputs from one registry entry, the warehouse mobile manipulator at its aisle site. This section collects those inputs in one place, so a chapter can cite a value by name rather than restate it. It also collects the records the chapters produce. The machine card of section 1.4.2 prints the parameters used most often; the data sheet below lists them all.

C.14.1 The machine data sheet

Each running-machine input carries its evidence category in the reader guide's vocabulary (table C.8). A derived value inherits the weakest category among its inputs, so most derived rows remain illustrative evidence even though they are computed exactly. A row marked *needs source* names the measurement that would supply it; until that measurement exists, any claim that depends on the row is open, as the tip-over check on the credible deceleration is. The safety laser scanner carries the certified stop for a person at the rack end, while the perception LiDAR feeds only the permission path's unrated admission checks above it. The safety scanner's rows describe a representative certified unit, not a qualified selection, and the stopping budgets in this book are the permission path's, not the scanner's. A certified protective field is sized with the scanner's own response time under ISO 13855 (International Organization for Standardization 2024a).

Table C.8: The running machine's data sheet: Every input the chapters take from the warehouse mobile manipulator and its aisle site, grouped by subsystem, with its evidence category and the MLSysIM field that holds it (`RM` is the machine, `AISLE` the site scenario). Values print from the registry when the book is built.

Quantity	Value	Category	MLSysIM field	Note
Body: base, arm, and drivetrain				
Base mass	300 kg	Illustrative	`RM.base.mass`	Class-profile value, gross
Arm mass	18 kg	Datasheet	`RM.arm.mass`	Panda-class arm
Tote-rack payload capacity	50 kg	Chosen	`RM.onboard_payload_-capacity`	
Loaded mass m	368 kg	Derived	`RM.loaded_mass`	Upper bound: base, arm, full tote rack
Footprint width	1 m	Illustrative	`RM.footprint_width`	
Drive limit v_{max}	1.5 m/s	Illustrative	`RM.base.max_velocity`	Class-profile value
Credible deceleration a_{brake}	2 m/s²	Illustrative	`AISLE.a_brake`	Loaded, dry floor; checked against traction and drive torque
Friction a_{brake} needs, all weight on driven wheels	0.204	Derived	`calc_required_-friction(AISLE.a_-brake)`	
Largest driven-wheel load share φ	0.815	Derived	`RM.drive_wheel_load_-share_max`	Hub motors' load rating over loaded mass

Quantity	Value	Category	MLSysIM field	Note
Friction a_{brake} needs at that share	0.250	Derived	`calc_required_friction(AISLE.a_brake, RM.drive_wheel_load_share_max)`	
Measured driven-wheel load share	needs source	Measured	`RM.drive_wheel_load_share`	*needs source*: corner-scale weighing of the loaded machine
Loaded center-of-gravity height h_{cg}	needs source	Measured	`RM.cg_height`	*needs source*: tilt-table or corner-scale measurement; tip-over unchecked
Center of gravity to leading support, arm stowed	needs source	Measured	`RM.tip_arm_stowed`	*needs source*: measured with the center-of-gravity height
Stop jerk bound $j_{\max}$	7.11 m/s^3	Derived	`calc_c2_stop_suffix(v_max, a_brake)['peak_jerk']`	Stipulated: the reference polynomial stop's peak jerk
Drive wheel radius	133 mm	Datasheet	`RM.drive_unit.wheel_radius`	Hub motor
Driven wheels	2	Chosen	`RM.drive_wheel_count`	
Hub-motor torque constant K_t	2.4 N·m/A	Derived	`RM.drive_unit.torque_constant`	Datasheet peak torque over peak current
Drive current limit	25 A	Chosen	`RM.drive_current_limit`	Set at the motor's datasheet peak
Hub-motor rated current	8.5 A	Datasheet	`RM.drive_unit.rated_current`	
Hub-motor load rating per pair	300 kg	Datasheet	`RM.drive_unit.load_rating_per_pair`	
Hub-motor rotor inertia	needs source	Datasheet	`RM.drive_unit.rotor_inertia`	*needs source*: not published; motor mass bounds J_{rotor}/r^2
Arm repeatable peak joint torque	87 N·m	Datasheet	`RM.arm.max_torque`	
Arm free-space TCP speed limit	1 m/s	Chosen	`RM.tcp_speed_limit`	
Servo axes on the fieldbus	9	Chosen	`RM.servo_axes`	Seven arm joints and two drive wheels
Body: drive bus and permission rail				
Drive bus, full charge	54 V	Datasheet	`RM.drive_bus_full_charge`	48 V-class pack
Drive bus, nominal	47.7 V	Datasheet	`RM.drive_bus_nominal`	
Drive bus, depleted	42 V	Datasheet	`RM.drive_bus_battery_low`	
Drive-bus source resistance R_{bus}	60 mΩ	Illustrative	`RM.drive_bus_resistance`	Needs a measured cell, BMS, fuse, and harness value
Converter input lockout	33 V	Datasheet	`RM.drive_bus_uvlo`	48-to-24 V converter feeding the application processor
Converter continuous input maximum	67.2 V	Datasheet	`RM.drive_bus_converter_max`	
Converter efficiency	0.91	Datasheet	`RM.drive_bus_converter_efficiency`	
Brake-chopper clamp	60 V	Chosen	`RM.drive_bus_clamp`	
Inverter switch rating	100 V	Chosen	`RM.drive_bus_switch_rating`	
Coincident inference and drive current step	70 A	Illustrative	`AISLE.i_rail_transient`	
Permission-rail hold-up	2 s	Chosen	`RM.permission_rail_holdup`

C.14.2 The record register

A **record** is a machine-checkable statement of an assumption together with its evidence, its producer, its consumers, and the conditions that invalidate it. Sixteen records form the **record chain** of figure 1.9, one from each chapter of Parts I to IV except chapter 3, whose proposer limits enter the handoff record, and one from chapter 18. Table C.9 gives each record one name. Two names shorten after first mention and in figure art, the provenance record and the belief record. Names in the last column are retired; where one survives in figure art, it names the same record. The wire formats in section C.15 lay out the records that cross a mailbox or are signed offline.

Table C.9: The record register: The sixteen records of the record chain, the chapter that produces each, and what each binds. Each record is a claim with conditions; none is a license to operate.

No.	Record	Produced in	What it binds	Retired names
1	Limit record	chapter 2	A limit's value or distribution, operating conditions, measurement uncertainty, margin, runtime detector, and provenance with its evidence category	Body limit record
2	Handoff record	chapter 4	The chunk lease, permission tick, clock domains, observation-age budget, and the handoffs between proposer and permission path, with the coupled stopping budget	Transport budget, handoff contract
3	Provenance record	chapter 5	Collection conditions, calibration revisions, plant identity, the scenario table the data covers, and the conditions it does not cover as known absences	Provenance Record (as a proper name)
4	Policy manifest	chapter 6	Architecture, weight digests, stored precision, training-regime sequence, declared operating domain, inference contract, and omission log	Training manifest

DRAFT

No.	Record	Produced in	What it binds	Retired names
5	Evaluation record	chapter 7	The target operating domain, trial population and protocol, finite-sample bound, coverage-gap catalog, and runtime monitor specifications	Evaluation Summary
6	Observation contract	chapter 8	Each observation's capture epoch, clock identifier, conversion bound to the permission clock, frame and calibration revision, covariance, and health flags	Perception Evidence record
7	Belief record	chapter 9	A represented quantity with its frame, evidence and estimate epochs, error-growth bound, validity region, expiry, query-work allocation, provenance, and lifecycle state	Scene Memory State record, spatial belief contract
8	Intent lease	chapter 10	A grounded target, affordance frame, tolerance, effort ceilings, and an expiry at the earliest of the evidence, administrative, and stopping deadlines; it grants a target, never a path	Intent Specification
9	Trajectory record	chapter 11	Frame, evidence time, initial reference state, the deadlines for start, nominal end, commit, and stop end, the matched stop suffix, and the parent intent lease's expiry	Trajectory Plan record, trajectory contract
10	Enforcement record	chapter 12	The enforcement contract (thresholds, barrier coefficients, loop period, fallback routing, validity region), the admitted command issued each tick, and the audit log of decisions	Admitted Command record (as the chain record), execution token
11	Placement record	chapter 13	Execution domain, privilege, period, unloaded and loaded response maxima, interconnect and supply settings, and the digest of the loaded test	Deployment Envelope
12	Authority record	chapter 14	The authority manifest (which actor may command which channel, and when) and the per-tick authority log of who held authority and what was proposed, admitted, and delivered	Intervention Event record, intervention record, forensic authority record
13	Fault record	chapter 15	For each fault trial, the claim, envelope point, injected fault, precommitted oracle, verdict, and retained trace; release receives the fault records with their coverage deficits	Verification Matrix, fault-record set
14	Release manifest	chapter 16	The claim root, argument digest, image hashes, calibration references, upstream record digests, verdict, standing conditions, expiry, and signature	Safety case dossier
15	Approval record	chapter 17	For each decision behind an admitted action, its owner and approval; each human role and whether a person can perform it; the permission stage and reporting duties; per-group exposure and detection; records about people; and the labor the deployment moves	(none)
16	Residual-claims register	chapter 18	For each open premise, the missing observable, the hazard it permits, the operating restriction, its owner, and the closure test	Claims register (unqualified)

The chain has two strands. Records 1 through 5 state what the plant can do and what the proposer has shown it can do; records 6 through 9 carry what the proposer proposes now. They meet in the enforcement record. The placement record then tests whether the permission path keeps its deadline on the chosen silicon, and records 12 through 16 carry the result into governance.

C.15 Wire Formats for the Record Chain

A mailbox decoder needs a bounded amount of work and an unambiguous representation. The layouts below specify byte offsets, field lengths, and validation rules across the proposal boundary between application processors and the independent enforcer. Fixed headers and bounded arrays make resource requirements explicit. The chosen serialization framework alone does not determine allocation or timing behavior.

1. *Zero Dynamic Allocation Invariant*: Deserialization must never invoke dynamic memory managers (`malloc`, `free`, C++ `new`, `delete`). Dynamic heap allocators manage internal free-list bins,

DRAFT

take global allocator mutexes, and suffer from heap fragmentation. Under memory pressure, heap operations can invoke the `brk()` or `mmap()` system calls, triggering kernel memory compaction or page faults that stall execution for tens of milliseconds. In hard real-time control, all record slots, mailbox staging areas, scratch buffers, and circular telemetry logs must be statically sized at compile time and preallocated in dedicated static SRAM or Data Tightly Coupled Memory (DTCM) pools.

2. *Bounded Parse and Validation Work*: Header fields have fixed offsets; arrays have validated counts and configured maxima. Reading one scalar is constant-time, but copying, hashing, and validating a complete record scale with its bounded length. Full trajectory admission remains interruptible and separate from the per-tick check.
3. *Natural Alignment Across Heterogeneous ABIs*: On heterogeneous SoCs combining 64-bit application processors (ARM Cortex-A or x86_64) and 32-bit real-time microcontrollers (ARM Cortex-R52 or Cortex-M7), data types must be naturally aligned. A scalar of size k bytes must reside at an offset satisfying:

$$\text{offset} \equiv 0 \pmod{k}$$

Specifically, 64-bit timestamps and integers (`uint64_t`, `float64`) align on 8-byte boundaries ($k = 8$), 32-bit values (`uint32_t`, `float32`) align on 4-byte boundaries ($k = 4$), and 16-bit integers (`uint16_t`) align on 2-byte boundaries ($k = 2$). Explicit padding bytes between narrower fields maintain these alignment invariants across both 32-bit and 64-bit compilers.

An alignment violation has direct microarchitectural consequences: a core may trap an unsupported unaligned access or split it into multiple bus operations. The result depends on instruction width, memory attributes, and processor configuration. A safety integrity classification does not itself specify those semantics. Explicit reserved bytes, scalar encodings, endianness, and schema versions define the wire representation. A native C structure is not that representation by default. Use checked offsets or explicit serialization and verify layout on each ABI. Alignment alone also does not guarantee atomicity of a wide access on a narrower core.

Not every record in table C.9 needs a byte layout. The layouts below cover the proposal header that every proposal carries and the records that cross a mailbox or are signed offline. Runtime proposals and evidence use bounded records where they cross mailboxes or fieldbuses, while limits, evaluation, enforcement configuration, placement evidence, and release artifacts are retained under canonical encodings and linked by digest. All records use standard little-endian byte ordering for multi-byte scalars (`uint64_t`, `uint32_t`, `uint16_t`, `float32`, `float64`). Lineage is established by embedding parent SHA-256 digests. Runtime corruption is caught via IEEE 802.3 CRC-32 checksums over headers and payloads. Operator authority is authenticated via AES-128 CMAC tags and Ed25519 digital signatures. The authority log is chained with HMAC-SHA-256. Offline records (placement, fault, release, approval) are identified by the SHA-256 digest of their canonical encoding, and the record that consumes one stores that digest under the consumed record's name.

C.15.1 Proposal header and chunk payload

Every proposal that crosses the proposal boundary opens with the same header, and `payload_kind` selects the payload that follows at `0x50`. Table C.10 lays out the header with the minimal chunk payload of section 4.4.1. The chunk carries kinematic setpoints only. Torque is computed on the permission side, where the tracker derives it from the admitted reference, so a learned proposal never names a motor torque.

Table C.10: Proposal header and chunk payload: Field offsets, scalar types, units, and invariants for a chunk proposal exchanged through the seqlock mailbox of algorithm C.1. The header occupies `0x00`–`0x4F` in every proposal; the other payload layouts in this section begin at `0x50`.

Offset	Field	Scalar type	Unit	Invariant and check
`0x00`	`sequence_id`	`uint64_t`	dimensionless	Strictly increasing per producer; a record not newer than the last accepted one is rejected.

DRAFT

Offset	Field	Scalar type	Unit	Invariant and check
0x08	t_evidence_ns	uint64_t	ns, permission clock	Capture epoch of the oldest evidence the proposal rests on, converted to the safety microcontroller's clock.
0x10	t_issue_ns	uint64_t	ns, permission clock	Time the producer published the record.
0x18	t_expire_ns	uint64_t	ns, permission clock	Requested absolute expiry; admission caps it by the successful admission time plus the configured lease and by earlier evidence, parent, and stop deadlines.
0x20	frame_id	uint64_t	dimensionless	Transform-tree key and calibration revision of the setpoints' frame.
0x28	parent_digest	uint8_t[32]	SHA-256	Digest of the record this proposal was derived from; establishes lineage, authenticates nothing.
0x48	sync_error_ns	uint32_t	ns	Bound on the evidence time's conversion error; added to every age the reader checks.
0x4C	payload_kind	uint16_t	enumeration	CHUNK for this payload; INTENT, TRAJECTORY, and OPERATOR select the other payloads.
0x4E	payload_len	uint16_t	bytes	Payload length; bounds the parser before any payload byte is read.
0x50	num_waypoints	uint16_t	count	Chunk horizon H; a count outside the configured range is rejected.
0x52	num_joints	uint8_t	count	Commanded joints N_j; must equal the configured count, and payload_len must equal $4 + 8HN_j$.
0x53	reserved	uint8_t	—	Zero.
0x54	joint_positions	float32[H][N_j]	rad	Commanded joint angles within the reach limits ($q_{\min} \le q \le q_{\max}$).
$0x54 + 4HN_j$	joint_velocities	float32[H][N_j]	rad/s	Commanded joint velocities within certified ceilings ($\lVert\dot{\mathbf{q}}\rVert \le \dot{q}_{\max}$).
0x50 + payload_len	crc32	uint32_t	checksum	Last field; IEEE 802.3 CRC-32 over all preceding bytes.

C.15.2 Intent payload

The intent lease of section 10.8 travels under the proposal header with payload_kind set to INTENT (table C.11). Three header fields take specific meanings. t_evidence_ns is the parent belief record's evidence epoch, never its estimate epoch. parent_digest is that belief record's digest, which the permission path matches against a retained record. t_expire_ns is the requested expiry, which the permission path shortens to the earliest of the evidence horizon, its configured lease ceiling, and the stop deadline. The six bounds values are three conservative position-error envelopes and three task tolerances in the base frame named by frame_id. They are not an encoding of a covariance, and the producer must justify any conversion from its covariance estimate, including calibration bias and the declared tail risk.

Table C.11: Intent payload: The intent lease as a proposal-header payload. Orientation tolerances and contact-mode rules come from an independently approved task profile; the quaternion is the proposed orientation only.

Offset	Field	Scalar type	Unit	Invariant and check
0x00–0x4F	proposal header	as above	as above	table C.10, with payload_kind = INTENT.
0x50	target_pose	float64[7]	m; unit quaternion	Base-frame position and orientation; finite values, normalized quaternion, workspace prefilter.
0x88	bounds	float32[6]	m	Error envelope e, then task tolerance r; $0 \le e_i \le r_i$, each checked against the approved task profile.

DRAFT

Offset	Field	Scalar type	Unit	Invariant and check
0xA0	wrench_request	float32[6]	N; N·m	Three requested forces and three torques; clamped or rejected against independent task and actuator limits.
0xB8	terminal_-request	uint32_t	enumeration	Requested terminal mode; the permission path selects a feasible approved response from the current load and contact state.
0xBC	crc32	uint32_t	checksum	IEEE 802.3 CRC-32 over all preceding bytes.

C.15.3 Trajectory payload

The trajectory record of section 11.8 replaces the chunk on the running machine and travels under the same proposal header, with payload_kind set to TRAJECTORY and parent_digest set to the digest of the active intent lease (table C.12). The header's t_expire_ns requests an absolute expiry. The MCU retains an admitted expiry no later than that request or the successful admission time plus the configured chunk lease. Earlier evidence and stop deadlines can shorten it further. The parent intent's expiry comes from the lease that parent_digest identifies. The MCU records admission time locally, without changing t_evidence_ns or t_issue_ns. The layout below illustrates a single polynomial stopping suffix per joint. It does not encode the piecewise S-curve worked in section 11.5.2. That profile requires its own specified bounded encoding and decoder, with decoding and validation charged to admission. The setpoint samples and the assumptions sidecar travel outside this fixed part. The permission path verifies sidecar_digest over both, validates the complete candidate in staging memory, and latches the admitted setpoints and stop suffix in protected memory before tracking begins.

Table C.12: Trajectory payload: The trajectory record as a proposal-header payload. The four deadlines are absolute times on the safety microcontroller's clock; the variable-length setpoint samples and the assumptions sidecar are bound by sidecar_digest and validated before activation.

Offset	Field	Scalar type	Unit	Invariant and check
0x00–0x4F	proposal header	as above	as above	table C.10, with payload_kind = TRAJECTORY.
0x50	sample_-period_ns	uint32_t	ns	Setpoint cadence Δt_{step}; must match the configured decoder.
0x54	num_samples	uint16_t	count	Nominal setpoints in the digested sample payload; bounds its size.
0x56	num_joints	uint8_t	count	Commanded joints N_j; must equal the configured count.
0x57	payload_-version	uint8_t	enumeration	Decoder version; an unknown version is rejected.
0x58	t_start_ns	uint64_t	ns, permission clock	First nominal sample.
0x60	t_commit_ns	uint64_t	ns, permission clock	Latest entry into the matched stop suffix; $t_{\text{commit}} = t_{\text{stop_end}} - T_{\text{stop}}$.
0x68	t_plan_exp_ns	uint64_t	ns, permission clock	End of the nominal setpoints.
0x70	t_stop_end_ns	uint64_t	ns, permission clock	Protected stop completion; $t_{\text{start}} \le t_{\text{commit}} < t_{\text{plan_exp}} < t_{\text{stop_end}}$.
0x78	sidecar_digest	uint8_t[32]	SHA-256	Digest over the setpoint samples and the assumptions sidecar; binds content.
0x98	seam_state	float32[3][N_-j]	rad; rad/s; rad/s²	Entry state $(q, \dot{q}, \ddot{q})$ of each joint.
0x98 + $12N_j$	stop_suffix	float32[6][N_-j]	polynomial coefficients	Stop-polynomial coefficients per joint, resident and feasible at t_{commit}; a quartic uses a zero fifth-order coefficient. Admission separately requires state-matched fallbacks before commitment.

Offset	Field	Scalar type	Unit	Invariant and check
0x98 + $36N_j$	crc32	uint32_t	checksum	IEEE 802.3 CRC-32 over all preceding bytes.

C.15.4 Enforcement record

The enforcement record of section 12.11 is configuration, not a proposal, so it carries no proposal header (table C.13). Three digests name what the record rests on: the evaluation record, the limit records behind the stopping envelope, and the validity region. Each threshold names the fallback-ladder rung that a failed check selects. Where the rung depends on whether the body is moving, the row names both, STOP in motion and HOLD at standstill. Refusing a replacement selects no rung if the active record still passes its own state, evidence, lease, and stopping checks. Failure of an active-record check selects the applicable fallback.

Table C.13: Enforcement record: Thresholds of the permission path with the fallback-ladder rung each failed check selects, and digests of the evaluation record, limit records, and validity region the thresholds rest on. The record is configuration and telemetry; it adds no packet to the proposal stream.

Offset	Field	Scalar type	Unit	Check, and the rung a failure selects
0x00	evaluation_record_digest	uint8_t[32]	SHA-256	Evaluation record whose runtime monitor specifications become this record's monitor channels.
0x20	limit_record_digest	uint8_t[32]	SHA-256	Canonical list of the limit records whose braking, onset, and actuator limits parameterize $d_{\text{stop}}(v)$.
0x40	validity_region_digest	uint8_t[32]	SHA-256	validity_region, the plant-parameter bounds the thresholds rest on. On the mobile manipulator it covers the arm at the door, where it equals the target ODD, and at the packing station through the mug pick and the handover approach. Each base configuration, normal or restricted, loads as its own enforcement record, so this field holds the region digest of that configuration and its friction premise. A live state outside it that the machine observes selects STOP.
0x60	loop_period_ns	uint32_t	ns	Permission-loop period T_{tick}; the placement record's nominal_period_ns must equal it.
0x64	deadline_ns	uint32_t	ns	Permission-path deadline inside the tick; a threatened overrun invokes a separately bounded response: STOP in motion, HOLD only at a qualified standstill. The mechanism must act even if this computation stalls.
0x68	evidence_age_ceiling_ns	uint32_t	ns	Operating ceiling on upper evidence age, qualified for admission and continued tracking. Refuse a candidate above it; cap its admitted expiry at t_evidence_ns plus the ceiling minus sync_error_ns. An expired active lease or evidence deadline selects STOP in motion and HOLD at standstill.
0x6C	watchdog_timeout_ns	uint32_t	ns	The self-watchdog is fed only after a completed tick; expiry requests INHIBIT through the independently wired trip.
0x70	t_stop_ns	uint32_t	ns	Stopping-time bound for the qualified profile from the maximum admitted speed. Admission reserves that profile's distance, pre-brake travel, and uncertainty allowances; loss of the required clearance selects STOP.

DRAFT

Offset	Field	Scalar type	Unit	Check, and the rung a failure selects
0x74	pos_tracking_bound	float32	m	$\lvert x_{\text{meas}} - r_{\text{cmd}} \rvert \le \epsilon_{\text{track}}$; STOP above it.
0x78	pos_critical_bound	float32	m	$\lvert x_{\text{meas}} - r_{\text{cmd}} \rvert \le \epsilon_{\text{crit}}$, with $\epsilon_{\text{crit}} > \epsilon_{\text{track}}$; STOP above it.
0x7C	vel_ceiling_limit	float32	rad/s	$\lvert \dot{q} \rvert \le \dot{q}_{\max}$; PROJECT (QP clamp).
0x80	torque_slew_ceiling	float32	N·m/s	$\lvert \dot{\tau} \rvert \le \dot{\tau}_{\max}$; PROJECT (slew limiter).
0x84	actuator_curr_limit	float32	A	$\lvert I_{\text{phase}} \rvert \le I_{\text{peak}}$; STOP.
0x88	dc_bus_overvolt_thresh	float32	V	$V_{\text{bus}} \le V_{\text{max_safe}}$; STOP, with the brake chopper absorbing returned energy.
0x8C	num_barriers	uint16_t	count	Barrier constraints K_b; must equal the configured count.
0x8E	num_approach_channels	uint16_t	count	Approach channels K_a; must equal the configured count.
0x90	cbf_barrier_params	float32[K_b][2]	normalized distance; s^{-1}	Margin δ_k and class-$\mathcal{K}$ rate γ_{cbf_k} of each barrier; $h_k(\mathbf{x}) \ge \delta_k$, else PROJECT, or STOP when no feasible input remains.
0x90 + $8K_b$	approach_channel_ids	uint32_t[K_a]	enumeration	Zone and activation condition of each channel, drawn from the validity region, such as the tool point inside the door zone or accept_item held.
0x90 + $8K_b + 4K_a$	approach_ceilings	float32[K_a]	m/s	Ceiling on tool-point approach speed while its channel is active; a faster proposal takes PROJECT (QP clamp), and the channel that bound it is logged.
0x90 + $8K_b + 8K_a$	crc32	uint32_t	checksum	IEEE 802.3 CRC-32 over all preceding bytes; a mismatch rejects the stored record, and no motion is admitted until a valid copy loads.

The operating evidence ceiling must charge capture-to-admission age and permitted tracking time while reserving the response and stopping distance derived in section 12.5. The perception dispatch-age gate applies at dispatch only. It cannot serve as this operating ceiling. The dispatch-to-admission interval remains a separate qualification obligation, and the partial stopping budget cannot establish the ceiling without that bound and the required reserve. Each runtime check uses the current MCU time and the retained evidence epoch; admission never makes old evidence fresh.

C.15.5 Placement record

The placement record of section 13.8 is offline evidence with a fixed header and a linked test report (table C.14). It carries no signature of its own; the signed release manifest binds it through `placement_record_digest`. `enforcement_record_digest` names the enforcement record whose `deadline_ns` was tested. `test_report_digest` identifies the external test report. That report states the declared worst-case execution time the loaded test must not exceed, together with distributions, sample counts, test conditions, mitigations, and untested states. A maximum that has not been measured is stored as all ones, never zero, the same unavailable-value convention the fault record uses.

Table C.14: Placement record header: Configuration values and observed maxima, with digests linking the tested enforcement record and the external test report. The header alone does not establish freedom from interference.

Offset	Field	Scalar type	Unit	Invariant and check
0x00	execution_domain_id	uint64_t	enumeration	Must match the declared topology (application processor, NPU, GPU, MCU, lockstep controller).
0x08	privilege_and_ring	uint64_t	privilege level	Proposer at EL0; enforcer at EL1 or above, or in the secure world.

DRAFT

Offset	Field	Scalar type	Unit	Invariant and check
0x10	nominal_period_ns	uint32_t	ns	Enforcer tick; equal to the enforcement record's loop_period_ns.
0x14	hard_deadline_ns	uint32_t	ns	The permission path's deadline inside the tick; equal to the enforcement record's deadline_ns.
0x18	unloaded_observed_max_-ns	uint64_t	ns	Largest response observed without competing load; a sample maximum, not a WCET.
0x20	loaded_observed_max_ns	uint64_t	ns	Largest response under the declared load; all ones until a loaded test runs. Independence stands only while it is at most the declared WCET.
0x28	shared_axi_channel_qos	uint64_t	configured QoS	Arbitration priority per claimant; controller semantics verified by register capture and a stress test.
0x30	max_pdn_droop_thermal_-trip	uint32_t[2]	mV; m°C	Configured rail-droop and thermal trip thresholds; the test report records the tests behind them.
0x38	hardware_mitigation_-flags	uint8_t[32]	bitfield	Active mitigations, such as a TCM snapshot, memory partitioning, or an isolated rail; register-locked after boot.
0x58	enforcement_record_-digest	uint8_t[32]	SHA-256	Enforcement record whose loop_period_ns and deadline_ns this record tests.
0x78	test_report_digest	uint8_t[32]	SHA-256	External test report, including the model and firmware digests under test.

C.15.6 Authority record and operator payload

The authority record of section 14.8 has two runtime layouts. A network operator's command is a proposal-header payload (table C.15). It is the one proposal whose sender's identity confers authority, so it carries an AES-128 CMAC tag under the operator role's key, the primitive whose per-frame cost section 14.5 prices. The static authority manifest fixes each role's channel grant, the command's component count, order, and units, and the key custody.

Table C.15: Operator payload: A network operator's command under the proposal header. The tag authenticates the role; the permission path still admits the command by its content.

Offset	Field	Scalar type	Unit	Invariant and check
0x00–0x4F	proposal header	as above	as above	table C.10, with payload_kind = OPERATOR.
0x50	nonce	uint64_t	—	Never repeated within a key's lifetime; a repeated nonce is rejected as a replay.
0x58	requested_channel_-mask	uint16_t	bitfield	Channels requested; must lie within the role's grant in the static manifest.
0x5A	operator_role_id	uint8_t	enumeration	Role whose key produced mac.
0x5B	reserved	uint8_t	—	Zero.
0x5C	command	float32[N_-c]	per manifest	Requested command components in manifest order, admitted like any other proposal.
$0x5C + 4N_c$	mac	uint8_t[16]	AES-128 CMAC	Tag over all preceding bytes; reject an invalid packet without revoking an otherwise valid active channel.
$0x6C + 4N_c$	crc32	uint32_t	checksum	IEEE 802.3 CRC-32 over all preceding bytes.

The authority log (table C.16), the per-tick part of the authority record, is written once per tick, not sent as a packet. Its time is on the safety microcontroller's clock; the mapping that relates it to

PTP and calendar time, with its error bound, lives in the static manifest together with the vector lengths, units, and component order. Each entry's `chain_link` is an HMAC-SHA-256, under the log key, over the previous entry's link and this entry's preceding fields, so alteration or interior deletion is detectable against a retained trusted anchor. Detecting truncation of the log also requires an independently retained final link or checkpoint.

Table C.16: Authority log entry: One entry per tick of the permission loop. A missing entry is a gap in the chain, never an implied pass, and the entry is a sampled decision trace, not proof of delivered force or contact.

Offset	Field	Scalar type	Unit	Recorded evidence and limit
0x00	`t_mcu_ns`	`uint64_t`	ns, permission clock	Event time of this tick's decision.
0x08	`actuator_channel_mask`	`uint16_t`	bitfield	Channels to which this decision applies; bus and DMA permissions enforce write scope.
0x0A	`preempt_trigger_code`	`uint16_t`	enumeration	Request, timeout, enabling-device loss, or protective input cause.
0x0C	`authority_state`	`uint8_t`	enumeration	`AUTO`, `PEND`, `BLEND`, `MAN`, `FALLBACK`, or `PROTECTIVE`.
0x0D	`fallback_rung`	`uint8_t`	enumeration	`PROJECT`, `HOLD`, `STOP`, or `INHIBIT` when the state is `FALLBACK`; `NONE` otherwise.
0x0E	`operator_role_id`	`uint8_t`	enumeration	Authenticated source role, interpreted against the static manifest.
0x0F	reserved	`uint8_t`	—	Zero.
0x10	`blend_factor_alpha`	`float32`	dimensionless	Progress in $[0, 1]$ of the enforcer-owned blending profile.
0x14	`policy_proposed_cmd`	`float32[N_c]`	per manifest	Command components before permission; not a motor write.
$0x14 + 4N_c$	`enforcer_clamped_cmd`	`float32[N_c]`	per manifest	Components admitted after the current constraint check.
$0x14 + 8N_c$	`actuator_delivered_cmd`	`float32[N_c]`	per manifest	Dispatched setpoint components; delivery at the drive needs separate evidence.
$0x14 + 12N_c$	`measured_plant_state`	`float32[N_s]`	per manifest	Sampled state components, with sensor timing in the manifest.
$0x14 + 12N_c + 4N_s$	`chain_link`	`uint8_t[32]`	HMAC-SHA-256	Keyed link over the previous link and this record's preceding fields; evidence of tampering only while the key and anchor stay in custody.

The compact layout above is the fixed decision trace, not the complete incident evidence bundle. Versioned companion records must preserve the remaining lease age, authenticated source identity, admission or rejection outcome, and sensor-event timing and uncertainty required by section 14.7. Each companion record must bind to the decision tick and channel mask under the same integrity scheme; missing companions remain declared evidence gaps. In `MAN`, `policy_proposed_cmd` stores the selected human proposal despite its historical field name.

C.15.7 Authority-transfer protocol

The authority-transfer protocol of section 14.3 and section 14.4 runs in the enforcer's 1 kHz loop on the safety microcontroller, where the four-phase handshake, integrator pre-biasing, and the C^2 quintic blend become one sequence of per-state steps. Each tick writes the authority-log entry of table C.16 under the state names used below. The cadence and jitter below are illustrative design targets; the target implementation must qualify them before actuator permission is granted.

Three cadence and memory invariants govern the loop:

- *Execution cadence:* Hard real-time periodic timer interrupt ($f_s = 1$ kHz, period $T_{\text{tick}} = 1.0$ ms, hardware timing jitter $< 1.0\,\mu$s).
- *Memory invariant:* Zero dynamic heap allocation (`malloc`/`free` forbidden; all state variables, mailboxes, and circular log buffers statically pre-allocated in DTCM SRAM).

- *Hardware authority:* Exclusive write of the admitted setpoints staged for the next EtherCAT frame to the drives, and of the safe torque off (STO) hardware cutoffs.

Each 1 kHz tick executes five state-machine steps:

1. Sample and validate plant state, available stopping reserve, independent protective inputs, and the current execution lease. An independent protective input selects its validated, state-matched stop path of section 12.9.
2. In `AUTO`, a manual request or policy handover request enters `PEND`; the policy may propose only while its existing permission remains valid. Set T_{timeout} to the smaller of the protocol ceiling and clearance-derived deadline. No later than the last permission tick before T_{timeout}, transfer to the state-matched fallback. An invalid network packet is rejected and logged, not interpreted as a stop request.
3. In `PEND`, verify the operator credential, nonce, enabling input, target freshness, actuator limits, and full transfer-plus-stop clearance. On `ACK`, at the next qualified **Commit** tick, revoke the policy's proposal token on the masked channels, latch $\mathbf{u}_0$ as its last *admitted* command, latch a checked human target $\mathbf{u}_1$, and set `BLEND`. The enforcer remains the only actuator writer. If the replacement fails admission, retain the current mode only while its own state, evidence, lease, and stopping checks pass; otherwise enter the independently validated fallback.
4. In `BLEND`, evaluate $\hat{t} = \min(1, (t - t_0)/\tau_{\text{blend}})$ and $\alpha(\hat{t}) = 6\hat{t}^5 - 15\hat{t}^4 + 10\hat{t}^3$. The enforcer proposes $\mathbf{u}_{\text{blend}} = (1 - \alpha(\hat{t}))\mathbf{u}_0 + \alpha(\hat{t})\mathbf{u}_1$, then checks that candidate against current state, torque/rate, and stopping limits before dispatch. These are **latched endpoints**, not simultaneous live policy and human actuator streams. If the lease, clearance, or tracking assumption fails, use the state-matched fallback. At $\hat{t} = 1$ with a live manual lease, set `MAN` and confirm that state to the operator.
5. In `MAN`, the enforcer checks each live human proposal. Lease expiry or enabling-device loss revokes manual proposals and transfers to the validated fallback. Log request, ACK, commit, candidate, admitted command, measured response, and clock uncertainty separately; the bounded high-rate record must not block the control tick.

C.15.8 Fault record

The fault record of section 15.11 is offline evidence, a fixed header signed with Ed25519 that links to the retained evidence bundle by digest (table C.17). The fault-record root (`fault_records_root`) that the release manifest binds is computed over the canonical encodings of these headers. `envelope_point` has a per-machine definition in the versioned fault-class manifest; for the mobile manipulator its four values are aisle speed (m/s), payload (kg), floor friction coefficient, and ambient temperature (K).

Table C.17: Fault-record header: The fixed part of one fault trial. The linked evidence bundle carries fault duration, hardware and software build identifiers, raw trace references and clock domains, detector identity, every margin value and scale, the measured physical outcome, secondary anomalies, and partial traces for non-pass verdicts.

Offset	Field	Scalar type	Unit	Purpose and interpretation
`0x00`	`trial_id`	`uint64_t`	—	Unique trial identifier in the versioned trial log.
`0x08`	`claim_ref_id`	`uint32_t`	index	Precommitted physical claim and its units.
`0x0C`	`envelope_point`	`float32[4]`	per manifest	Declared operating point of the trial.
`0x1C`	`fault_injection_mode`	`uint16_t`	enumeration	Injected fault class.
`0x1E`	`injection_target_node`	`uint16_t`	enumeration	Hardware boundary receiving the injection.
`0x20`	`fault_magnitude`	`float32`	per fault class	Injection amplitude; its unit is fixed by the fault-class manifest.
`0x24`	`t_det_ns`	`uint32_t`	ns	Fault trigger to detector assertion.
`0x28`	`t_takeover_ns`	`uint32_t`	ns	Fault trigger to measured takeover; subtract `t_det_ns` for the post-detection interval.

DRAFT

Offset	Field	Scalar type	Unit	Purpose and interpretation
0x2C	stl_robustness_rho	float32	claim's unit	Raw signed margin for claim_ref_id; other predicate margins remain in the bundle.
0x30	verdict_status	uint8_t	enumeration	PASS, FAIL, INVALID, or UNOBSERVABLE.
0x31	reserved	uint8_t[3]	—	Zero.
0x34	oracle_digest	uint8_t[32]	SHA-256	Immutable predicate and oracle configuration.
0x54	evidence_digest	uint8_t[32]	SHA-256	Separately retained trial evidence bundle.
0x74	signature	uint8_t[64]	Ed25519	Signature over all preceding bytes; the key identifier is in the versioned manifest.

For a trial aborted before injection, detector time, takeover time, and robustness margin are unavailable rather than zero. The layout stores all ones (0xFFFFFFFF) in an unavailable uint32_t time slot and a canonical quiet NaN in an unavailable float32 margin slot, and the signed evidence bundle records a validity flag for each measured field and why it is absent. The oracle checks those flags and the verdict before doing arithmetic, and excludes unavailable slots from pass counts and from latency or margin statistics. The versioned manifest fixes the NaN bit pattern so that hashing remains reproducible.

C.15.9 Fault-injection protocol

The fault-injection protocol of section 15.8 runs one hardware-in-the-loop trial on target silicon, from the precondition audit to the signed header of table C.17. Every exit it takes sets one value of that header's verdict_status. The illustrative fixture below must qualify its timing, interlocks, and measurement uncertainty before any physical trial.

Three substrate and interlock invariants govern the testbed:

- *Execution substrate:* Hard real-time FPGA plant rig and testbed orchestrator ($f_s = 1$ kHz, hardware timestamping jitter < 500 ns).
- *Memory invariant:* Pre-allocated static DMA buffers in the host test orchestrator; zero runtime dynamic heap allocation on the safety microcontroller.
- *Safety interlock authority:* Independent optical or laser truth sensors wired to hardware crowbar relays capable of cutting target actuator power within 2.0 ms of a physical envelope breach.

Each hardware-in-the-loop fault trial executes five sequential stages:

1. **Precondition audit (stage 1).** Sample baseline environmental sensors via $\mathcal{J}_{\text{truth}}$ (temperature, rail voltage, and wheel speed). Compare each measurement with its declared same-unit tolerance; do not take one norm across kelvin, volts, and meters per second. If any precondition fails, log ERR_PRECONDITION_OUT_OF_SPEC, set the verdict to INVALID, and abort.
2. **Synchronization and steady-state arming (stage 2).** Arm the FPGA plant simulator, power up the target two-processor system, and start the periodic control loop (1 kHz). Establish a synchronized reference clock across the logic analyzer, FPGA plant, and truth digitizers via a 10 MHz PXI clock. Allow the physical plant state $\mathbf{x}(t)$ to stabilize in the nominal operating envelope for $t_{\text{settle}} = 2.000$ s. If baseline tracking error $\|e_{\text{track}}\| > \epsilon_{\text{nom}}$, assert ERR_BENCH_INSTABILITY, set the verdict to INVALID, and abort.
3. **Fault injection trigger (stage 3).** At monotonic test epoch t_{inject}, the hardware test orchestrator asserts the trigger line to the inline injection rig and records the injection timestamp $t_{\text{fault_start}} \leftarrow t_{\text{now}}$ in nanoseconds on the reference clock:
    - *Proposer stall (F1):* The orchestrator kills the chunk-policy task one tick after a lease renewal.
    - *Sensor latency or bias (F2):* An FPGA interceptor latches a navigation-camera frame or holds a stale encoder payload while preserving its valid hardware timestamp.
    - *Frame loss (F3):* A fieldbus disturbance node drops or corrupts EtherCAT frames at a drive's slave port.

- *Drive-bus droop (F4a):* A programmable supply standing in for the pack at its depleted point steps the shared drive bus below the converter lockout of table 15.2 for $\Delta t_{\text{duration}} = 5.0$ ms, while an independent digitizer records the permission rail and the permission path's heartbeat.
- *Permission-rail feed loss (F4b):* A solid-state switch opens the permission rail's feed during the longest resident stop in the qualified loaded envelope. The illustrative all-weight inspected-floor ceiling is a screening case, not the qualified injection condition.
- *Actuator mechanical stall:* A four-quadrant dynamometer applies step counter-torque $\tau_{\text{stall}} = 3.5 \times \tau_{\text{rated}}$.

4. **Enforcer response and takeover audit (stage 4).** Monitor the target MCU's safety enforcer pins, CAN bus telemetry, and gate-driver PWM lines via an isolated logic analyzer. If the external containment rig trips on a structural envelope breach, the hardware crowbar cuts actuator power; assert `ERR_PHYSICAL_BREACH` and carry the trial to stage 5, where the violated containment predicate returns `FAIL`:
   - Detect assertion of the non-maskable interrupt (NMI) or diagnostic flag: $t_{\text{det}} \leftarrow t_{\text{now}} \implies \Delta t_{\text{det}} = t_{\text{det}} - t_{\text{fault_start}}$.
   - Detect hardware multiplexer preemption of the motor driver: $t_{\text{takeover}} \leftarrow t_{\text{now}} \implies \Delta t_{\text{takeover}} = t_{\text{takeover}} - t_{\text{fault_start}}$.
   - Independently witness powered deceleration onset and standstill, rather than inferring either from a flag or multiplexer transition. Preserve the claim's physical reference epoch: F1 measures from the last successful lease renewal, while F4a measures from the undervoltage flag; the injection epoch remains a separate diagnostic timestamp.
   - Detect the physical plant's transition to its safe bounded regime: $t_{\text{bounded}} \leftarrow t_{\text{now}} \implies \Delta t_{\text{bounded}} = t_{\text{bounded}} - t_{\text{fault_start}}$.
5. **Robustness evaluation and record serialization (stage 5).** Ingest the truth trajectory $\mathbf{x}_{\text{obs}}(t)$ from independent instrumentation over the declared trial window. If required truth frames are missing, set the verdict to `UNOBSERVABLE` and retain the partial trace. For an observable trial, compute each precommitted predicate's signed margin in its own unit, as the STL robustness of section A.7 defines it. Return `PASS` only when every required margin is nonnegative and all predeclared timing and travel bounds pass, including independently witnessed deceleration onset and stopping distance from the claim's reference event. Fault-to-detection and fault-to-drive-takeover times are additional diagnostics, not substitutes for physical response; otherwise return `FAIL`. A dimensionless aggregate may be computed only after predeclared per-predicate normalization. Link the fixed fault-record header to the variable-length evidence bundle by digest, sign the header under the specified custody scheme, and retain both.

C.15.10 Release manifest

The release manifest of section 16.8 is a signed offline artifact, not a mailbox record, so it has a canonical encoding in place of fixed offsets. Fields appear in the order that table C.18 lists, each variable-length field carries a length prefix, and the adjudicator's Ed25519 signature covers the encoding of every preceding field. Every digest is SHA-256. The expiry is the one calendar time in the record chain, and it is checked against a tamper-resistant real-time clock rather than the safety microcontroller's monotonic clock.

Table C.18: Release manifest: Canonical field order of the signed release artifact. A new signed version can supersede a manifest only after the current physical conditions are checked, and the hardware root anchors keys rather than storing mutable digests.

Field	Encoding	Binds	Check before permission
`claim_manifest_id`	`uint8_t[16]` UUID	Top-level safety claim	Linked to the root node of the signed argument graph.

DRAFT

Field	Encoding	Binds	Check before permission
`argument_digest`	`uint8_t[32]`	Complete claim–argument–evidence graph	Matches the graph the adjudicator reviewed.
`policy_weights_digest`	`uint8_t[32]`	Learned model weights	Mismatch refuses release.
`enforcer_bitstream_digest`	`uint8_t[32]`	Enforcer logic image	Mismatch refuses release.
`rtos_kernel_digest`	`uint8_t[32]`	Real-time kernel image and drivers	Verified by the hardware root of trust at power-on.
`calib_trace_pointers`	length-prefixed list of signed evidence references	Calibration certificates	Missing or stale evidence refuses unless a separately signed restricted case covers it.
`fault_records_root`	`uint8_t[32]`	Signed fault-record headers (section C.15.8)	Missing, unauthenticated, or mismatched root refuses.
`authority_record_digest`	`uint8_t[32]`	Static authority manifest and the authority log's initial chain anchor (section C.15.6)	Mismatch refuses release.
`placement_record_digest`	`uint8_t[32]`	Placement record (section C.15.5)	Mismatch refuses release.
`evaluation_record_digest`	`uint8_t[32]`	Evaluation record	Mismatch refuses release.
`verdict_classification`	`uint8_t` enumeration	`UNCOND`, `COND`, or `REFUSE`	Selects the permitted operating envelope.
`standing_conditions`	length-prefixed array of (premise, check rate, trip)	Physical premises checked in operation	Measurements or inspections follow each declared cadence; each tick checks retained validity, expiry, and monitor health. An unknown required premise takes the assessed stop.
`telemetry_drift_budget`	length-prefixed task-specific limits and triggers	Tracking and timing drift	A bound violation revokes; a trend prompts inspection.
`verdict_expiry`	UTC calendar time (ISO 8601)	Validity period of the verdict	A real-time clock reading past the expiry voids the permit.
`lifecycle_budget`	`uint64_t[2]` (hours, cycles)	Wear allowance	An exceeded budget or an invalid counter refuses motion.
`adjudicator_signature`	key identifier plus `uint8_t[64]` Ed25519 signature	The whole manifest	Verifies under an authorized, unrevoked adjudicator key.

C.15.11 Release-gate protocol

In section 16.8, before the motor power stages are energized, the release gate attests the silicon state, verifies the manifest of table C.18 and its image digests, and audits the standing conditions in the order below. The hardware root of trust anchors an authorized, revocable adjudicator verification-key chain. Protected storage holds the signed manifest and signed evidence graph. The signature covers every versioned manifest field, including the identity of the signing key, and the verifier checks the key chain and its revocation state before trusting the signature. The individually signed fault records of section C.15.8 enter the manifest as one digest over the complete set in its declared order. The verifier checks each record signature, the ordering, completeness, and that root against the reviewed evidence index. A digest alone establishes neither record validity nor test adequacy.

Fail-closed authorization begins with `Permit_gate = 0` and the physical plant in its assessed nonoperating state. All returned decisions use the signed enum `UNCOND`, `COND`, or `REFUSE`; an implementation may log a reason code separately:

1. Verify the adjudicator key chain and revocation status, the manifest signature, expiry, signed operating-hour and cycle budgets, and every active image digest. Any invalid, missing, or expired item returns `REFUSE`. A different software bank requires its own signed case and a new check of physical conditions.

2. Authenticate the complete set of fault records and calibration references against the signed graph. A missing fault record, bad record signature, or root mismatch returns `REFUSE`, even if the manifest says `UNCOND`. Stale calibration also returns `REFUSE` under the full case. It can support `COND` only when a *separately signed* restricted case explicitly covers that calibration state and all of its evidence and limits still validate.
3. Check the state-dependent standing conditions, including brake test, separation, timebase, and monitoring health. `KNOWN_FALSE` and `UNKNOWN` both return `REFUSE` while retaining distinct logged causes. Apply the approved state-matched stop or hold of section 12.9.
4. If every check passes and the signed verdict is `UNCOND`, load the signed full envelope and return `UNCOND`. If every restricted condition passes under a signed `COND` case, load its signed reduced envelope and return `COND`. A signed `REFUSE` case or any other state returns `REFUSE`. In both operating modes the learned policy only *proposes* actions; the independent enforcer checks each candidate and controls actuator permission. Force trip thresholds must include measured detection and response headroom below the contact criterion.

C.15.12 Approval record

The approval record of section 17.9 is an offline artifact like the release manifest: a canonical encoding in the field order of table C.19, length-prefixed variable fields, SHA-256 digests, and an Ed25519 signature by the adjudicator over every preceding field. The release gate reads it after the manifest checks of section C.15.11, as one more standing condition.

Table C.19: Approval record: Canonical field order of the signed approval record. Every check that refuses returns the premise to the adjudicator with its cause logged, the handling the release gate gives an unknown physical premise.

Field	Encoding	Binds	Check before permission
`record_id`	`uint8_t[16]` UUID	This version of the approval record	Matches the identifier the manifest's standing conditions name.
`release_manifest_digest`	`uint8_t[32]`	The release manifest it governs	Mismatch refuses release.
`upstream_digests`	`uint8_t[32]` each: authority record, enforcement record, fault-record set	The records whose decisions it names	Mismatch refuses release.
`permit_stage`	length-prefixed record: grantor, stage, configuration digest, domain reference	The permission stage and what it covers	A configuration digest different from the manifest's refuses.
`decisions`	length-prefixed array of (type, owner role, approval reference, expiry)	Each decision behind an admitted action class	An entry with no owner, or past its expiry, returns `REFUSE` with the cause logged.
`human_roles`	length-prefixed array of (duty, required time, available time, utilization bound, verdict)	Each human role the safety argument cites	A role cited as a countermeasure with verdict `INFEASIBLE` or `UNKNOWN` returns `REFUSE`.
`reporting_duties`	length-prefixed array of (recipient, trigger, deadline)	What must be reported, to whom, and by when	Missing duties for the stage refuse; the disclosure log is kept beside the record and is not checked at each boot.
`exposure`	length-prefixed array of (group, chose exposure, measure, sample size, rate, interval)	Each group exposed and its per-group detection	A group the design relies on detecting with no entry returns `REFUSE`.
`data_declarations`	length-prefixed array of (record class, purpose, retention, readers, last audit)	Each record class that identifies people	An expired declaration or failed audit suspends that use and returns the premise to the adjudicator.
`labor`	length-prefixed record: takeover, dispatch, sweep, and monitoring hours; barred uses	The labor the deployment moves	Recorded for review; it does not gate motion.
`validity_window`	UTC calendar time (ISO 8601), start and end	The period the record covers	A real-time clock reading outside the window refuses.

DRAFT

Field	Encoding	Binds	Check before permission
`adjudicator_signature`	key identifier plus `uint8_t[64]` Ed25519 signature	The whole record	Verifies under an authorized, unrevoked adjudicator key.

C.15.13 Residual-claims register

The residual-claims register of section 18.3.3 tracks every physical premise the release rests on but does not observe, so that an open claim is carried across software deployments and hardware revisions. Like the release manifest, it is an offline artifact whose mandatory fields (table C.20) follow a canonical order rather than fixed offsets.

Table C.20: Epistemic residual-claims register: Canonical field order of the register. The header binds it to one platform, build, and operating window; each entry must carry its claim, the missing observable, the hazard and its time to harm, the containment that holds meanwhile, and the predeclared test that would close it.

Manifest Category	Field	Physical Unit	Invariant & Operational Contract
Manifest Header	`system_identifier`	—	Unique embodied platform ID (e.g., `WMM-AISLE-01`)
Manifest Header	`hardware_build_rev`	—	Target silicon and chassis revision (`HW-REV-3.2`)
Manifest Header	`software_digest`	—	Digest of the released binary
Manifest Header	`validity_limit_hours`	hours	Configured operating window before review
Residual Claims	`entry_id`	—	Unique claim tag (e.g., `CLAIM-FRIC-001`)
Residual Claims	`target_safety_claim`	—	Explicit safety invariant ($d_{\text{stop}} \leq D_{\text{clear}}$)
Residual Claims	`missing_observable`	SI units	Unmeasured physical state (e.g., surface friction μ)
Physical Hazard	`governing_law`	—	Newton-Euler, Navier-Stokes, Joule heating
Physical Hazard	`time_to_harm`	seconds	Time from unmodeled transition to irreversible yield
Operational Containment	`containment_type`	—	`FIRMWARE_PARAM_CLAMP`, `PASSIVE_MECHANICAL`, or `OPERATING_RESTRICTION`; validate the selected limit
Operational Containment	`authority_limit`	m/s, N	Hard numeric setpoint ceiling ($v_{\max}$, $F_{\max}$)
Operational Containment	`kinetic_energy_ceiling`	J	Maximum allowable kinetic energy under fault ($E_k \leq E_{\max}$)
Assurance & Inspection	`proof_test_interval`	hours	Scheduled test interval; evidence between tests still depends on the operating restriction
Assurance & Inspection	`accountable_owner`	—	Named role responsible for maintaining the containment, arranging its inspections, and approving the closure evidence
Predeclared Closure	`closure_modality`	—	Transducer technology or formal method required
Predeclared Closure	`sample_trials`	count	Case-specific independent exposure, sized by the zero-failure rule of section A.8 for the declared miss-rate bound
Predeclared Closure	`confidence_level`	—	Declared one-sided confidence level of that bound

D

The Sense–Plan–Act Paradigm

This appendix uses Sense–Plan–Act to locate failures in sensing, motion proposals, and physical execution. Its reference tables connect observable symptoms to timing, state, and force budgets, then identify the evidence needed to test a remedy. The framework also separates a policy's ability to propose useful behavior from the permission path's responsibility to admit motion and preserve a feasible fallback.

D.1 How to Use This Appendix

Engineers consult this reference when architecting cyber-physical boundaries, evaluating whether end-to-end learned policies can run safely on hardware, or diagnosing operational failures across perception, planning, and control. Each recurring design question or production failure symptom maps to the section that specifies its governing physical contract (table D.1).

Table D.1: S·P·A architectural and diagnostic navigation: Symptom-to-section index mapping operational failures and design trade-offs to their governing physical contracts.

When you encounter this architectural or diagnostic symptom	Consult	For this physical contract or diagnostic framework
Evaluating classical S·P·A vs. end-to-end VLA vs. hierarchical physical AI	section D.2	Representation, timing, and authority contracts across architectural choices
Triaging single-axis failures in evidence age, proposal validity, or torque limits	section D.3	Three-axis taxonomy and constraint budgets across Sense, Plan, and Act
Spatial memory retains phantom obstacles or misclassifies unobserved space	section D.4.1	$S \cap P$ epistemic handoffs, evidence epochs, and raycast eviction
Action-chunk seams command violent torque spikes or exhaust braking margin	section D.4.2	$P \cap A$ kinetic handoffs, C^2 quintic blending, and stopping suffixes
End-effector oscillations or limit-cycle chatter occur during rigid contact	section D.4.3	$A \cap S$ contact passivity, contact-specific response budgets, and impedance control
Safety thread overruns, SoC memory contention, or brownout during inference bursts	section D.4.4	$S \cap P \cap A$ permission decisions, CBF-QP filters, and silicon isolation

Matching observable production symptoms to physical telemetry and remedies	section D.6	Production troubleshooting matrix with measured diagnostic discriminators
Establishing verification gates and acceptance criteria before physical release	section D.7	S·P·A systems scorecard across all axes and intersection handoffs

D.1.1 Four-pass diagnostic protocol

When an embodied system violates a safety envelope, misses an execution deadline, chatters during contact, or trips hardware interlocks, ad-hoc parameter tuning can mask the underlying boundary failure. Work through the diagnosis in four systematic passes that separate symptom capture from causal intervention:

DRAFT

1. **State the physical symptom and binding budget**: Record the observed stopping-distance breach, contact-force transient, thermal trip, or enforcer deadline overrun, including physical units, payload, operating state, and the threshold declared in the machine's limit record (chapter 2).
2. **Localize the candidate axis or intersection**: Use table D.3 for a preliminary triage across the three core axes. When the symptom involves interface timing, state representations, or actuation authority, move directly to the intersection landscape in table D.4.
3. **Test the quantitative hypothesis**: Measure the candidate constraint or budget using the instruments in table D.6, such as timestamp skew, bus queue time, phase current, or tracking error.
4. **Intervene and remeasure across the causal boundary**: Apply a principled remedy and rerun the test over the declared load, timing, and fault envelope.

The symptom selects a candidate entry point, not a diagnosis. Contact oscillations motivate an Act–Sense ($A \cap S$) feedback test; a torque transient motivates a Plan–Act ($P \cap A$) seam test. Phantom obstacles motivate a Sense–Plan ($S \cap P$) evidence test. Deadline jitter under concurrent inference motivates a shared-resource test at the permission decision ($S \cap P \cap A$). Measurements must distinguish these hypotheses from mechanical faults, sensor noise, and other causes.

D.2 Architectural Choices and Their Contracts

A stalled planner and an unstable contact loop require different repairs even when both belong to the same robot. Sense–Plan–Act names functional responsibilities; it does not require that every component wait for the preceding component to finish. Classical estimators, learned policies, and feedback controllers can all participate in concurrent, multirate systems. The useful architectural comparison concerns which representation crosses each interface, how old it is, and which component can authorize motion.

D.2.1 Modularity, reactive control, and learned proposals

Early robotics systems such as Shakey combined perception, symbolic planning, and physical execution.[1] Brooks' subsumption architecture demonstrated a different decomposition into asynchronous behavior layers (Brooks 1986; Brooks 1991).[2] These approaches motivate a durable distinction between deliberation and rapid feedback. They do not establish that modular robotics must be synchronous, stateless, or unable to handle uncertainty. A modular interface can carry covariance, observation history, and explicit failure status; a reactive controller can retain state.

Learned policies expand the behaviors that can be proposed from images, language, and demonstrations. Vision-language-action models, including RT-2, demonstrate generalization to novel objects and commands (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023), while diffusion policies represent multimodal action choices (Chi et al. 2025). These capabilities can reduce the need to specify every recognition rule or manipulation strategy by hand. Their success depends on the training distribution, feedback, and deployment conditions. Neither an end-to-end training objective nor a modular software boundary determines actuator authority; the deployed system must establish that contract separately.

[1] **Shakey and deliberative robotics**: Shakey is an early example of integrating perception, symbolic planning, and mobile execution; Moravec (Moravec 1988) discusses this period of robotics. The diagnostic use of Sense–Plan–Act here does not require reproducing its execution schedule.

[2] **Brooks' subsumption architecture**: Brooks (Brooks 1986; Brooks 1991) organized behavior into asynchronous layers with suppression and inhibition. The finite-state modules could retain internal state, so subsumption should not be equated with a memoryless sensor-to-action map.

D.2.2 Timing and representation tests

For a blocking sensor-to-actuation path, the latency of one observation's response is

$$T_{\text{total}} = T_{\text{sense}} + T_{\text{plan}} + T_{\text{act}}.$$

Each term must include the relevant queueing, transport, and execution delay. Pipelining can overlap work on successive observations and improve throughput, but it does not remove the age of the observation used for the current command. Batching independent cameras, candidate trajectories, or robots is possible when their deadlines permit it. Future observations from one robot remain conditional on its intervening actions and cannot be treated as already available independent samples.

DRAFT

For approximately constant speed during an uncorrected delay, the distance traveled is

$$d_{\text{delay}} = \int_0^{T_{\text{total}}} v(t)\,dt \approx vT_{\text{total}}.$$

A local controller may continue to stabilize the plant during that interval; the distance is therefore not necessarily blind travel. It is the motion that the delayed observation cannot yet correct. Section 12.3.1 combines delay travel with the selected braking profile and clearance margins. In a linearized loop, a pure delay also adds phase $-\omega T_{\text{total}}$ radians at angular frequency ω; the allowable delay depends on the loop's crossover frequency and available phase margin.

Representations impose a separate test. If a geometric state $\mathbf{Z}_{\text{geom}}$ is computed solely from sensory data $\mathbf{S}$, the data processing inequality gives

$$I(\mathbf{S};\mathbf{Y}_{\text{task}}) \geq I(\mathbf{Z}_{\text{geom}};\mathbf{Y}_{\text{task}}),$$

where $\mathbf{Y}_{\text{task}}$ is a task-relevant variable. The inequality supplies no percentage of lost information; equality is possible when the representation retains all information needed for that task. A bounding box can support clearance reasoning while omitting latch state or material compliance. A learned representation may retain useful task cues, but metric clearance checks still need quantities with calibrated units and uncertainty bounds. Even raw images may not identify friction or hidden mass, so learning does not remove the need for additional sensing or physical qualification.

Runtime choices affect both tests. Shared memory, direct memory access (DMA), and preallocated inference buffers can reduce copies and allocation overhead. They also require buffer ownership, coherent snapshots, and measured contention bounds. A sequence lock can require retries; static allocation alone does not bound execution time. Chapter 13 develops the isolation evidence needed when inference and permission checks share hardware.

D.2.3 Architectural comparison

Capabilities remain separate from obligations across proposal and permission roles (table D.2). The permission architecture can accompany either a classical or a learned proposer.

Table D.2: Architectural comparison across proposal and permission roles: Classical and learned components offer different ways to construct behavior; neither earns physical authority from its implementation alone.

Architectural dimension	Modular proposer	Learned proposer	Independent permission path
Useful capability	Explicit geometry, dynamics, and search constraints	Recognition and action strategies learned from data	Admit motion against declared physical limits
Representation	Metric state, maps, uncertainty, and task symbols	Images, latent features, language, and action candidates	Timed state estimates, limits, and executable commands
Timing obligation	Bound the age of inputs and arrival of plans	Measure proposal latency and handle missing updates	Meet the configured response deadline under admitted load
Failure to test	Model mismatch, omitted uncertainty, stale state	Distribution shift, invalid targets, late proposals	Missing premises, infeasible filtering, deadline failure
Fallback responsibility	Propose recovery or a replacement plan	Propose recovery or a replacement plan	Own a validated response without waiting for the proposer

D.2.4 The proposal boundary and rate hierarchy

The five-level machine separates the Brain's proposals from permission to execute them (section 1.7).[3] Intent generation, trajectory proposals, permission checks, and motor-current control can run at different rates. Those rates follow the plant, contact conditions, and measured computation budget; they are not universal properties of model classes. A sufficiently fast learned controller can participate in a feedback loop, but its timing and stability still require qualification.

Action chunks let a slower proposer supply multiple execution steps. They also increase the interval over which a proposal can become stale. The permission path therefore checks the measured entry state, current evidence, dynamic limits, and the available fallback before commitment.

[3] **The proposal boundary**: The authority boundary separating candidate behavior from permission to execute it. A learned proposal acquires actuation authority only through the qualified permission path; qualification remains conditional on the machine's stated assumptions.

DRAFT

Rejecting a successor leaves still-valid active authority intact. If no successor is admitted by the earlier admission cutoff, the permission path schedules transfer to the resident or state-matched fallback at the commitment deadline. Expired evidence, state bounds, or leases can require an earlier transfer. A stopping suffix is the book's recurring example; some loads and contacts require a validated hold or release instead of an unconstrained stop.

The proposal boundary is an authority boundary inside the machine. The causal boundary is where an admitted command produces physical work. Deterministic execution below the proposal boundary helps make timing inspectable, but it does not certify the sensors, model assumptions, or entire machine by itself.

D.3 Diagnostic Summary of the S·P·A Axes

The S·P·A taxonomy groups diagnosis by three responsibilities: capturing evidence, proposing behavior, and applying force. The groups overlap because a physical failure often crosses an interface. Table D.3 identifies the constraint to measure before selecting a remedy.

Table D.3: S·P·A axis reference: The axes organize diagnosis around measured constraints and budgets, with the chapter that develops each contract.

Axis	Operational role	Constraint or budget to test	Diagnostic action	Book locus
Sense (S)	Capture and estimate physical state	Evidence age, field of view, clock conversion, uncertainty, and sensor transport	Compare capture and per-cell evidence epochs with a measured state and the permission deadline	chapter 8, chapter 9
Plan (P)	Propose a target and trajectory	Intent validity, compute latency, dynamics, and stopping-suffix admission	Compare proposed targets and future states with independently checked limits	chapter 6, chapter 10, chapter 11
Act (A)	Apply and measure force	Current, torque, thermal headroom, brake response, and kinetic clearance	Measure command-to-force response and achieved stop under the declared load	chapter 2, chapter 4, chapter 12

D.3.1 The sense axis: Evidence age and temporal registration

A fresh map publication can contain old observations. Sense diagnosis therefore follows the capture epoch through clock conversion, transport, and estimation rather than treating message arrival as the observation time. Exposure duration and rolling-shutter readout can also spread one image across several physical states. Chapter 8 develops this distinction; section C.7 supplies the clock-conversion model.

Let t_{capture} be the capture epoch converted to the permission clock and ϵ_{sync} a bound on conversion error. A conservative age check is

$$t_{\text{age}} = t_{\text{curr}} - t_{\text{capture}} + \epsilon_{\text{sync}} \leq T_{\text{inv}}.$$

The validity limit must follow the task's motion and uncertainty bounds. For an obstacle whose speed is bounded by $v_{\max}$, an initial position uncertainty radius r_0 expands conservatively as

$$r_{\text{risk}}(t_{\text{age}}) = r_0 + v_{\max} t_{\text{age}}.$$

This bound assumes the stated speed limit holds and does not account for an obstacle that was never observed. Expired evidence cannot renew a clearance claim merely because the map was republished.

D.3.2 The plan axis: Proposal quality and admitted horizon

A useful plan must specify an achievable task and arrive in time to be executed. Learned intent models and policies can supply semantic targets and dexterous action candidates, while search and optimization can construct trajectories from explicit models. Both need closed-loop evaluation. Low prediction error on demonstrations does not characterize the states induced by the deployed policy. The $\mathcal{O}(S^2\epsilon)$ behavioral-cloning bound concerns worst-case cumulative task cost under stated assumptions, not a universal distance-drift law (section A.5; Ross et al. (2011)).

DRAFT

For a chunk of H waypoints separated by Δt, the proposed horizon is $H\Delta t$. Only the portion supported by current evidence, timing, and fallback authority may be admitted. Chunking reduces proposal frequency but can delay correction; single-step control remains viable when the model and runtime satisfy the required feedback budget. Chapter 11 develops the seam and stopping checks that turn either proposal form into executable motion.

D.3.3 The act axis: Electromechanical dynamics and thermal ceilings

A normalized policy output must eventually map to a physical setpoint. For a motor with torque constant K_t, the motor-side torque is approximately $\tau_{\text{motor}} = K_t i_q$ under the applicable field-oriented-control convention. Current response depends on winding inductance, resistance, back-EMF, and available voltage; it cannot follow an arbitrary instantaneous command. Chapter 2 develops these actuator limits and their measurement.

Gear reduction also changes the inertia seen at the joint. For an ideal rigid reducer with speed ratio $N_{\text{gear}} = \omega_m/\omega_j$, rotor inertia J_{rotor} contributes $N_{\text{gear}}^2 J_{\text{rotor}}$ on the joint side. In a single-joint model,

$$\tau_{\text{out}} = N_{\text{gear}}^2 J_{\text{rotor}} \ddot{q} + \tau_{\text{load}}, \qquad \tau_{\text{motor}} = \tau_{\text{out}}/N_{\text{gear}},$$

where τ_{load} includes the other joint-side inertial and load torques and losses are neglected. A step in acceleration produces a step in required torque; its magnitude depends on inertia and the step size. Infinite ideal jerk does not imply infinite torque or a particular current spike.

A lumped winding thermal model gives another diagnostic budget:

$$C_{\text{th}} \frac{dT_{\text{winding}}}{dt} = I_{\text{phase}}^2 R(T_{\text{winding}}) - \frac{T_{\text{winding}} - T_{\text{amb}}}{R_{\text{th}}}.$$

Here the current and resistance must use a consistent equivalent-winding convention. Continuous and peak current limits, duty cycle, cooling, and measured temperature determine admissible torque. Permanent-magnet demagnetization can occur below the Curie temperature; the relevant limit is the motor's qualified operating envelope.

Single-axis tests narrow the candidate cause. Interface tests then determine whether the failure arose from a stale estimate, an infeasible trajectory seam, or interference with the permission path.

D.4 The Intersection Landscape

When a mobile manipulator clips a cart that just rolled out of a cross-aisle, the fault often spans more than one subsystem: a voxel layer that held a stale free-space timestamp, a trajectory handoff that delayed braking, or a shared memory bus that stalled the safety check. The Sense, Plan, and Act (S·P·A) triad meets across three pairwise interfaces and one central permission region (figure D.1). Its three pairwise interfaces are $S \cap P$ (locating object position in current time), $P \cap A$ (verifying that proposed trajectories satisfy dynamic limits), and $A \cap S$ (measuring physical state evolution after actuation). The independent permission decision sits at their central three-way intersection ($S \cap P \cap A$), where a qualified permission path gates all motor commands against physical budgets before actuation. Each intersection below pairs its physical handoff contract with a discriminating measurement.

Each intersection is a testable handoff. Table D.4 names the failure mode and the evidence needed before a proposed fix earns permission.

Table D.4: The S·P·A intersection taxonomy: Four handoffs locate the earliest broken physical contract and the evidence required to repair it; the axis reference in table D.3 links to the underlying chapters.

Intersection	Handoff contract	Failure to test	Evidence and candidate remedy
$S \cap P$: belief	Observations become timed, framed state estimates	A fresh map publication hides an old voxel or an unseen object remains unknown	Check per-cell evidence epochs, free vs. occupied rays, and frame transforms; use a separately validated collision layer

DRAFT

Intersection	Handoff contract	Failure to test	Evidence and candidate remedy
$P \cap A$: motion	A proposal becomes an admitted, state-matched trajectory	A seam requests a torque transient or the stop suffix no longer fits clearance	Check entry state, derivatives, lease, and clearance; reject an infeasible seam; retain valid active authority until its fallback-start deadline
$A \cap S$: feedback	Actuation changes the state that sensors report	Contact force rises before the next useful sample or an actuator saturates	Measure command-to-force and sensor-return delay; choose a local reflex and passive limit where justified
$S \cap P \cap A$: permission	The independent gate turns a proposal into physical action	Compute, memory, power, or clock interference delays refusal	Measure response under contention; revoke tracking and qualify isolation or relocate the path if its bound fails

D.4.1 $S \cap P$ spatial belief and epistemic handoffs

A planner that treats an unmapped blind corner behind a stacked pallet as traversable free space can accelerate into an obstacle before the range sensor ever clears the corner. The Sense–Plan ($S \cap P$) intersection formalizes the **epistemic handoff**. It translates raw, asynchronous, multimodal sensor observations into a metric spatial belief state with bounded age and uncertainty, which planning algorithms and affordance models can query without executing ungrounded actions. This handoff bridges Part II and Part III of the book, taking sensor calibration and domain bounds from the provenance record (chapter 5) and observation streams from the observation contract (chapter 8) to populate the belief record (chapter 9).

In an embodied machine, the primary handoff contract requires that every spatial cell or bounding volume $\mathbf{p} \in \mathbb{R}^3$ in the volumetric occupancy representation $\mathcal{M}$ carries an explicit evidence epoch t_0 and a tri-state classification:

$$\mathcal{M}(\mathbf{p}) \in \{\text{Observed Free } (\mathcal{M}_{\text{free}}), \text{Observed Occupied } (\mathcal{M}_{\text{occ}}), \text{Unobserved Unknown } (\mathcal{M}_{\text{unknown}})\}$$

For an occupancy grid, let $p_t(\mathbf{p})$ denote the probability that cell $\mathbf{p}$ is occupied and $L_t(\mathbf{p}) = \log[p_t(\mathbf{p})/(1-p_t(\mathbf{p}))]$. With the usual conditional-independence approximation, the update from range measurement z_t is

$$L_t(\mathbf{p}) = L_{t-1}(\mathbf{p}) + \log \frac{p(\text{occupied at } \mathbf{p} \mid z_t)}{1-p(\text{occupied at } \mathbf{p} \mid z_t)} - L_0(\mathbf{p}),$$

where L_0 is the prior log-odds. Raycasting identifies the cells traversed before a surface return and the cell containing the hit (section A.3.6). A valid range return supplies free-space evidence along the ray before its surface hit, subject to the sensor model. A missing return alone does not establish free space. The permission path enforces a strict epistemic invariant before any trajectory planner may claim clearance through a spatial volume:

$$t_{\text{age}} = t_{\text{curr}} - t_0 + \epsilon_{\text{sync}} \leq T_{\text{inv}}$$

where ϵ_{sync} bounds clock-conversion uncertainty (section C.7). If $t_{\text{age}} > T_{\text{inv}}$, the cell's status degrades from currently supported free space ($\mathcal{M}_{\text{free}}$) to unknown space ($\mathcal{M}_{\text{unknown}}$).

Unknown space supplies no clearance evidence for ordinary motion admission. Planning algorithms must never equate unobserved space with traversable free space. The age-based expansion in the Sense-axis test applies to previously localized obstacles under a speed bound; it does not locate an obstacle hidden in never-observed space. Diagnostic testing for $S \cap P$ failures begins by inspecting raw sensor-to-map latency, comparing the per-voxel evidence epoch against ground-truth measurements, and validating raycast eviction queues. Failures to preserve these distinctions have three characteristic forms:

1. *Epistemic blindness*: The planner plans aggressive trajectories through unobserved space, treating unmapped blind spots behind occluding pallets or walls as empty. If an obstacle or human steps from behind a blind corner, the machine cannot stop within its remaining sensing margin.
2. *Phantom obstacles and stale log-odds*: When dynamic obstacles vacate a region, failure to project negative evidence along sensor optical rays (due to beam divergence, dark surface absorption, or missed returns) leaves elevated occupancy log-odds in voxel memory (section A.3.6). The permission path can stop the machine even though a separate view shows a clear aisle.

DRAFT

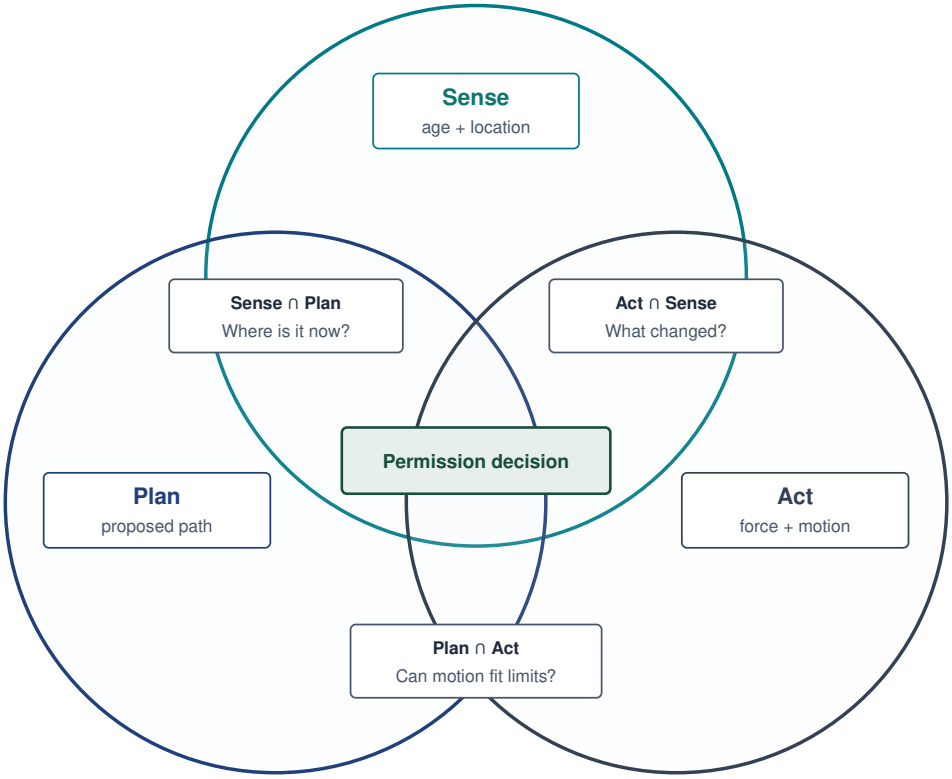

Figure D.1: The S·P·A intersection landscape: Sense, Plan, and Act meet pairwise in three physical decisions, locating the object now, checking that proposed motion fits limits, and measuring what changed after acting. Their center is the permission decision, where an independent permission path checks the shared physical budget before actuation.

3. *Extrinsic calibration drift and spatial skew*: Mechanical vibration or thermal warping alters the coordinate frame transform $\mathbf{T}_{bc} \in SE(3)$ between sensors and the mobile base. A pitch error $\delta\theta_{\text{pitch}}$ produces a height error of approximately $r\delta\theta_{\text{pitch}}$ at range r for small angles in radians, potentially turning the floor into an apparent obstacle and corrupting affordance preconditions (chapter 10).

D.4.2 $P \cap A$ admitted motion and kinetic seam feasibility

Splicing a newly decoded action chunk directly onto an active joint trajectory can command an instantaneous velocity or acceleration jump that rings the drivetrain or overruns the remaining stopping distance. The Plan–Act ($P \cap A$) intersection governs the **kinetic handoff**: admitting candidate trajectory setpoints proposed by statistical neural policies (Brain) and converting them into continuous, dynamically feasible joint commands executed by motor drives (Body). This interface bridges the intent lease (chapter 10), policy manifest (chapter 6), and trajectory record (chapter 11) against the physical plant ceilings recorded in the limit record (chapter 2).

Modern generative policies, such as diffusion decoders and vision-language-action (VLA) models, propose actions in discrete horizons or chunks (H waypoints spanning duration $H\Delta t$). The permission path cannot admit a raw chunk as an open-loop actuator reference. Instead, the seam connecting the currently executing trajectory to the incoming proposal must preserve the required reference continuity and remain compatible with the measured entry-state bounds. For a C^2 reference handover:

$$\mathbf{q}(t_0^+) = \mathbf{q}(t_0^-), \quad \dot{\mathbf{q}}(t_0^+) = \dot{\mathbf{q}}(t_0^-), \quad \ddot{\mathbf{q}}(t_0^+) = \ddot{\mathbf{q}}(t_0^-)$$

where t_0 is the handover epoch. A quintic polynomial can match the endpoint position, velocity, and acceleration constraints (section B.5) over blend interval τ_{blend}:

$$\mathbf{s}(\hat{t}) = \mathbf{a}_0 + \mathbf{a}_1\hat{t} + \mathbf{a}_2\hat{t}^2 + \mathbf{a}_3\hat{t}^3 + \mathbf{a}_4\hat{t}^4 + \mathbf{a}_5\hat{t}^5, \quad \hat{t} = \frac{t - t_0}{\tau_{\text{blend}}}$$

The entire admitted chunk must also satisfy componentwise limits $|\dot{q}_i| \le \dot{q}_{i,\max}$, $|\ddot{q}_i| \le \ddot{q}_{i,\max}$, and $|\dddot{q}_i| \le j_{\max}$ for every joint i. Derivatives of the normalized polynomial require factors of $1/\tau_{\text{blend}}$, $1/\tau_{\text{blend}}^2$, and $1/\tau_{\text{blend}}^3$, respectively. Endpoint continuity alone does not establish those bounds.

A further admission condition is an executable stopping suffix (chapter 11). For straight-line motion toward a stationary obstacle, constant speed v during response delay τ_{delay}, and constant braking deceleration $a_{\text{brake}} > 0$ afterward, a screening calculation is

$$d_{\text{stop}}(v) = v\,\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} \le D_{\text{clear}}(t).$$

This expression is not generally equivalent to a jerk-limited or C^2 stop. Admission must use the actual profile, uncertainty margins, and load-dependent braking limits; section 12.3 develops that budget. A multidimensional path also needs collision checks over its swept volume, not only a scalar endpoint distance.

At a chunk seam, compare the requested acceleration change with the joint-side inertia and measured current response. A discontinuity can exceed torque limits or excite flexible modes, but the failure magnitude is machine-specific. Along the chunk, check whether a fallback remains feasible from each admitted state. Rejecting a late or invalid successor does not itself revoke the active command. The executor preserves valid active authority and starts its fallback by the commitment deadline, allowing for the earlier admission and response cutoff. A measured latency percentile helps size proposal service; it does not guarantee that the next update will arrive before the admission cutoff. Diagnostic action therefore combines synchronized current and encoder traces at chunk boundaries, lease-expiration telemetry, and an explicit check of the stopping profile from the measured transfer state.

D.4.3 $A \cap S$ physical feedback, contact dynamics, and reflex latency

When a stiff gripper strikes a steel fixture at 0.2 m/s, contact force can climb past the wrist sensor's overload rating in a few milliseconds, long before the next 30 Hz camera frame finishes exposure. The Act–Sense ($A \cap S$) intersection closes the causal loop across the **causal boundary**: actuator forces move joints and exert contact forces against the environment, altering physical reality, which is then captured by sensors and fed back into the control loop. Governed by the limit record (chapter 2), handoff record (chapter 4), and evaluation record (chapter 7), this boundary embodies the first law, irreversibility (section 1.10). Energy delivered into a physical contact cannot be recalled.

Passivity and phase margin provide two ways to assess contact feedback (Hogan 1985). With force and velocity signs chosen so that Fv is power entering the system, a passive interaction port satisfies

$$\int_0^t F(t')v(t')\,dt' \ge -E(0),$$

where $E(0)$ is the initially stored energy. This energy bound is not a force limit; a passive system can still deliver a damaging impact.

For a simple mass–spring contact model, effective mass m_{eff} and stiffness k_{contact} define the natural time scale

$$T_{\text{contact}} = \sqrt{\frac{m_{\text{eff}}}{k_{\text{contact}}}}.$$

It indicates how quickly contact dynamics can evolve, not a universal maximum stable delay. Stability also depends on damping, controller gains, sampling, actuator dynamics, and saturation. In a linearized single-crossover loop, an added pure delay consumes approximately $\omega_c T_d$ radians of phase margin at crossover ω_c. Section B.10 develops energy-based checks, while section B.5.5 treats sampling delay.

DRAFT

Contact hunting can result from delayed feedback, excessive gain, friction, or mechanical backlash. Measuring force rise against command-to-force and sensor-return delay distinguishes these causes. For a locally linear contact, $F_{\text{contact}} \approx k_{\text{contact}} \Delta x$ relates penetration to force; approach speed and effective mass determine how much motion and energy accumulate before correction. A low-rate planner may set a contact goal, but the feedback path that regulates force must meet the contact-specific response budget.

Local impedance or admittance control and passive compliance can reduce contact sensitivity. A target impedance can take the form

$$\mathbf{M}_d(\ddot{\mathbf{x}} - \ddot{\mathbf{x}}_d) + \mathbf{D}_d(\dot{\mathbf{x}} - \dot{\mathbf{x}}_d) + \mathbf{K}_d(\mathbf{x} - \mathbf{x}_d) = \mathbf{F}_{\text{ext}},$$

where the desired inertia, damping, and stiffness shape the response to external force. Realizing this relation requires adequate sensing and actuator authority; it does not establish stability for arbitrary delay or contact. Qualify the combined controller, tooling, and surface over the admitted operating conditions.

D.4.4 $S \cap P \cap A$ independent permission decisions and silicon isolation

If a vision-backbone DMA burst stalls the shared memory fabric or droops the supply rail while the safety filter is evaluating a braking barrier, the motor drives continue executing the prior velocity command toward the obstacle. At the center of the triad sits the tripartite intersection where Sense, Plan, and Act converge: the **independent permission decision**. This is the physical realization of the third law, *proposal is not permission* (section 1.10). The statistical Brain proposes candidate trajectories; the Nervous System arbitrates permission against hard physical invariants; the Body actuates only what is admitted.

The permission path needs bounded response time under the admitted workload. Isolation can use dedicated hardware or a qualified partition; a processor label alone proves neither timing nor independence. One possible filter is a control barrier function quadratic program (CBF-QP, chapter 12, section B.4):

$$\min_{\mathbf{u}} \frac{1}{2}\|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2 \quad \text{s.t.} \quad L_{\mathbf{f}}h(\mathbf{x}) + L_{\mathbf{g}}h(\mathbf{x})\mathbf{u} + \kappa(h(\mathbf{x})) \geq 0, \quad \mathbf{u} \in \mathcal{U}_{\text{adm}}.$$

Here $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$ is the modeled dynamics, h defines the candidate safe set $\mathcal{C} = \{\mathbf{x} : h(\mathbf{x}) \geq 0\}$, $L_{\mathbf{f}}h = \nabla h \cdot \mathbf{f}$ and $L_{\mathbf{g}}h = \nabla h \cdot \mathbf{g}$, and κ is an extended class $\mathcal{K}$ function. This first-order form applies when the chosen barrier has the required control dependence and regularity. Position constraints on acceleration-controlled systems may require a higher-order or kinetic barrier.

A feasible QP result is one admission condition. Forward invariance additionally depends on the model, initial state, feasible inputs, state-estimation margins, and implementation timing. Sampled execution must account for behavior between checks. If evidence is missing or the solver misses its deadline, the permission path must invoke a validated fallback without waiting for the Brain. If no feasible safety-preserving action remains, solver failure does not create one; emergency response can limit harm without restoring the lost invariant claim.

Three measurements distinguish common failures at this intersection:

- **Shared-memory interference**: Measure acquisition, validation, and dispatch under the worst admitted DMA and inference traffic. A compute-only WCET excludes delays on the path to the actuator.
- **Electrical interference**: Measure supply voltage during accelerator load changes. Parasitic inductance contributes droop with magnitude $|\Delta V| \approx L_{\text{parasitic}}|dI/dt|$, while capacitance, resistance, and regulator response also shape the transient. Compare the waveform and duration with the supervisor's operating limits.
- **Premise invalidation**: Compare the assumed braking or contact bound with achieved response. A filter based on dry-floor friction can remain feasible in its model while an unobserved oil spill makes its command physically unrealizable.

Candidate repairs include local memory, bounded bus arbitration, separate power domains, and narrower operating limits. Each repair needs remeasurement; no single isolation technique resolves all interference or model errors. Chapter 18 records premises that the deployed machine cannot establish from its current evidence.

DRAFT

D.5 Architectural Record Chain

The records from chapter 2 through chapter 18 connect plant limits, proposed behavior, runtime decisions, and release evidence (section 1.11). Table D.5 maps each record to its main S·P·A responsibility; table C.9 gives what each record binds. A record makes assumptions and evidence inspectable; its presence alone does not enforce an invariant or certify a machine. The table groups records by their teaching role, not by wire-message order. Configuration and qualification records constrain runtime decisions; an emitted admitted command records a particular permission decision.

Table D.5: The S·P·A architectural record chain: Named records link physical limits, proposals, permission decisions, and release evidence. The record contents require validation against the deployed machine.

Chapter and title	Record	S·P·A locus	Constraint or evidence recorded	Primary failure mode diagnosed
chapter 2: The Physical Body	Limit record	Act, $A \cap S$	Motor torque $\tau_{\text{motor}} \leq \tau_{\max}$, thermal dissipation $I_{\text{phase}} \leq I_{\text{cont}}$, stopping distance $d_{\text{stop}}(v)$	Inverter thermal trip, rotor resonance, structural yield
chapter 3: The Cognitive Brain	Proposer limits (enter the handoff record)	Plan	Chunk horizon H, candidate setpoint bounds, proposer lease request	Unbounded candidate setpoints, unconstrained sampling cadence
chapter 4: The Nervous System	Handoff record	$S \cap P \cap A$	Bus cycle time T_{bus}, qualified jitter bound, chunk lease ceiling T_{lease}	Fieldbus priority inversion, seqlock torn read, lease expiration overrun
chapter 5: Physical Data	Provenance record	Sense, $S \cap P$	Dataset calibration bounds, ODD operational envelope limits	Covariate shift, out-of-distribution actuation commands
chapter 6: Policy Training	Policy manifest	Plan	Denoising evaluation count N_{eval}, chunk horizon H, Lipschitz bound L_{lip} if established	Multimodal mode-averaging collapse, explosive policy Lipschitz constant
chapter 7: Closed-Loop Evaluation	Evaluation record	$A \cap S$	Closed-loop task performance, intervention outcomes, collision evidence, and test-domain coverage	Open-loop loss deception, unmodeled closed-loop yaw drift
chapter 8: Sensor Perception	Observation contract	Sense	Observation age t_{age}, bounded clock-conversion error ϵ_{sync}, bounding covariance Σ_{body}	Rolling shutter distortion, timestamp skew, camera extrinsic calibration drift
chapter 9: Spatial Memory	Belief record	$S \cap P$	Per-cell evidence epoch t_0, tri-state classification (free/occupied/unknown), raycasting eviction	Phantom obstacle emergency stops, stale voxel retention, unobserved space mistaken for free space
chapter 10: Grounded Intent	Intent lease	Plan	Task tolerance bounds $\mathbf{r}$, affordance predicate validity, terminal mode admissibility	Affordance hallucination, ungrounded task goal selection
chapter 11: Trajectory Planning	Trajectory record	$P \cap A$	C^2 quintic polynomial seam continuity, componentwise jerk ceilings, stopping suffix guarantee	Seam velocity/acceleration discontinuity, reflected rotor inertia shock, stop suffix exhaustion
chapter 12: Safety Enforcement	Enforcement record	$S \cap P \cap A$	Admission checks and their premises, response-time budget, resident state-matched fallback ownership	Infeasible QP projection, enforcer deadline overrun, unsafe command leakage to motor registers
chapter 13: Workload Placement	Placement record	$S \cap P \cap A$	Silicon partitioning, dedicated TCM memory, AXI QoS priorities, qualified supply-voltage envelope	Shared memory bus contention, DRAM bank conflict, power rail brownout during NPU bursts
chapter 14: Supervisory Intervention	Authority record	$S \cap P \cap A$	Four-phase bumpless transfer, supervisory token state machine, contact-force relaxation	Intervention takeover jerk, operator authority lock-out, transfer state discontinuity
chapter 15: Adversarial Verification	Fault record	$S \cap P \cap A$	Tail-risk estimates and their assumptions, hardware fault injection coverage, sim-to-real gap	Rare-event tail collision, undetected hardware bit-flip, unmodeled contact compliance gap

DRAFT

Chapter and title	Record	S·P·A locus	Constraint or evidence recorded	Primary failure mode diagnosed
chapter 16: Deployment Release	Release manifest	$S \cap P \cap A$	Goal Structuring Notation (GSN) warrant validity, applicable assurance requirements, signed operational envelope	Operating outside qualified ODD, unsupported claim warrants, sign-off on unvalidated assumptions
chapter 17: Responsible Physical AI	Approval record	System-wide	A named owner for each decision behind an admitted action, the feasibility of each human role, per-group detection and exposure, declared records about people	An unowned decision, a human role no person can perform, an unmeasured group of people, records used outside their declared purpose
chapter 18: Engineering Physical AI	Residual-claims register	System-wide	Explicit uncertified premise register (such as friction floor $\mu \geq \mu_{\min}$), epistemic ceiling recognition	Premise invalidation (such as uninspected floor oil slick), catastrophic failure beyond epistemic ceiling

The four governing laws organize this evidence chain. Irreversibility requires budgets for delay, force, and fallback. Endogenous data requires evaluating the states that the policy itself induces. Proposal is not permission assigns admission authority independently of proposal quality. Permission must be earned requires the release case to state where those checks apply and which premises remain unresolved. Together, the chain helps locate missing evidence when a symptom crosses several chapters.

D.6 Physical AI Production Troubleshooting Matrix

When an operational machine violates physical limits or software invariants, table D.6 links the symptom to a discriminating measurement. Software traces can carry physical telemetry, but a CPU profile alone cannot establish a force or current transient. The records need a common time basis so that a physical event can be aligned with the command and evidence that preceded it.

Current probes and encoder traces help resolve chunk-seam events. Motor phase measurements require the rotor angle and the appropriate coordinate transform to recover i_q and i_d; a probe does not measure those rotating-frame components directly. Protocol analyzers reveal frame timing, while available system-on-chip (SoC) performance counters and controlled contention tests help attribute delays. Solver telemetry should include status, residuals, constraint margins, and fallback selection. Those fields can expose numerical or modeled infeasibility, but identifying a friction-premise failure also requires measured physical response.

Table D.6: Physical AI production troubleshooting matrix: Each row is a hypothesis, measurement, and candidate remedy; acceptance depends on the machine's declared limits.

Observable symptom	Candidate boundary	Discriminating measurement	Candidate response
Contact hunting while the arm opens the spring-latched cage door	$A \cap S$	Measure phase margin and force rise against the sensor-to-torque delay under the actual contact stiffness	Qualify a local impedance loop, approach-speed limit, and passive compliance for that contact
Torque or current transient at an action-chunk seam	$P \cap A$	Compare encoder, phase-current, and requested acceleration traces at the measured entry state	Admit a state-matched C^2 bridge and reserve a stopping suffix; the reduction in chapter 11 is profile-specific
Phantom obstacle stop in an aisle	$S \cap P$	Distinguish observed free, occupied, and unknown rays; inspect per-voxel evidence age	Clear only observed free space and retest the occupancy-to-permission conversion
Enforcer misses its configured deadline during camera ingress	$S \cap P \cap A$	Correlate response-time misses with bus queue, bank switches, cache misses, and DMA ownership	Qualify QoS bypass or a coherent local safety snapshot; remeasure under contention
Link or workpiece yields during contact	A	Compare measured force and displacement with the tested material and tooling limits	Reduce admitted speed or force and qualify a compliant load path

DRAFT

Observable symptom	Candidate boundary	Discriminating measurement	Candidate response
Policy update arrives after its admitted chunk horizon	$P \cap A$	Measure the update tail, lease expiry, and fallback transfer state	Shorten the admitted action or use a stop the permission path owns; do not extend permission from a percentile alone
Safety microcontroller (MCU) rail droops during accelerator bursts	$S \cap P \cap A$	Measure rail waveform, path slack, supervisor threshold, and resulting response time	Characterize decoupling, current slew, or physical power isolation
Base drifts toward a rack face despite low offline prediction error	$A \cap S$	Compare closed-loop yaw bias, lateral clearance, and surface-dependent braking	Test closed-loop rollouts and impose a feasible corridor and stop bound

D.7 The S·P·A Systems Scorecard

Before physical release, use table D.7 to connect verification gates to declared acceptance criteria across the three axes and their handoffs. Aggregate task success is useful evidence, but it can conceal rare severe outcomes and does not by itself justify a release. Each check needs the actual limits, operating envelope, confidence or hard-bound semantics, and validated fallback for the machine.

Hardware-in-the-loop tests can exercise these checks in continuous integration. Passing the suite supports the tested claims; it does not turn sampled observations into a deterministic guarantee over untested conditions.

Table D.7: The S·P·A physical AI systems scorecard: Example release checks across the three axes and their handoffs. Each row requires a case-specific threshold and evidence.

Boundary	Example acceptance check for a declared machine	Response if the check fails
Sense: capture clock	Bound capture-to-MCU conversion error and include it in evidence age	Resynchronize or withhold motion when the bound expires
Sense: ingestion	Measure worst admitted sensor/DMA queue occupancy, drop rate, and transfer time under concurrent load	Reserve capacity or reduce sensing load; dropped frames do not renew belief
Plan: chunk horizon	Admit a successor before the admission/response cutoff so fallback can start by the commitment deadline	Retain still-valid active authority and start the owned fallback by the commitment deadline or earlier validity expiry; measured update tails do not extend permission
Plan: dynamics	Check position, velocity, acceleration, torque, and stopping suffix against the actual joint and path limits	Reject or replan an infeasible chunk
Act: brake and contact	Validate achieved deceleration and force response for load, wear, surface, and temperature	Derate speed, change tooling, or refuse the untested state
Act: thermal	Keep measured winding and drive temperature inside device ratings under the duty cycle	Reduce duty or enter the validated stop/hold mode
$S \cap P$: spatial evidence	Preserve each cell's evidence epoch and distinguish observed free, occupied, and unknown	Refuse unknown clearance or obtain a new observation
$P \cap A$: seam	Check the matched entry state, derivative limits, and full stopping clearance before commit	Retain still-valid active authority; start the owned fallback by its commitment deadline or earlier if evidence, state, or lease validity expires
$A \cap S$: reflex	Bound sensing-to-force response against a contact-specific harm deadline	Reduce approach energy or add a validated passive limit
$S \cap P \cap A$: compute	Qualify the permission path's WCET against its deadline in the cycle budget of chapter 12, with acquisition, validation, write, and dispatch budgeted separately	Revoke tracking permission before the cycle overrun consumes stopping margin
$S \cap P \cap A$: shared silicon	Measure enforcer response under worst admitted bus, rail, and thermal contention	Qualify QoS/local snapshots or relocate the path if isolation cannot be shown
$S \cap P \cap A$: permission	Verify model/state assumptions, feasible CBF input, clock and estimate margins, and a state-matched fallback	Refuse the proposal when a premise is missing; a QP result alone proves no path safety

DRAFT

Glossary

This glossary defines key terms used throughout *Physical AI*. Terms are organized alphabetically.

A

Action Chunking A policy technique in which a model predicts a sequence of future actions rather than one action per inference. Executing part of a chunk amortizes inference latency but leaves that interval open loop with respect to new policy observations. Receding-horizon replanning or temporal ensembling can improve responsiveness and continuity; neither chunking nor blending establishes kinematic feasibility or collision clearance. (Chapter 3, chapter 11, chapter 6)

Active Probing The deliberate application of a small, bounded input that makes two observationally indistinguishable states produce different observations before the response deadline, such as a controlled pull on a latch below its contact ceiling. Its cost is time and an excitation that must itself fit the operating envelope. (Chapter 18)

Administrative Lease (T_{admin}) The bound, inside an intent lease, on how long the application processor may hold a goal without renewing it. It caps the harm a hung or crashed host can do while its last goal stays active; it is one of the three deadlines whose earliest sets the intent lease's expiry. (Chapter 10)

Advantage The amount by which taking a particular action in a state beats the policy's usual choice there, $A^{\pi}(s, \mathbf{a}) = Q^{\pi}(s, \mathbf{a}) - V^{\pi}(s)$. Policy-gradient and advantage-conditioned methods shift probability toward positive-advantage actions. (Chapter 6)

Approval Record The record that names, for each decision behind a machine's admitted actions, the person who approved it and answers for it, together with the human roles the design relies on, the permission stage and its reporting duties, the groups exposed to the machine, the records kept about people, and the labor the deployment moves. The release gate reads it as a standing condition, so a decision with no owner refuses operation. (Section 17.9, section C.15.12)

B

Back-EMF Back electromotive force, the voltage $e_{\text{bemf}} = K_e \omega_m$ that a spinning motor induces in its own windings in opposition to the supply. In SI units K_e equals the torque constant K_t. At speed, back-EMF can leave the inverter too little voltage headroom to control current, silently lowering the braking torque the drive can deliver. (Chapter 2)

Behavioral Cloning (BC) An imitation-learning method that trains a policy by supervised learning to map sensory observations directly to expert control actions, treating sequential decision-making as a regression or classification task. While computationally efficient on static demonstration archives, standard behavioral cloning ignores the closed-loop consequences of its own control outputs. Small single-step errors can therefore move the robot away from the demonstration distribution, where later errors may compound without learned recovery behavior. (Chapter 6, chapter 5)

Belief State An estimate of a physical quantity carried forward from dated sensor evidence, stated in a reference frame, together with the evidence epoch of the last measurement that constrained it and a declared law for how its error bound $E(\Delta t)$ grows while no new evidence arrives. The permission path may rely on a belief only until that bound reaches the task tolerance, at its invalidation horizon. (Chapter 9)

Belief State Invalidation Horizon (T_{inv}) The elapsed time beyond which an unobserved spatial or kinematic state estimate can no longer be certified to lie within a task's safe tolerance envelope. Derived from disturbance and motion bounds or a declared probabilistic uncertainty model, it limits how long perceptual memory supports the claim. A covariance-based horizon retains the confidence assumptions of that model. Downstream planners that treat spatial beliefs older than this horizon as valid free space risk commanding collisions with dynamic obstacles. (Chapter 9, section B.8)

Bumpless Transfer A dynamic control handoff protocol that matches controller state and commanded references across control authorities to avoid abrupt changes in actuator effort. When supervisory control transitions abruptly between an autonomous neural policy and a human operator, unmatched commands can induce mechanical shocks, structural oscillations, or loss of traction. Bumpless transfer employs dynamic transition ramps and feedback state tracking to transfer command authority smoothly; effort and slew limits still require separate checks. (Chapter 14, section B.5)

DRAFT

C

Causal Boundary The interface through which a digital command produces physical forces, currents, or flows. A proposal can be rejected before it crosses; once executed, it can alter the environment and dissipate energy, and restoring a command in memory does not restore the machine's prior physical state. Recovery requires another physical action, so a qualified permission check must precede actuation. The permission path sits above this boundary, at the proposal boundary of section 1.7. (Chapter 1, chapter 2)

Causal Confusion (Causal Misidentification) An imitation learning failure mode where a policy conditions on spurious, non-causal features that correlate with expert actions in training demonstrations rather than the true physical affordances of the task. High-capacity neural models exploit incidental visual cues (such as interface indicators, dashboard lights, or past actions) that disappear or change under physical deployment. When deployment breaks these correlations, the policy can select inappropriate actions even if its demonstration loss was low. (Chapter 6)

Chunk Lease (T_{lease}) The execution lease of the autonomous chunk policy, which bounds how long an admitted chunk may keep driving the actuators before a renewal must arrive. It is chosen, then checked against the ceiling the stopping budget derives, and it enters the pre-brake delay because a stalled proposer is noticed only when its lease expires. (Chapter 4, chapter 12)

Clearance Inset (C_{inset}) The separation a consumer holds between an estimated obstacle position and the machine's envelope so that the true obstacle stays at least the required clearance away, except with a stated tail probability measured under the conditions of use. It rests on residuals measured against ground truth, so it includes the calibration bias and heavy tail that a reported covariance omits. A percentile inset is not a hard bound; only a justified bound on the error or a feasible stop within the remaining delay budget closes the residual tail. (Chapter 8, chapter 11)

Closed-Loop Evaluation Measuring a policy's performance, safety, and stability through interactive rollouts on physical hardware or in simulation, rather than through static loss metrics on a held-out dataset. Because an autonomous policy continuously perturbs its own operating environment, evaluation requires logging closed-loop metrics such as task completion rates, safety-margin violations, and mean operating time between interventions. Open-loop validation error alone does not measure the consequences of policy-induced distribution shift. (Chapter 7, chapter 6)

Closure Test The test, declared before any data are collected, whose passing would retire an operating restriction held against an open premise in the residual-claims register, for example a failure-free trial campaign that bounds a new detector's miss rate. Until it passes, the restriction holds. (Chapter 18)

Common-Cause Analysis Tracing routing, power paths, and clock trees so that no single physical event, such as a shared cable carrier, a shared converter reference, or a common silicon erratum, can disable two paths whose failures an argument treats as independent. (Chapter 15, chapter 13)

Compounding Rollout Error The accumulation of task error when a policy's actions move it into states poorly represented in expert demonstrations. Under standard finite-horizon imitation-learning assumptions, a per-step expert-distribution error rate ϵ can yield worst-case excess accumulated task cost of order $\mathcal{O}(S^2\epsilon)$ over horizon S. This is not a universal law for physical displacement, tracking error, or collision probability. (Chapter 6, section A.5)

Configuration Space The set of all configurations of a mechanism; for a manipulator, a configuration is the collection of joint positions $(q_1, \ldots, q_n)$. Removing the configurations occupied by obstacles leaves the free space $\mathcal{C}_{\text{free}}$. A path through configuration space still lacks timing, which an executable trajectory adds. (Chapter 11)

Conformal Prediction Set The set of candidate answers that a calibrated threshold cannot exclude. Calibrating the threshold on held-out labeled cases gives the set a chosen marginal coverage level across cases, provided new cases are exchangeable with the calibration set. A set with more than one member is a principled trigger for asking a person rather than guessing. (Chapter 10)

Control Barrier Function (CBF) A scalar function $h(\mathbf{x})$ of the plant state whose nonnegative region is the safe set $\mathcal{C}$ and whose rate of change the control input can influence, so that admitting only inputs with $\dot{h} \geq -\kappa(h)$, for an extended class-$\mathcal{K}$ rate function κ that vanishes at zero, keeps a state that starts in $\mathcal{C}$ inside it (forward invariance) while the model, actuator, and timing assumptions hold. A Lyapunov function certifies convergence toward a point; a barrier function certifies that the state never leaves a region. For a torque-controlled plant, h must carry speed and braking authority, because raw distance has relative degree two and gives the input no direct control authority at the boundary. (Chapter 12, section B.4)

Credible Deceleration (a_{brake}) The sustained deceleration a machine can actually exert against its environment under stated conditions, a validated low tail rather than a datasheet peak. Traction, tip-over, and the drives' current-limited torque each bound it, so it changes with payload, floor friction, and arm pose. (Chapter 2, chapter 12)

Cross-Embodiment Transfer A learning paradigm in which a single policy or foundation model is trained on sensorimotor data gathered across heterogeneous robot morphologies, kinematic chains, and actuator dynamics to generalize to novel target embodiments. Achieving cross-embodiment generalization requires accounting for differences in observations, action semantics, and body dynamics, for example through shared representations or embodiment-specific adapters. Its primary challenge is preventing negative transfer induced by unmodeled dynamic discrepancies, link inertia variations, and differing joint velocity boundaries. (Chapter 5, chapter 6)

D

Defeater A physically realizable condition that invalidates a warrant in a safety-case argument, as an oil film can defeat the braking traction a stopping claim assumes. Adversarial review is the systematic search for defeaters. (Chapter 16)

Diffusion Policy A generative policy that produces continuous action sequences by iteratively denoising a noisy candidate conditioned on observations. It can represent multiple demonstration modes without forcing their average, but generated chunks still require feasibility and clearance checks. The number and cost of denoising steps contribute to inference latency. (Chapter 6, section A.5.2)

Domain Randomization (DR) A sim-to-real transfer methodology that systematically perturbs physical parameters (mass, friction, damping, motor torque limits), sensor characteristics (noise covariance, latency, camera pose), and visual textures across simulated training episodes. By exposing the policy to a broad distribution of simulated environments, domain randomization encourages the neural network to learn invariant representations and feedback behaviors robust to the chosen variation; transfer still depends on whether that variation covers the relevant physical conditions. If randomized too narrowly, the real world falls outside the training hull; if randomized too broadly, learning can become harder or the resulting behavior overly conservative. (Chapter 6)

Dynamic Reachability The property that the end effector can move from its measured state to a target pose, within its velocity, acceleration, jerk, and thermal limits, before the evidence supporting that target expires. Static reachability asks only whether some joint configuration reaches the pose; dynamic reachability adds the clock, so a target well inside the workspace can still be unreachable on one capture. (Chapter 10)

Dynamic Stopping Distance (d_{stop}) The clearance needed to stop from the current state, including pre-brake delay, the selected braking trajectory, and localization and protective allowances. With constant speed v during delay and constant braking deceleration $a_{\text{brake}} > 0$, the model is $d_{\text{stop}} = v\tau_{\text{delay}} + v^2/(2a_{\text{brake}}) + \delta_{\text{loc}} + \delta_{\text{margin}}$. A ramped or jerk-limited stop requires its own profile integral; the permission path must reserve that distance together with the tracking inset and any remaining timing margin. (Chapter 2, chapter 12)

E

End-Effector The tool, gripper, or hand at the distal tip of a manipulator that performs the intended interaction with the workpiece. Workspace and keep-out checks are written against its pose rather than against joint angles. (Chapter 3)

Endogenous Covariate Shift A distribution shift in sequential decision-making where an embodied agent's own execution errors drive its physical body into states unrepresented in its training demonstrations, thereby presenting the policy with novel out-of-distribution observations. An offline action-loss objective does not itself constrain the states visited by the deployed policy, so errors can compound along the trajectory. In physical systems, this shift can cause task failure or boundary violations; corrective data and feedback can improve recovery but require evaluation in the affected states. (Chapter 1, chapter 5, chapter 6)

Endogenous Experience (The Action–Observation Loop) The closed-loop data generation process in which an agent's executed actions causally determine its subsequent physical states and sensory observations ($s_{t+1} \sim p(s \mid s_t, \mathbf{a}_t)$). Unlike passive supervised learning on fixed, exogenous datasets, physical AI experience generation forms an irreversible dynamical feedback loop where minor control perturbations alter future data collection trajectories. Consequently, data generation and policy deployment cannot be separated in embodied agents. (Chapter 1, chapter 5)

Envelope Trichotomy A three-valued epistemic classification of cyber-physical runtime health that partitions system status relative to its certified operating envelope into *known-true* (verified valid telemetry inside bounds), *known-false* (verified limit breach), and *unknown* (epistemic uncertainty from sensor corruption, frame drops, or estimator divergence). In embodied AI, both *known-false* and *unknown* withhold tracking permission and select the qualified fallback for the current state and surviving hardware. (Chapter 16)

Evidence Epoch (t_0) The physical time reference of the measurement that last constrained an estimate, such as a camera's exposure midpoint or the instant a hardware register latches an encoder count. Republishing or predicting a belief advances its publication and estimate epochs, but only a new measurement advances its evidence epoch. (Chapter 9, chapter 8)

Evidence Horizon The longest time the evidence behind a proposal keeps its target within tolerance. For a tracked target whose residual motion can accelerate at a_{slip}, it follows from setting the open-loop drift $\frac{1}{2}a_{\text{slip}}\Delta t^2$ equal to the margin $r_{\text{tol}} - e_0$. It is one of the three deadlines whose earliest sets an intent lease's expiry. (Chapter 3, chapter 10)

Execution Lease Authority an admitted command source holds to keep driving the actuators without renewal. It begins at admission, not at dispatch, and its expiry invokes the state-matched fallback rather than the next proposal. The chunk lease and the manual lease are its two instances on the running machine. (Chapter 4, chapter 12, chapter 14)

Exposure Wall The limit on what failure-free operation alone can establish about a rare failure rate. Under a stationary Poisson failure model, bounding a catastrophic rate $\lambda = 10^{-9}$ per hour at 95 percent confidence requires about $-\ln(0.05)/\lambda \approx 3.0 \times 10^9$ failure-free hours of exposure from the same configuration, an argument Butler and Finelli made for flight software. The required exposure makes direct demonstration

impractical, so claims at that level also need architectural evidence, fault injection, and justified operating premises. (Section 7.9, chapter 15, section A.8)

Extended Kalman Filter (EKF) A recursive state estimator for nonlinear measurement or motion models that runs the Kalman filter's predict and update steps on a first-order linearization about the current estimate. When the model curves appreciably across the prior's spread, the reported covariance can understate the true error, so the filter's consistency must be tested rather than assumed. (Chapter 9)

Extreme Value Theory (EVT) The statistical theory that supplies limiting distribution families for extremes, much as the central limit theorem supplies one for sums. Its threshold form models every observation above a high threshold with the generalized Pareto distribution; its block-maxima form models one maximum per block with the generalized extreme value distribution. (Chapter 15, section A.10)

F

Fallback Ladder The ordered set of responses the permission path selects when a proposal cannot be admitted unchanged or its premises fail. Its rungs are PROJECT (minimal-intervention projection of the proposal onto the safe set), HOLD (a state-matched powered hold), STOP (a controlled, state-matched stop), and INHIBIT (drive torque inhibit with a separately rated brake). Each response requires a validated entry region and surviving hardware; selection must occur while that response remains feasible. An invalid replacement need not revoke an active trajectory whose own premises still hold. (Section 12.9, chapter 14)

Flow Matching Policy A generative policy trained to predict a vector field that transports samples from a base distribution toward a conditional action distribution. The training probability path and sample coupling determine the transport construction; straight conditional paths do not imply globally optimal transport or straight learned sample trajectories. Sampling cost depends on the trained field, numerical solver, and required accuracy, so fewer inference steps than diffusion must be demonstrated for the selected policies. (Chapter 6)

Force Closure A grasp property: every external force and torque on the held object can be balanced by contact forces that each lie inside its friction cone. Force closure says a balancing set of forces exists, not that the gripper can produce it within its force limit or without crushing the object. (Chapter 10, section B.7.5)

Forward Invariance A property of a dynamical system, control policy, and set $\mathcal{C}$: every trajectory starting in $\mathcal{C}$ remains in $\mathcal{C}$ for all future time under the stated assumptions. A barrier certificate can establish this property for a modeled system with feasible controls. Applying the result to hardware requires maintaining the state, disturbance, actuation, and timing premises of the certificate. (Chapter 12, section B.4)

Forward Occupancy Set The region a tracked actor could occupy a given time after its last measurement, grown from its measured position by its speed bound and its tracking uncertainty. A proposed motion is admitted only if it stays clear of every such set over the motion and its stop. (Chapter 10)

Four-Stream Action Tap The tuple $(a_{\text{req}}, a_{\text{cmd}}, a_{\text{enf}}, a_{\text{meas}})$ that records one action at each of its four causal stages, the requested action, the mapped command, the enforced command, and the measured response. Keeping all four makes any single choice of training label interpretable, provided the taps are stamped in one hardware-synchronized timebase. (Chapter 5)

Free-Space Depth (d_{free}) The distance from a hull's surface to the nearest place that no live evidence vouches for, read from a distance field built with every occupied, unknown, or expired cell treated as an obstacle. It is the clearance a map can certify for motion. (Chapter 9)

Freshness Deadline (Δt_{fresh}) The largest age, counted from the capture of a measurement to the onset of the actuator's response, that a measurement of a moving target may reach before the target's motion alone spends the allowable position error. It equals the error tolerance divided by the fastest credible velocity of the tracked state, and every stage from exposure to torque onset shares it. (Chapter 2)

Friction Cone The set of forces a Coulomb contact can transmit, $\|\mathbf{f}_{k,\parallel}\| \le \mu f_{k,\perp}$, a cone about the contact normal with half-angle $\arctan\mu$. A nonadhesive contact can push but not pull, so a gripper holds an object only through forces inside its friction cones. (Chapter 10, section B.7.5)

Future-State Conditioning Generating candidate motion plans from the state anticipated at execution time rather than the stale state measured when planning began, which removes the reference jump at trajectory handoff that planning latency would otherwise create. Activation still depends on the permission path checking the seam against the current state estimate and its error bound. (Chapter 11)

G

Generalist Policy A robot policy pretrained on pooled demonstrations from many robots and tasks, then post-trained on demonstrations of the target task. Pretraining supplies broad visual and motor priors; post-training supplies the task, the embodiment, and the evidence the target deployment needs. (Chapter 6)

Grounded Affordance An affordance expressed in the robot's own frame and units, namely a feature pose in the base frame, an approach direction, an aperture, and a contact wrench ceiling, each tied to dated sensor evidence through a calibrated measurement chain. Unlike a detector box or a language label, it says where and how the gripper may make contact. A learned grasp score or a confident detection is not grounding, because neither carries a metric error bound, a wrench limit, or an evidence epoch that the permission path could admit or expire. (Chapter 10, chapter 8)

H

Hardware Lease A countdown timer on the safety microcontroller that enforces a lease's expiry without the cooperation of the process that issued the authority. It is the mechanism behind every other lease, since a hung host cannot extend authority that a hardware timer is counting down. (Chapter 10, chapter 12)

Heterogeneous Silicon Partitioning Allocation of learned workloads and time-critical permission or control loops to different compute resources, with hardware protection of memory and peripheral access. Separate processors and dedicated buses can remove specific interference and fault paths, but shared power, clocks, interconnects, or thermal limits can retain common-mode failures. Timing and fault-containment claims therefore require evidence for the actual partition and declared load and fault envelope. (Chapter 13, section C.8)

Human-Gated Aggregation An interactive imitation-learning scheme in which the expert decides when to take over and only the takeover segments enter the dataset as labels. It avoids training on the learner's own failing commands. (Chapter 5)

Human Oversight Role A duty that a design assigns to a person, such as stopping the machine, taking over a channel, or approving a motion, and that the safety argument relies on. It counts as a countermeasure only if its holder has the time, the information, and the authority to act within the time the hazard leaves; a remote assistant who serves many machines must also be free when a request arrives. (Section 17.3)

I

Importance Sampling A Monte Carlo method that draws test runs from a proposal distribution that visits the failure region often, then weights each run by the ratio of the operational to the proposal likelihood to remove the bias. It estimates rare failure rates with far fewer runs than plain sampling, but only for the declared operational distribution. (Chapter 15)

Inevitable Collision State (ICS) A physical system state $\mathbf{x}(t)$ from which no admissible, physically executable control trajectory within actuator and friction limits can prevent impact with environmental obstacles over an infinite time horizon. Unlike geometric obstacle clearance, an ICS explicitly accounts for plant momentum, friction limits, dynamic obstacle trajectories, and finite actuator braking authority. A machine can enter an ICS before contact; insufficient stopping distance establishes this only when no other admissible evasive trajectory avoids impact. (Chapter 2, chapter 11, chapter 12)

Innovation The difference between a measurement and the estimator's prediction of it, which is what the measurement says that the prediction did not. A zero innovation confirms an estimate only along directions the sensors can observe. (Chapter 9)

Intent Grounding Refusal A typed rejection of a goal itself, returned when the referent is unresolved or no candidate grasp survives the physical checks a learned generator did not perform, such as an inverse-kinematics solution inside joint limits, jaw aperture, and a collision-free approach corridor. Unlike a planning failure, which finds no collision-free path to a valid goal, it rejects the goal before the planner is invoked, so no best guess over unresolved referents reaches trajectory generation. (Chapter 10, chapter 14)

Intent Lease The record, eighth in the record chain, that turns a grounded human goal into a bounded, expiring request that grants a target, a tolerance, and effort ceilings, but never a path. It expires at the earliest of its evidence horizon, its administrative lease, and its stopping deadline, and expiry withdraws the authority based on that intent and requires re-grounding or a qualified state-matched fallback. Unlike an execution lease, it bounds which trajectories may be admitted, not how long an admitted command may run. (Chapter 10, chapter 11)

Intervention Masking An evaluation distortion in which repeated, proactive interventions by human supervisors intercept a policy before it reaches a boundary failure. Because the supervisor intervenes during nascent drift, assisted success and accident counts alone do not reveal how the unaided policy would have behaved after takeover. Logs must distinguish intervention classes, exposure, and task outcomes. Reporting these separately prevents assisted task completion from being mistaken for evidence of independent policy competence. (Chapter 14, chapter 7)

Intervention Rate The number of events in a declared intervention class divided by active operating time, or by distance when a distance-based rate is reported. The rate depends on the intervention policy and exposure population; human takeovers and automatic corrections must remain distinguishable. It does not by itself establish safety or stability. (Chapter 7, chapter 14)

J

Jerk The rate of change of acceleration, $j = \dot{a} = \dddot{x}$, in $\mathrm{m/s^3}$. A jerk limit makes a brake ramp its deceleration up instead of stepping it, which spares occupants, payloads, and transmissions a shock but lengthens the stop, because full deceleration arrives later. (Chapter 11, chapter 1, chapter 12)

K

Kinodynamic Feasibility The property that the machine can track a candidate trajectory, including its seams and its stop, while every joint stays within its position, velocity, acceleration, jerk, torque, and current limits;

the kinodynamic feasibility envelope is the set of initial states from which this holds. Collision freedom is necessary but not sufficient, and checking only discrete waypoints can miss an interpolant that overshoots a limit between samples. (Chapter 11, chapter 2)

L

Learner-Action Contamination A data-collection failure in which the failing policy's own commands enter the dataset as expert labels, so the retrained policy learns to answer the cues of an approaching hazard with the commands that caused it. (Chapter 5)

Legible Intent Motion and signals that let a person who does not know a machine's goal infer it early enough to get out of the way, as opposed to motion that is predictable only to someone who already knows the plan. It helps the people a machine puts at risk protect themselves, and signals should promise only what measured detection supports. (Section 17.6.1)

M

Manual Lease ($T_{\text{lease,man}}$) The execution lease of a human operator in manual mode, renewed by authenticated heartbeats. It replaces the chunk lease in the pre-brake delay while the operator drives, so it must fit the stopping reserve of the mode in which it is granted. (Chapter 14)

Mean Time Between Interventions (MTBI) Active operating time divided by the number of events in a declared intervention class. MTBI is the reciprocal of the time-based intervention rate when the count is nonzero; a zero-event run requires an exposure-based statistical bound rather than a claim of infinite reliability. Interrupted trials and the intervention policy affect interpretation, so MTBI alone does not establish safety or stability. (Chapter 7, chapter 14)

Memory Wall The limit on a workload's rate that arises when its operands cannot reach the arithmetic units as fast as those units could consume them, so that the bytes moved from off-chip memory, not the operations performed, set the time per evaluation. Faster arithmetic does not move it; only fewer bytes per evaluation (fewer or narrower weights, or weights resident on chip) or more bandwidth does. It is distinct from memory capacity, since a model can fit in memory and still be too slow to stream. (Chapter 3)

Metric 3D Lifting (Spatial Grounding) The construction of a three-dimensional scene representation in physical units and a declared coordinate frame from sensor observations. Metric scale requires calibrated geometry, depth measurements, or another validated scale reference; image features and reconstruction methods alone do not resolve monocular scale ambiguity. The representation supports reachability and collision checks only within its uncertainty, coverage, and information-age bounds. (Chapter 8, chapter 10)

Minimal Risk Maneuver (MRM) A fallback maneuver intended to reduce risk after a fault or loss of nominal authority, such as a controlled stop or transition to a supported resting configuration. Its feasibility depends on the current state, available clearance, and surviving sensing, actuation, and power. The designation does not guarantee a hazard-free outcome or require every machine to reach an immediate standstill. (Chapter 12, chapter 14)

Minimal-Intervention Safety Shield A safety filter that modifies a nominal control proposal only as needed to satisfy modeled safety and actuator constraints. The CBF-QP safety filter solves $\mathbf{u}^* = \arg\min_{\mathbf{u}} \|\mathbf{u} - \mathbf{u}_{\text{nom}}\|^2$ subject to barrier and input constraints, potentially acting before the safe-set boundary is reached. Its guarantee depends on feasibility, model and state bounds, and execution timing; minimizing input deviation neither maximizes task performance nor supplies a fallback when the feasible set is empty. Its effect on the system hazard rate is conditional on the proposal rate and its interception coverage, so a shield does not remove the need to bound the proposer's failure rate. (Chapter 12, chapter 18, section B.4)

Missing Observable The unmeasured physical quantity on which an open claim depends, such as a friction coefficient or a latch strength, stated in terms of the physical claim rather than as an out-of-distribution latent state. Naming it lets a team choose between adding sensing, establishing a physical bound, and restricting the task. (Chapter 18)

Mode Averaging (Multimodality Catastrophe) A learning failure in which a regression policy averages distinct valid action modes into an unsuitable action, potentially causing a physical hazard. Mean squared error favors the conditional mean, which can lie between valid pathways. When human demonstrators navigate around an obstacle by choosing either a left or right detour, a naive regression model averages the competing action modes, commanding an interpolation that steers the robot directly into the obstacle. Mixture models, discrete strategy choices, or generative decoders can represent distinct modes; their selected actions still require physical feasibility checks. (Chapter 6, chapter 3)

Mode Confusion A mismatch between the mode an operator believes the automation is in and the mode it is actually in, so that an action correct for the believed mode is wrong for the actual one. On a machine whose actuator channels change hands separately, the operator's belief about one channel can be stale while the operator acts on another. Committed channel masks and per-channel announcement address it; correct ownership at the bus does not. (Chapter 14)

Monitored Premise Expiration The withdrawal of operational authority when runtime monitoring finds a required safety-case premise false or unknown, for example because measured temperature exceeds a limit or sensor packets are missing. Linking runtime telemetry to safety case warrants makes detectable premise failures grounds for restricting authority; unmonitored premises still require independent evidence. When

a monitored premise expires, the system transitions autonomously into a restricted or refusal operational regime. (Chapter 16)

O

Observability The property that the history of a machine's sensor outputs over a finite window, together with its known inputs and dynamics, determines the state uniquely, so that distinct physical trajectories produce distinct measurement sequences. Along an unobservable direction the innovation stays zero whatever the error, so a contracting covariance there reflects the model's assumptions rather than evidence. (Chapter 9, section B.8)

Observation Contract A specification of the spatial, temporal, and semantic claims a perception subsystem supplies downstream, including coordinate frames, capture times, coverage, uncertainty, and validity flags. It distinguishes deterministic bounds from statistical confidence regions and names how detectable violations revoke a claim. A contract cannot make occluded or unmonitored conditions observable; unsupported claims must remain unknown. (Chapter 8, chapter 3)

Observational Indistinguishability The condition in which two physical states that require different responses produce the same observation history, under every input the machine may admissibly apply, until the deadline by which a state-specific response must begin. Unlike classical unobservability, it is tied to a deadline and to the admissible inputs. A more capable classifier on the same channel cannot separate the states; only a new channel, active probing, or a response valid in both states changes the outcome. (Chapter 18)

Operating Envelope The declared set of external conditions and internal execution states, each stated with its units and tolerances, over which a machine's protective claim must hold and at which every trial of that claim is run. It extends the operational design domain with the machine's own state, such as processor load, drive bus voltage, and bus traffic. Values that are each in range can combine into a point outside the envelope, so its coupled corners must be tested. (Chapter 15, chapter 16)

Operational Design Domain (ODD) The object poses, surface conditions, payloads, speeds, and disturbances in which a machine is meant to operate, written down as the scenario table. A dataset supports the part of the ODD that its occupancy join covers; the rest is its known absence. The sets nest: the policy manifest claims a declared ODD within the ODD, evaluation samples a target ODD within the declared ODD, and verification extends the target ODD to the machine's internal conditions as the operating envelope that a release verdict authorizes in whole, in part, or not at all. (Section 5.7, chapter 6, chapter 7, chapter 15, chapter 16)

Operational Independence The property that no activity, fault, or overload in the proposal domain can push the permission path's execution past its deadline or disable its authority to refuse, through any resource the two share. Unlike spatial isolation, it also covers time, supply, clock, reset, and heat; it is the placement-level form of what functional-safety standards call freedom from interference. A separate core or chip is not independent by construction, since each shared resource is a hypothesis that needs a bound. (Chapter 13)

Moral Crumple Zone The position of a person who absorbs blame for an outcome that a system's design controlled, typically the operator nearest the event, named by analogy with the crumple zone of a car. A human role without the time, information, or authority to act creates one. (Section 17.3)

P

Paired Probing Validating a simulator component by applying identical open-loop command sequences to the simulator and to the physical hardware, then measuring the difference between the resulting state trajectories against explicit error budgets. A difference beyond the tolerance for the operating envelope makes the simulator defective for that training task. (Chapter 6)

Performance Level (PL) The ISO 13849-1 grade, a (lowest) to e (highest), of how reliably a safety-related control function performs, based on its architecture, diagnostic coverage, and component failure rates. Standards for the application set the required level; person detection on a driverless industrial truck, for example, requires PL d. (Chapter 8, chapter 12, chapter 16)

Permission Path The independent mechanism with bounded latency, which the learned model cannot delay or corrupt, that alone may permit an action to reach an actuator. It checks each proposal against fresh evidence, the stopping envelope, and a fallback feasible from the current state, and refuses when any check fails. (Section 1.7, chapter 4, chapter 12)

Permission Stage A grant that allows a named configuration of a machine to operate in a named domain, among named groups of people, on named evidence, and under named reporting duties, such as testing with a safety driver, driverless testing, or open deployment. A machine leaves a stage on evidence gathered there, and a stage is withdrawn for a configuration change, an incident, or a withheld record. (Section 17.4)

Physical Artificial Intelligence (Physical AI) The engineering of closed-loop machines in which learned models influence, without synchronous human approval, physical actions that change subsequent observations. A system is in scope when it combines a learned model, consequential physical feedback, and delegated physical authority. Its actions must fit the plant's physical limits and the time available to respond, and a useful proposal still needs an independent permission decision. (Chapter 1, chapter 3)

Physical Plant The apparatus being controlled, such as a robot's wheeled base or arm, whose state keeps changing while the computer calculates. (Chapter 1, chapter 2)

Problem of Many Hands The difficulty of assigning responsibility for an outcome that many people each helped produce, so that each can truthfully point to someone else. For a physical machine, the decisions behind one admitted action (policy, enforcer, envelope, crossing rule, staffing) belong to different parties and mostly appear in no runtime log. (Section 17.2)

Proposal Boundary The line between a learned model, which may only propose an action, and the permission path, a mechanism designed to make the actuation decision independently of the model, within a qualified latency and fault envelope. The permission path checks each proposal against fresh evidence, the stopping envelope, and a fallback feasible from the current state, and it refuses when any check fails. The proposal boundary separates the Brain from the Nervous System in the book's five-level machine. (Section 1.7, chapter 4, chapter 12)

Q

Qualification Ladder The ordering of four qualification environments, software-in-the-loop, processor-in-the-loop (PIL), hardware-in-the-loop (HIL), and physical fault rigs, by how much of the loop from sensing through inference, buses, drives, and plant is real, and therefore by falling trial throughput. The order is not a hierarchy of evidence, because a higher rung cannot subsume a lower one. Each rung yields a distinct category of evidence and stays blind to the physical mechanisms outside its boundary, so extensive software-in-the-loop passes say nothing about clock drift, DMA stalls, interrupt jitter, or supply sag. (Chapter 15)

Quantization Storing a model's weights, and optionally its activations, in fewer bits than training used. Weight-only quantization cuts the bytes a bandwidth-bound decode step must read; it does not speed up compute-bound phases unless the processor has kernels for the lower-precision arithmetic. (Chapter 3)

R

Record Chain The sixteen records, one produced by each chapter of Parts I to IV except the one on the learned proposer and one by the conclusion, that carry the book's assumptions and evidence from the limit record to the residual-claims register. One strand states what the plant can do and what the proposer has shown it can do; the other carries what the proposer proposes now; they meet in the enforcement record. A record makes a claim inspectable; it does not establish the claim. (Section 1.11, section C.14.2)

Reflected Rotor Inertia (J_{ref}) The apparent rotational inertia of an actuator rotor seen at the load-side joint output, $J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$ for transmission ratio N_{gear}. In high-reduction joints it dominates the apparent load, caps joint acceleration, and concentrates impact energy on the gear teeth before drive current can be interrupted. (Chapter 2)

Relative Degree The number of times a function of the state, such as a barrier function $h(\mathbf{x})$, must be differentiated with respect to time before the control input appears explicitly. Raw distance has relative degree two for torque, so a barrier written on distance alone gives the input no instantaneous control authority at the boundary. (Section B.4, chapter 12)

Release Verdict The signed decision that sets how much authority a named machine's permission path may grant, `UNCOND` for the full assessed operating envelope, `COND` for a separately evidenced restricted envelope, or `REFUSE` when any required premise is missing, contradicted, or unknown, in each case only while its standing conditions hold. It is decided before operation and never moves the proposal boundary; under every verdict the permission path still admits each action. (Chapter 16)

Replacement Latency (L) The elapsed time from the capture of the observation a new proposal rests on to the admission of that proposal. It is the sum of the capture-to-dispatch observation age and the dispatch-to-admission interval Δ_{da}. (Chapter 11, chapter 13)

Rolling Shutter An image sensor readout in which rows are reset, exposed, and read out sequentially, each row starting one row period after the previous one, so a single frame samples a moving scene at progressively later times. A global shutter instead exposes every pixel over the same interval. (Chapter 8)

Rule of Three The approximation that zero failures in n independent trials bounds the per-trial failure probability below about $3/n$ at 95 percent confidence, because $-\ln 0.05 \approx 3$. The bound holds only under the trials' sampling assumptions. (Chapter 7, section A.8)

S

Safe Torque Off (STO) A drive safety function that prevents the drive from generating motor torque through its torque-producing power stage. STO does not itself brake a moving load, hold a gravity-loaded mechanism, or isolate the electrical supply. Its use in a stopping or restraint path requires a plant-specific assessment of coasting, stored energy, and any separately rated mechanical brake. (Chapter 12, chapter 2)

Safety Case (Claim–Argument–Evidence) A structured argument that a named machine, in a stated operating envelope and under a stated fault model, meets explicit physical criteria, written as claims that decompose through stated arguments into retained evidence. Unlike a test report, it states why the evidence supports a claim about conditions the machine has not yet met and names the assumptions under which the reasoning stops holding. It is written with the design, and in this book's architecture its verdict decides what the permission path lets the machine do. (Chapter 16)

DRAFT

Safety Integrity Level (SIL) The IEC 61508 grade, 1 (lowest) to 4 (highest), of the risk reduction a safety function must provide, expressed as a band of tolerable dangerous failure rates. Not to be confused with software-in-the-loop testing, which some texts also abbreviate SIL. (Chapter 16)

Safety Laser Scanner A planar time-of-flight sensor type-tested as a protective device (IEC 61496-3) whose safety output reports only that something occupies a configured protective field. On a mobile base it carries the certified stop for a person in the path; a perception LiDAR without that rating cannot. (Chapter 8, chapter 12)

Safety Microcontroller The small, independently clocked processor that runs the permission path's deadline-critical checks, watchdogs, and hardware leases, and commands the drives' stop functions. On the running machine it sits on its own board link with no memory shared with the application processor. (Chapter 4, chapter 13)

Scenario Table The operational design domain divided into cells over low-dimensional task and environment parameters, such as pose offsets, surface friction, payload, and lighting, so that a dataset's measured occupancy can be joined against it. Cells the join leaves empty are the dataset's known absences. (Section 5.7)

Sequential Probability Ratio Test (SPRT) Wald's test that updates a log-likelihood ratio after each trial and stops as soon as it crosses an acceptance or rejection boundary set by the allowed error probabilities. It permits early acceptance without inflating false acceptance, provided hypotheses, outcome, and boundaries are declared before testing. (Chapter 7, section A.9)

Shadow Mode Deployment Staging in which a candidate policy runs on the live sensor streams and writes the commands it would have proposed to an isolated buffer with no actuator authority, while the incumbent controller supplies proposals and the enforcer keeps sole output ownership. Because the incumbent's admitted commands determine the plant trajectory, agreement in shadow mode says nothing about the states the candidate's own actions would reach. (Chapter 16, chapter 7)

Shared Autonomy A collaborative control architecture in which a human supervisor and an autonomous policy concurrently exert control authority over an embodied system's physical degrees of freedom. Authority allocation may be realized via continuous haptic virtual fixtures, dynamic compliance blending, or task-space privilege partitioning. The central challenge of shared autonomy is maintaining an intuitive, transparent authority distribution that avoids conflicting commands while preserving the qualified safety constraints. (Chapter 14)

Sim-to-Real Contact Exploit A training failure in which a reinforcement learning policy discovers and exploits unphysical numerical artifacts in a simulator's contact solver, such as interpenetration spring restitution, infinite friction sticking, or instantaneous impulse relaxation, to achieve high simulated reward. Because these mathematical solver relaxations do not exist in the physical world, the learned policy can lose performance or violate constraints when deployed on hardware. Mitigation can include improved contact models, randomized parameters, energy-consistency checks, and physical validation. (Chapter 6)

Sim-to-Real Gap (Sim-to-Reality Gap) The systematic discrepancy in dynamics, contact mechanics, sensor transduction, and execution latency that exists between a computational physics simulation and the real physical environment. Policies optimized purely in simulation frequently fail upon physical deployment when the selected models omit or misrepresent effects such as frictional contact, transmission backlash, compliance, or execution delay. Bridging this gap is the central challenge of simulation-based policy training in physical AI. (Chapter 6, chapter 7)

Simultaneous Localization and Mapping (SLAM) Estimating a machine's pose while building the map it localizes against. Modern systems store past poses as a graph of odometry and scan-match constraints; a loop closure adds a constraint when a place is revisited and can shift every pose and map cell at once, which is why map-anchored beliefs must carry the map revision that placed them. (Chapter 9)

Spatial Information Age (t_{age}) The time elapsed between the exposure midpoint at the transducer and the consumption of the resulting observation by a policy, state observer, or control loop; running text calls it observation age. Mass keeps moving while the pipeline computes, so the age becomes travel $v\,t_{\text{age}}$ that enters the stopping budget through the pre-brake delay. A frame's arrival timestamp in userspace understates it by the capture and transport time already spent. (Chapter 8, chapter 9)

Speed and Separation Monitoring (SSM) A collaborative-robot safety mode, set out in ISO 10218-2:2025, that slows or stops the robot so that a protective separation distance to a person is never breached. That distance covers the person's travel over the robot's reaction and stopping time, the robot's own travel and stopping distance, and the position uncertainty of both. Power and force limiting, the complementary mode, instead bounds the force of a contact that is allowed to happen. (Chapter 10, chapter 12)

Standing Condition A relied-on premise of a release verdict paired with a detector or site procedure, a checking cadence set by the physical failure mechanism rather than the software release cycle, and a validated response for when the premise becomes false or unknown. Standing conditions make a release revocable. (Section 16.5)

Stopping Budget The accounting of the distance a moving machine needs to stop, tested against the usable clearance in $d_{\text{stop}} \le D_{\text{clear}}$. Its elementary form is travel during the pre-brake delay plus braking travel, $v\tau_{\text{delay}} + v^2/(2a_{\text{brake}})$; the finished budget adds the allowances and delays that each part of the machine introduces, so added delay consumes clearance in proportion to the machine's speed. (Chapter 1, chapter 2, section 12.3.1)

Stopping Envelope The set of plant states, clearance and speed along each direction of travel, from which the resident braking response, begun after the accounted delay, arrests motion before the nearest boundary with the localization, protective, and tracking allowances still reserved. It turns $d_{\text{stop}} \le D_{\text{clear}}$ into a speed

ceiling. Payload, floor friction, and winding temperature move its boundary, so an envelope computed from a datasheet deceleration overstates it when the machine is loaded. (Chapter 12)

Stopping Suffix A precomputed braking trajectory reserved with an admitted motion plan to reach a controlled standstill within declared clearance and actuator limits. It is usable only from its validated entry region, with the necessary state continuity, traction, drive authority, and power available. If authority expires from another state, the permission path needs a separately qualified state-matched response. (Chapter 11, chapter 14)

Supervisory Intervention The transfer of the right to propose commands on named actuator channels between a learned policy and an authenticated person, committed on a control tick and bounded by a lease, while every command continues to pass the same permission check. The operator gains only the right to propose, not the actuators, and because the transfer is a delay on a moving machine it is priced in the stopping budget. (Chapter 14)

T

Takeover Reaction Budget (T_{Σ}) The supervisory waiting interval from a takeover demand to receipt of the first human command, modeled here as $T_{\Sigma} = T_{\text{sensory}} + T_{\text{cognitive}} + T_{\text{motor}} + T_{\text{comm}}$. The communication term includes transport and the authority handshake; plant response, braking, and any subsequent blending require separate budget terms. A takeover can be credited with preventing harm only if this complete response fits before the last feasible intervention time. (Chapter 14)

Task and Motion Planning (TAMP) Planning that couples a symbolic search over discrete actions, such as grasp and place, with geometric samplers that find the continuous grasp poses, joint configurations, and paths each action needs. Failure to find a valid sample leaves the symbolic step unverified; it does not establish that no feasible configuration exists. (Chapter 10)

Temporal Ensembling A filtering technique for action-chunked policies that combines predictions for the same execution time from overlapping chunks, often through an exponentially weighted average. It can reduce inter-chunk discontinuities but does not guarantee bounded jerk, preserve distinct action modes, or establish feasibility. Weighting older predictions also trades responsiveness for smoothing. (Chapter 3, chapter 6, chapter 11)

Temporal Logic Falsification Verification posed as adversarial optimization, in which an optimizer searches initial conditions and time-varying disturbance trajectories within a bounded budget to minimize the quantitative robustness of a Signal Temporal Logic (STL) requirement, a real-valued measure of how far a trajectory is from violating or satisfying it. A trajectory with negative robustness is a counterexample; an unsuccessful search yields no certificate. (Chapter 15, section A.7)

Test Oracle The predicate, fixed in full before a trial runs, that compares each independently witnessed quantity of the trial's trace with its bound from a declared reference event and returns the trial's verdict. Each comparison carries a signed margin in its own unit, which lets a near miss inform the next trial. (Chapter 15)

Time Parameterization Choosing the timing $s(t)$ along a fixed geometric path $\mathbf{q}(s)$ so that every joint velocity, acceleration, torque, and jerk stays within the body's limits, usually to minimize traversal time. (Chapter 11)

Time-to-Harm (t_{harm}) The predicted interval until a specified harmful event under a stated continuation of the current motion and disturbance assumptions. Comparing it with detection, decision, actuation, and braking time helps assess response urgency, but a scalar timing inequality alone does not prove clearance or forward invariance. A protective response must begin while it remains feasible; once that region is lost, initiating emergency braking cannot guarantee avoidance. (Chapter 18)

Trajectory Spline Blending (C^2 Continuity) Interpolation across trajectory seams that matches position, velocity, and acceleration through C^2 continuity, using suitably constrained polynomials or splines. Acceleration continuity removes acceleration steps but does not imply continuous jerk, which requires C^3 continuity, or bound the magnitude of jerk. The blend must separately satisfy velocity, acceleration, jerk, torque, and clearance limits over the entire segment. (Chapter 11, chapter 3)

V

Vision-Language-Action (VLA) Model A multimodal model that conditions action predictions on visual observations and language, often with robot proprioception. Outputs may be discrete action tokens, continuous controls, or trajectory chunks. Built on high-capacity transformer backbones pretrained on Internet-scale vision-language datasets and fine-tuned on robotics demonstrations, VLA models synthesize open-vocabulary semantic reasoning with spatial affordance grounding. Because their internal weights lack physical safety and stability guarantees, their outputs are treated as unprivileged candidate proposals requiring downstream kinodynamic and barrier filtering. (Chapter 3, chapter 10)

W

World Model An internal generative model that learns to simulate the forward transition dynamics, contact mechanics, and sensory observations of the physical environment conditioned on the agent's prospective actions. In physical AI, world models support counterfactual trajectory evaluation and model-predictive rollouts without executing each candidate on hardware. A learned predictive model is not automatically a

validated digital twin. Their reliability is limited by epistemic uncertainty over non-smooth contact changes and the sim-to-real gap. (Chapter 3, chapter 11, chapter 6)

Worst-Case Execution Time (WCET) The longest time a task can take to run to completion on a given processor, over every admissible input and every state its caches, pipeline, and buses can be in, with no other task competing for the processor. It is the C term of a response bound; blocking and interference from other tasks and interrupts are separate terms with their own bounds, which a shared multicore can inflate. A measured maximum can refute a declared WCET but never establish it. (Chapter 4, chapter 13)
